
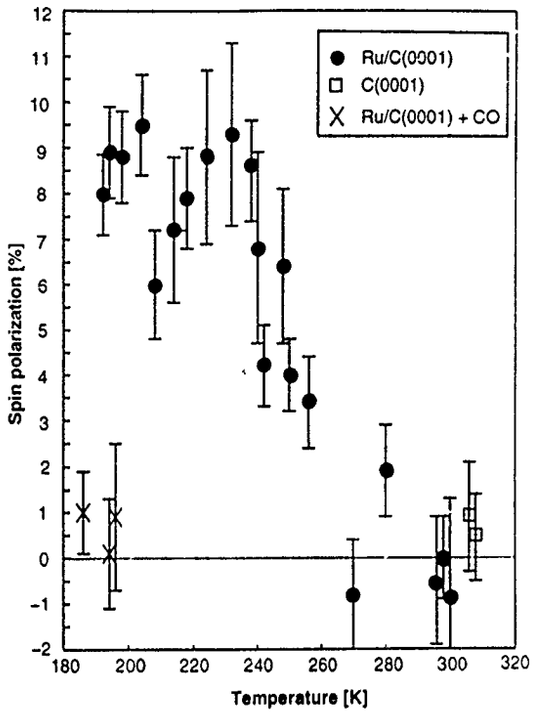

FIG. 4. ESP of 3 eV electrons as function of temperature for a ML-thin Ru film on C(0001) (solid circles), for the clean C(0001) surface (open squares), and for the CO covered Ru ML film on C(0001) (crosses).

4. Solid circles represent the ESP of a Ru ML film as function of temperature T. The low temperature value of the ESP is between +8% and +9%, i.e., the film is indeed ferromagnetic. The positive sign indicates a predominance of electrons with magnetic moment oriented parallel to the applied magnetizing field. With increasing temperature, the ESP drops to zero within a narrow temperature range. This behavior of the ESP is completely reversible. It is not the intent of the present publication to evaluate the critical exponent of the two-dimensional (2D) phase transition near the surface Curie temperature T_{Cs}, which is located at around 250 K.

We performed additional SPSEE measurements on adsorbate covered Ru ML films. At 300 K, we exposed the clean Ru film to 10 L of CO, which is the saturation coverage of CO at the clean Ru/C(0001) surface. From Fig. 4 (crosses), it can be directly seen that chemisorption of CO results in zero ESP within the experimental errors which is identical to the result we obtain for the clean graphite surface (see Fig. 4, open squares).

In conclusion, we have demonstrated that Ru can be grown laterally on a HOPG C(0001) surface until the first ML is completed. We find that the deposited Ru ML film is ferromagnetic below a surface Curie temperature $T_{Cs} \approx 250$ K. This is the first observation of 2D ferromagnetism of a 4*d* element.

Spin reorientation transition in Ni films on Cu(100)

S. Z. Wu, G. J. Mankey, F. Huang, and R. F. Willis
Department of Physics, The Pennsylvania State University, University Park, Pennsylvania 16802

The magnetic anisotropy of Ni films grown on single-crystal Cu(100) was studied *in situ* using the surface magneto-optic Kerr effect. The easy axis of magnetization lies in the plane of the film for ultrathin films and it is perpendicular to the film above a switching thickness. This behavior is attributed to a specific contribution to the magnetocrystalline anisotropy energy induced by a change in the film microstructure above a critical thickness. In the Ni/Cu(100) system, the magnetoelastic interface anisotropy favors perpendicular magnetization which becomes comparable to the shape anisotropy at the switching thickness. We compare the switching thickness and magnetization of films grown using different processing conditions.

For ultrathin ferromagnetic films, there is a magnetization reorientation phase transition where the easy axis of magnetization is perpendicular to the film surface and switches to in plane as film thickness is increased.[1,2] Within the framework of the magnetic Hamiltonian, this transition can be interpreted as the increasing dominance of the thickness-dependent shape anisotropy which favors in-plane magnetization overcoming the spin-orbit magnetocrystalline anisotropy term which favors perpendicular magnetization. In addition to a thickness-dependent transition, a reorientation transition can also occur as a result of varying temperature of a film with fixed thickness. The temperature dependence can be modeled with an empirical temperature-dependent coefficient for the spin-orbit term in the Hamiltonian.[3] This transition has been observed for Fe/Ag(100),[4] Fe/Cu(100),[5] and Co/Au(111).[6] For the Ni films studied in this work, there is a different behavior.

Bulk Ni is the canonical Heisenberg ferromagnet. It has a spin moment of 0.6 bohr magnetons,[7] a Curie temperature T_C of 627 K,[8] a critical exponent $\beta \sim 0.4$, and a weak magnetocrystalline anisotropy with the easy axis of magnetization in the [111] direction and the hard axis in the [100] direction.[9] Ni monolayers have been studied theoretically with the self-consistent local orbital method[10,11] and a perturbative tight-binding approach.[12] These calculations predict that a (100) oriented Ni monolayer has a preferred direction of magnetization in the plane of the film. More recent state-tracking first principals calculations demonstrate the magnetocrystalline anisotropy energy for monolayers is dependent on band filling and strain.[13,14] To what extent the results for truly two-dimensional monolayers can be used for describing the magnetic properties of films of finite thickness has yet to be determined. The critical behavior of Ni films on Cu(100) has been studied[15] and it was shown that the magnetic phase transition power law exponent crosses over from a two-dimensional *XY* model behavior to a three-dimensional Heisenberg model behavior at a film thickness of 7 monolayers (ML). These measurements show films thicker than a single monolayer exhibit two-dimensional magnetic properties.

Both Ni and Cu are fcc crystals with lattice constants of 3.52 and 3.61 Å, respectively, so Ni has a lattice constant 2.5% smaller than Cu. Ni films maintain an in-plane lattice constant identical to Cu up to a critical thickness of 10 ML.[16,17] The surface free energies for Ni and Cu are 2.45 and 1.85 J/m^2, respectively.[18,19] Since Cu has a surface free energy 0.6 J/m^2 lower than Ni, it tends to segregate to the surface at elevated temperatures.[20] In addition, Ni and Cu form a continuous series of solid solutions. In order to produce atomically smooth pseudomorphic layers of Ni on Cu, the films must be grown at a temperature high enough for the incoming Ni to form smooth layers yet low enough to suppress bulk diffusion which favors both alloy formation and surface segregation. The formation of a surface alloy can be detected by a reduced magnetization since Ni_xCu_{1-x} alloys are nonmagnetic when x is below 0.4.[21]

Our sample preparation procedures and film thickness calibration techniques have been reported before.[22] The magnetic behavior of films produced with three different processing conditions were studied in this work: Ni films grown at 300 K on a substrate roughened by 500 eV Ar^+ bombardment, Ni films grown at 300 K on a smooth substrate, and Ni films grown at 400 K on a smooth substrate. The composition of the samples was determined by Auger electron spectroscopy, with all of the films showing a small (<10%) but measurable amount of carbon and oxygen contamination. The magnetic properties were measured *in situ* by the surface magneto-optic Kerr effect (SMOKE) with the substrate cooled to 200 K.

To perform the SMOKE measurements, a linearly polarized He-Ne laser was incident on the sample surface at 70° from the surface normal with the polarization vector in the incident plane. The reflected light is analyzed by a Wollaston prism in combination with two photodiodes which allows simultaneous detection of the two orthogonal light components. The laser was rotated to ~0.08° from extinction in the null channel. By measuring ΔI, the difference between the Kerr intensity at remanence, the Kerr ellipticity can be derived: $\phi'' = \delta/4\Delta I/I$, where I is the Kerr intensity at zero net magnetization and δ is the angle the laser is rotated from extinction. A four-pole electromagnet applies the external magnetic field either parallel or perpendicular to the film plane with a maximum magnetic field of 150 Oe.[23] This arrangement allows the measurement of both the longitudinal and polar Kerr Effects.[24] A typical hysteresis loop is shown in Fig. 1, the height of the loop at zero external field is proportional to the remanent magnetization M_r and the external magnetic field at zero net magnetization is called the coercive field or coercivity H_c.

To study the magnetization of the films, we measured the

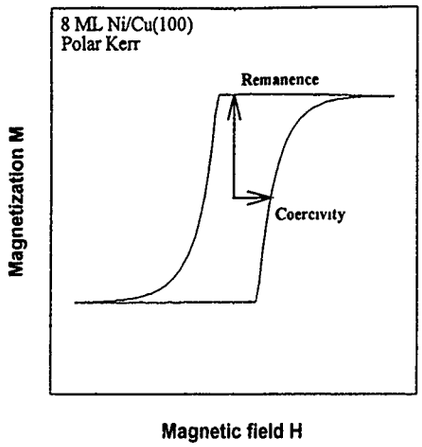

FIG. 1. A hysteresis loop for the out-of-plane magnetization of 8 ML Ni on smooth Cu(100) substrate grown at T_g=400 K. The magnetization at zero external field is the remanence. The external field at zero net magnetization is called the coercive field or coercivity.

remanence and coercivity as functions of Ni film thickness from 4 to 20 ML with the three different processing conditions. The results are shown in Figs. 2 and 3.

First we will examine the data for Ni films grown on a smooth Cu surface at the optimum growth temperature of 400 K. For film thicknesses below 8 ML, there are relatively weak Kerr ellipticities in both the parallel and perpendicular directions (Fig. 2). The magnitudes of the ellipticities cannot be directly compared because the polar and longitudinal Kerr effects have different sensitivities. The sensitivity for the polar Kerr effect is roughly ten times that of the longitudinal Kerr effect for our experimental setup, so the magnetization in the parallel direction is about ten times larger than the magnetization in the perpendicular direction. This is consistent with ferromagnetic resonance studies of Ni films on Cu(100) which showed the anisotropy energy favors in-plane magnetization below 7 ML.[25] The magnitudes of both components are comparable to those of films grown at 300 K indicating there is not a significant amount of alloying with the Cu substrate since this would result in a lower Kerr ellipticity for the 400 K growth temperature films.

The most striking difference between the films grown at 300 and 400 K on a smooth substrate is the behavior of the coercive field at low thickness (Fig. 3). The coercive field stays nearly constant for 400 K growth temperature films where it increases monotonically for the 300 K growth temperature films. This shows the films have different domain structure with the 400 K films exhibiting a behavior characteristic of single domain films and the monotonically increasing coercivity for the 300 K growth temperature films characteristic or multidomain structure with an increasing domain size as the film thickness is increased.

At 8 ML film thickness, there is an abrupt increase in both magnetizations. This abrupt increase in magnetizations is accompanied by a sudden change in the coercive fields as well. The coercive field in the perpendicular direction drops to half its initial value indicating that the easy axis of magnetization is now in the perpendicular direction. The coercive

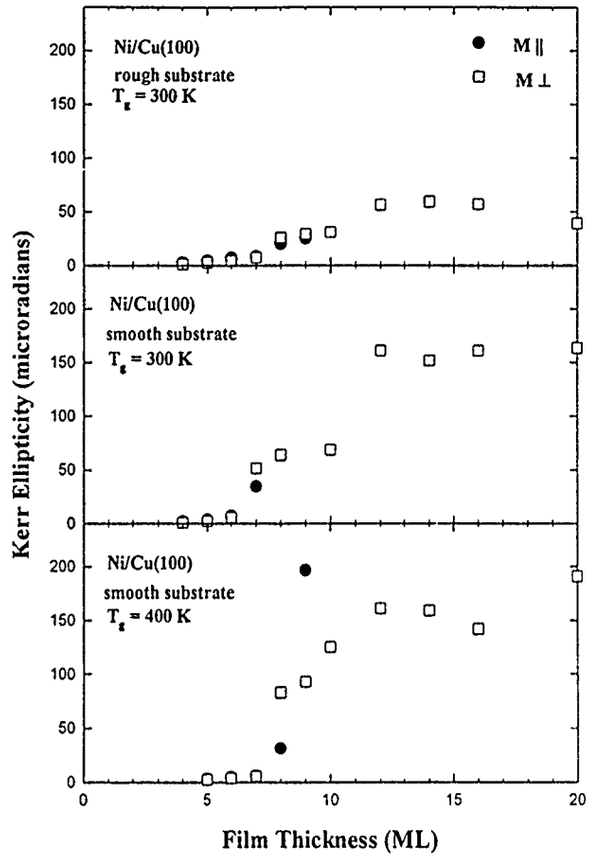

FIG. 2. Remanence vs Ni film thickness for three different film/substrate systems measured at temperature T=200 K. For each of the plots there is an abrupt increase in both parallel and perpendicular magnetizations at approximately 8 ML. Because of the limitation of our maximum applied magnetic field, the magnetization of the films could not be saturated in the parallel direction above 10 ML. This implies that the parallel component could also be increasing above this thickness.

field in the parallel direction increases sharply above the switching thickness, ultimately going above the maximum field attainable with our experimental apparatus. The slope of the perpendicular coercive field versus film thickness above the switching thickness is 1.2 Oe/ML. The abrupt change in the easy axis of magnetization is characteristic of a magnetic reorientation phase transition where the easy axis of magnetization changes from in plane to perpendicular at the switching thickness of 8 ML. This effect has been observed with x-ray magnetic circular dichroism measurements at a film thickness of 10 ML.[26]

We do not attribute the magnetization reorientation phase transition to any gross structural change since the LEED spots are similar both below and above the switching thickness for films grown at 400 K. However a subtle structural change occurs at thicknesses greater than 10 ML where the Ni(100) film transforms from a strained face centered tetragonal structure at low thickness with an in-plane lattice constant of the Cu substrate to a relaxed face centered cubic structure with an in-plane lattice constant identical to bulk Ni.[16] Small differences in the thickness where the structural strain relaxation change occurs may be due to different film preparation procedures or different levels of carbon and oxy-

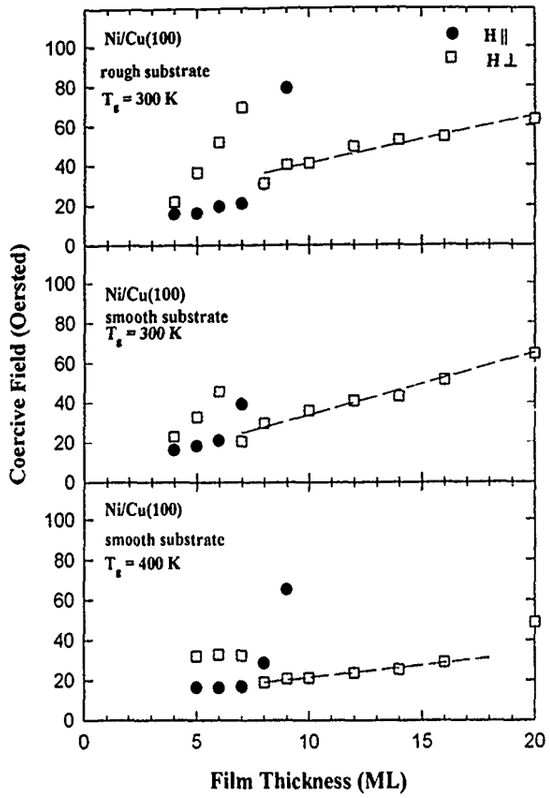

FIG. 3. Coercivity vs Ni film thickness for three different film/substrate systems measured at temperature T=200 K. For each of the systems, the coercivity in the perpendicular direction drops at the switching thickness indicating that the easy axis of magnetization is now in the perpendicular direction. The coercive field in the parallel direction increases sharply above the switching thickness, ultimately going above the maximum field attainable with our experimental apparatus.

gen contamination. This slight structural relaxation change nevertheless affects the anisotropy through the spin-orbit interaction It is sensitive to small changes in interatomic nearest-neighbor distances and by the different symmetry properties of the overlapping wave functions for the two structures. A recent calculation of the magnetocrystalline anisotropy energy showed that as a general trend, decreasing the atomic spacing will increase the energy term which prefers a perpendicular magnetization.[13,14]

In order to study the effect of interfacial strain on the switching thickness, we performed similar measurements for films deposited on a rough substrate. Interfacial roughness increases the amount of vertical strain and decreases the uniaxial anisotropy in films with perpendicular spontaneous magnetization.[27,28] The Kerr intensity for the films deposited on the rough substrate is significantly lower than that of the films deposited on a smooth substrate which shows that the magnetization of the rough films is reduced. Surprisingly, the switching thickness remains the same at 8 ML film thickness where there is a rapid decrease in the polar coercive field. However the polar Kerr ellipticity is three times weaker and the coercive field is twice as large as the films grown at 400 K. This reflects the different domain structure of the rough films and suggests that the structural change still occurs at 8 ML film thickness.

All these measurements show that the Ni films grown on Cu(100) have a predominantly in-plane magnetization for films below 8 ML thickness. Above a switching thickness the magnetization develops a strong out-of-plane component. We attribute this anomalous behavior to both structural and magnetic micromorphology of the Ni thin films. Ultrathin films of Ni have a multidomain magnetic microstructure which is a combination of perpendicular and in-plane domains, with the in-plane domains dominating below 8 ML. At a critical film thickness there is a structural transition and a perpendicular magnetization develops. The surface roughness can affect the magnetic strain anisotropy in a complicated fashion because the Ni layers can expand in both the in-plane and perpendicular direction. In the thinnest films, an in-plane interfacial strain anisotropy component is dominant. However, with increasing thickness, an out-of-plane component develops. The measurements indicate a mix of in-plane and out-of-plane magnetization domains, the latter shows a sudden increase at an onset thickness of 8 ML. At much greater film thickness, Ni/Cu(100) films show a transition back to in-plane magnetization.[29]

Magnetization-related transport anomalies in metal/ferromagnetic insulator heterostructures

G. M. Roesler, Jr., M. E. Filipkowski, P. R. Broussard, M. S. Osofsky, and Y. U. Idzerda
Naval Research Laboratory, Code 6340, Washington, DC 20375-5343

Magnetoresistance measurements have been performed on epitaxial metal/ferromagnetic insulator bilayers. They are more sensitive to magnetic behavior at the interface of such structures than magnetization measurements. It is clear from the magnetoresistance data that previously reported slope discontinuities in the resistance versus temperature of such heterostructures are magnetic in origin. These studies demonstrate that the conduction electrons of the metal are coupled to the spins in the magnetic insulator, and act as probes of the magnetic state at the interface between the two materials. An example of the usefulness of this probe is shown by magnetoresistance measurements on a Ag/EuO bilayer.

Thin film heterostructures of nonmagnetic metals and magnetic insulators represent a new class of systems in which the interaction of conduction electrons and magnetism may be investigated. They are in some respects analogous to all-metallic magnetic heterostructures, which have demonstrated remarkable behaviors such as giant magnetoresistance[1] and antiferromagnetic coupling through interlayers.[2] The primary qualitative difference between an all-metallic heterostructure and one involving insulators is that the conduction electrons in the latter are confined to the metal layer (except for tunneling processes), and interaction with localized moments is essentially restricted to those at the interface. Measurements of the in-plane resistance versus temperature in such systems[3] contain a strong feature near the Curie temperature of the insulator, for sufficiently thin metallic layers. In this paper, we describe magnetization and magnetoresistance measurements on such structures. Not only do these measurements confirm that the resistivity anomaly previously seen is magnetic in origin, but they reveal the utility of resistivity measurements in probing the magnetic state at the metal/insulator interface.

The metal/ferromagnetic insulator structures were prepared under conditions of heteroepitaxy, in a VG system with a base pressure of 10^{-10} mbar, on the [100] plane of yttria-stabilized zirconia (YSZ) substrates. The ferromagnetic insulator used, EuO, was chosen for its relatively low Curie temperature of 70 K and ease of thin film preparation. Pressure during EuO deposition is typically 10^{-6} to 10^{-7} mbar due to outgassing of the boron nitride crucible containing the EuO. The lattice constants of EuO and YSZ are identical, 5.184 Å, although the oxygen lattices of the two are of different symmetry. At a deposition rate of about 0.2 Å/s, EuO was found to grow epitaxially and two dimensionally on YSZ, with some three dimensionality of the surface occurring after about three unit cells have been deposited. For consistency, all of the samples reported in this work involve 100 Å EuO layers grown at a substrate temperature of 300 °C. Our EuO films have shown 70 K Curie temperatures by magnetization and Kerr rotation measurements. We are unaware of other work in which EuO films have been prepared epitaxially, but EuS films have been epitaxially grown.[4] It is probably essential that ultrahigh vacuum conditions be used in the preparation of these metal/magnetic insulator structures, to ensure intimate contact, and to ensure that the thin metal layers needed to demonstrate coupling are of high quality. If thick metal layers are used, as in one study of a thick Pb/EuS bilayer,[4] coupling may be difficult to detect. In our samples, resistivity anomalies are not seen for metal layers thicker than 200 Å.

Metal layers are evaporated *in situ* after EuO growth is completed, at typical pressures of 10^{-8} to 10^{-9} mbar. Because resistance measurements, x-ray diffraction, etc. must be done *ex situ*, a 200 Å Si passivation layer is applied to all samples. This is important to prevent degradation of the EuO due to moisture, and to minimize oxidation of V films, since the magnetic oxides of V could influence the scattering in the films. Resistance measurements are four-terminal ac or dc measurements with contacts in a van der Pauw configuration.

Figure 1 contains a comparison of the resistance of two metal/ferromagnetic insulator bilayers, one composed of a 36 Å Ag layer on EuO, the other 45 Å of V on EuO. Slope discontinuities, such as those reported in Ref. 3, are evident in both sets of $R(T)$ data, at 50 K for the Ag/EuO bilayer and at 90 K for the V/EuO bilayer. *Whenever* a dR/dT discontinuity is observed in our V/EuO structures, it occurs at 90 K; and at 50 K in Ag/EuO structures (sometimes with an additional feature at 13 K). Thus, a common trait of these structures is a *characteristic temperature* T^* determined by the

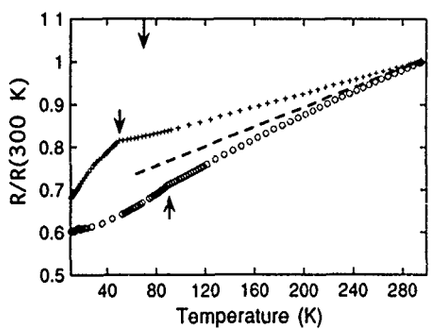

FIG. 1. The resistance of bilayers of 36 Å V on 100 Å EuO (circles) and 45 Å Ag on 100 Å EuO (crosses), normalized to room temperature. Arrows on the data show the location of T^* (dR/dT discontinuities) for the two samples. The top arrow is at the EuO Curie temperature (70 K). The dashed straight line is to make the curvature of the two data sets above T^* more apparent.

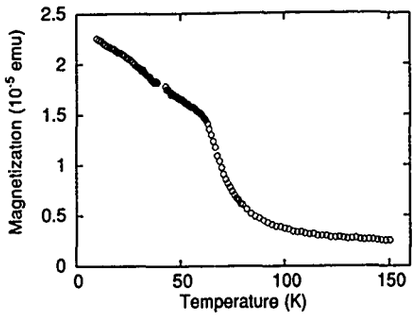

FIG. 2. Perpendicular magnetization of a 20 Å Ag film grown on 150 Å EuO on yttria-stabilized zirconia. The magnetization of the bare substrate has been subtracted from the data. Departure from Curie–Weiss behavior is apparent below about 70 K.

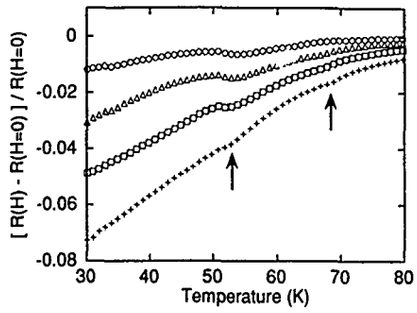

FIG. 3. Magnetoresistance of a 45 Å Ag film on 100 Å EuO in fields of (top to bottom) 1, 2, 3, and 4 T. The arrows indicate cusps in the 4 T data, which nearly correspond to Curie temperature of EuO (upper cusp), and to the slope discontinuity of the zero-field resistance that defines T^*_{Ag}.

metal element, and perhaps by other conditions such as strain or epitaxial arrangement. Figure 1 also illustrates some qualitative differences between the Ag/EuO and V/EuO samples we have grown. In the V-containing samples, the slope of the resistance always remains positive and has negative curvature down to T^*_V, whereas in Ag-containing samples, the resistance develops a positive curvature above T^*_{Ag}. For very thin (20 Å) Ag layers (not shown), *R(T)* exhibits a local maximum at T^*_{Ag}. This implies that the physics governing the scattering behavior in these two systems is qualitatively different. A further difference between V/EuO and Ag/EuO interfacial magnetism is apparent in the different values of T^* in the two systems. Compared to the bulk EuO Curie temperature of 70 K, T^*_V is shifted upward in temperature, whereas T^*_{Ag} is shifted downward.

The proximity of the *dR/dT* discontinuities to the EuO Curie temperature suggests that those features are magnetic in origin. Two experiments to confirm this, soft x-ray magnetic circular dichroism (SXMCD) and Hall effect, were reported in Ref. 3. No dichroism was observed in the SXMCD measurement, giving no confirmation of *d*-band splitting, and no anomalous Hall voltage was noted. A change in magnetic scattering due to magnetic ordering still seemed the most likely cause of the resistance anomalies. To verify this, magnetization and magnetoresistance measurements were performed on Ag/EuO heterostructures. Figure 2 shows the magnetization of a Ag/EuO bilayer measured on a SQUID magnetometer with the magnetic field perpendicular to the film plane. The magnetization of the bare substrate (weakly paramagnetic) has been subtracted from the data. Curie–Weiss behavior is evident at high temperatures. Departure from Curie–Weiss behavior begins in the 60–70 K range, but there is no distinct feature corresponding to T^*_{Ag}. This is not surprising if the anomaly at T^*_{Ag} represents an interfacial phenomenon, since any transition there involves only a fraction of the magnetic ions in the sample.

Magnetoresistance measurements proved more successful in resolving the bulk and interface behavior, and in associating the anomaly at T^*_{Ag} with magnetism. The magnetoresistance of a 45 Å Ag layer on EuO is shown in Fig. 3 for various magnetic fields applied perpendicular to the film plane. For fields of 1, 2, and 3 T, the magnetoresistance is nonmonotonic with temperature, having a maximum magnitude a few degrees above T^*_{Ag}, and a minimum magnitude at about T^*_{Ag}. At 4 T, the magnetoresistance is no longer nonmonotonic with temperature, but slope changes are visible both at the EuO Curie temperature and at T^*_{Ag}. Whatever the microscopic mechanism, a magnetic field strongly influences the scattering behavior at T^*_{Ag}. The magnetoresistance is negative even far above the Curie temperature, as is typical of systems containing disordered magnetic ions. One interpretation of the phenomenon at T^* is a reduction in scattering due to ordering of spins caused by local (exchange) fields. An ordering of perhaps one-quarter to one-half of the scattering centers would be consistent with the observed magnetoresistance.

Similar behavior has been observed in V/EuO heterostructures near T^*_V. The magnetoresistance of a V/EuO bilayer in a field of 1 T is shown in Fig. 4. The curve $\Delta R = \Delta R_0 (T_0/T)^2$, which is the magnetoresistance scaling expected for spin-flip scattering from disordered ions, is superimposed on the data. The close fit to the data at high temperatures and the abrupt departure just above T^*_V suggest that the maximum magnitude of magnetoresistance is due to an *extra scattering mechanism*, in addition to spin-flip scattering, which is significant within a few degrees of T^*.

These magnetization and magnetoresistance measurements demonstrate an association between magnetism and

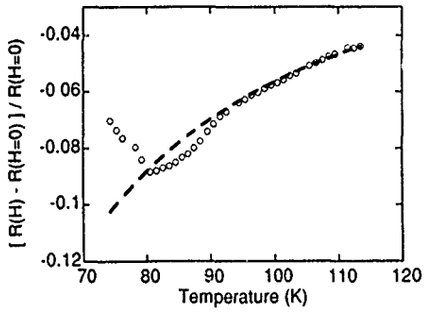

FIG. 4. Magnetoresistance of a 20 Å V film on 100 Å EuO in a field of 1 T. The dashed curve is $\Delta R = \Delta R_0 (T_0/T)^2$, where ΔR_0 is the magnetoresistance at $T_0 = 113$ K.

resistance anomalies in these metal/magnetic insulator heterostructures. The microscopic behavior responsible for this association could be as simple as alignment of the localized Eu^{++} spins by the molecular field of the EuO. Or a more complex phenomenon, such as a many-body polarization of the conduction electrons due to the overlap of their wavefunctions with the Eu^{++} f orbitals, could be responsible. Regardless of the mechanism, the conduction electrons respond to changes in scattering which are associated with magnetism, and therefore *act as probes of the magnetic state at the interface.*

We show as an example of the utility of this interaction the magnetic behavior of a Ag/EuO multilayer which exhibited a T^* of 13.5 K rather than the usual 50 K. Because the total thickness of this multilayer was over 500 Å, some surface roughness may have allowed contact between Ag and EuO planes not ordinarily in contact in thin bilayer samples. The resistance of the multilayer is shown in Fig. 5 for the magnetic field both in-plane and out-of-plane. With the field in-plane, the magnetoresistance is small and negative above T^*, and nearly zero below T^*. When the field is out-of-plane, magnetoresistance is strongly positive at low temperatures, and the downward shift of T^* is stronger than with the field in-plane. These measurements suggest that an in-plane anisotropy exists in this sample.

The coupling of conduction electrons to localized spins at a metal/magnetic insulator interface may in future prove to be useful both for probing the magnetic state of such interfaces and for understanding fundamental processes involved in electron-spin interactions. It will be important to develop an understanding of the microscopic processes which determine the magnetic and scattering behavior illuminated by these measurements. For example, two fundamental questions are why T^*_V and T^*_{Ag} are different, and why they are displaced in opposite directions from the Curie temperature of bulk EuO. Determining the role of epitaxy and interface arrangement in the behavior of these structures will be the subject of future studies. Also of interest is the nature of the 13 K anomaly in Ag/EuO films, which is only occasionally observed in these structures.

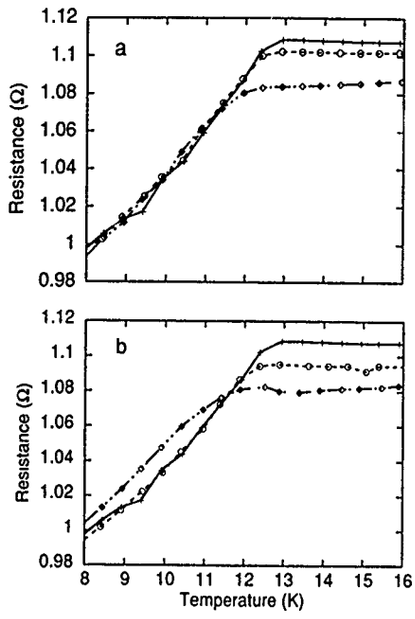

FIG. 5. Resistance in a magnetic field of an Ag/EuO multilayer of composition (20 Å Ag/30 Å EuO)$_{10}$, with magnetic field (a) in plane, and (b) out of plane. Magnetic field strengths: $H=0$ (crosses, solid curves), 2 T (circles, dashed curves), and 4 T (diamonds, dot-dashed curves).

The magnetic domain structure and microscopic magnetization reversal processes in epitaxial Fe/GaAs(001) films with cubic anisotropy and in-plane easy axes have been investigated by a Lorentz microscope equipped with a magnetizing stage. For the films of a few hundred angstroms thickness we observe the single domain remanent state predicted for a two-dimensional film but find that domains play a crucial role in the magnetic reversal process. For reversal along the in-plane ⟨110⟩ directions (hard axes), magnetization reversal proceeds via a combination of coherent rotation and displacements of weakly pinned 90° domain walls at critical fields. For magnetization reversal along the in-plane ⟨100⟩ directions (easy axes), an irregular checkerboard domain structure develops at the critical field and both 180° and 90° domain walls coexist. The reversal of the domains with magnetization vector opposite to the applied field direction takes place by a combination of two 90° reorientations. We discuss how these processes are related to the magnetic anisotropies present in the film and the macroscopic M-H hysteresis curves.

I. INTRODUCTION

The magnetic properties of thin epitaxial Fe films and various types of Fe multilayer films grown on semiconductor substrates are of particular interest since they open up possibilities for a broad range of applications[1] and also permit fundamental studies in magnetism.[2–4] The structural and magnetic properties of these epitaxial Fe films are the focus of current experimental investigations.[3–5] Recently, the magnetization reversal processes in epitaxial Fe/GaAs(001) thin films have been studied by the longitudinal and transverse magneto-optical Kerr effects (MOKE).[4–6] From these studies, it is now clear that the simple coherent rotation model cannot explain all the details of the magnetization process in these Fe/GaAs(001) films and that magnetic domain processes play an important role in the magnetization reversal around the transition fields. However, to our knowledge, the detailed domain evolution during magnetization reversal in such epitaxial Fe films has not been reported.

II. EXPERIMENT

The Fe films were grown on As-desorbed GaAs(001) substrates in an ultra high vacuum chamber.[7] During growth, the pressure was less than 5×10^{-10} mbar. The optimum substrate temperature of 150 °C and a deposition rate of 1 Å min^{-1} were used for the Fe growth. To prevent oxidation, completed Fe films were covered by a Cr cap layer. In this work, a new selective chemical etching technique was employed to prepare Lorentz microscope specimens.[7] By using this method, an electron transparent uniform "window" (up to 300×300 μm in size) appropriate for magnetic domain studies can be fabricated. The macroscopic magnetization reversal behavior of the Fe films was studied using a MOKE magnetometer.[5,8] The magnetic domain structure in the Fe films was revealed using a Lorentz electron microscope equipped with a magnetizing stage.[9]

III. RESULTS

A. Microstructure

The epitaxial growth of bcc Fe films was confirmed by transmission electron diffraction. The surface topography of the Fe films was investigated by scanning tunneling microscopy (STM). STM images reveal that the films have a surface roughness amplitude of about 10 Å over lateral distance of several hundred angstroms. Detailed structural results are reported elsewhere.[10]

B. Microscopic magnetization reversal processes

1. ⟨110⟩ hard directions

For the applied field aligned parallel to the ⟨110⟩ in-plane hard direction, the MOKE hysteresis loop of an Fe(150 Å)/GaAs(001) film with cubic anisotropy (K_1/M=259 Oe, $K_u\sim0$) is inset in Fig. 1. It can be seen that initially there is a gradual decrease of the component of the magnetization parallel to the applied field direction from saturation as the field strength is reduced from the saturation value. An abrupt jump occurs at a small negative field followed by a further gradual decrease until negative saturation is reached. At this transition field, Barkhausen discontinuities are observed in the detailed MOKE loops indicative of the irreversible movement of domain walls.

To gain insight into the mechanisms by which the magnetic switching behavior described above took place, the Fe(150 Å)/GaAs(001) film was subjected to field cycles in the Lorentz microscope. First, a single domain state was induced by applying a magnetic field (H_i) along one of the ⟨110⟩ directions, say the [1$\bar{1}$0] direction. Then the field was reduced to zero. In the remanent state, the Fe film was found to be still in a single domain configuration. This single domain state persisted up to a critical reverse field strength $H_r = H^h_{crit}$ applied along the [$\bar{1}$10] direction at which domain walls were first observed (H^h_{crit} = 5.6 Oe for a field amplitude

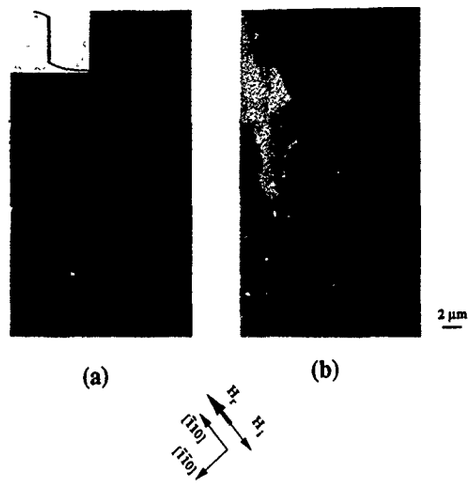

FIG. 1. Foucault images of an Fe(150 Å)/GaAs(001) film for the field applied along the hard axis. The component of induction mapped was parallel to the applied field direction for reverse field strengths ($H_r \| [1\bar{1}0]$) of (a) H^h_{crit}, (b) 1.10 H^h_{crit}. The MOKE hysteresis loop along this direction is inset.

of 120 Oe). Only a few domain walls appeared, extending several hundreds of microns across the whole area of the window. A Foucault image, sensitive to the component of induction parallel to the field direction and recorded at the critical field strength is shown in Fig. 1(a). In this image, a single wall running almost parallel to the $[1\bar{1}0]$ direction can be seen. Figure 1(b) shows what happened when the field strength was increased to a value of 1.10 H^h_{crit}. In this case the domain wall seen in Fig. 1(a) remained pinned at the original position but another domain wall moved into the field of view from the top right-hand corner. A further small increase of field led to the disappearance of domain walls from the whole of the visible area of the sample. Repetition of the field cycle described above showed that the fields at which walls appeared and disappeared were highly reproducible. Further, it was noted that Foucault images sensitive to magnetic induction perpendicular to the field direction were never found to show contrast variations, indicative of a constant (or zero) magnetization component in that direction. These images are consistent with the magnetization orientations indicated by the arrows shown in Fig. 1.

The overall magnetization reversal process for fields along the ⟨110⟩ direction can now be explained with reference to Fig. 2. As the field strength is reduced from a high value in the $[1\bar{1}0]$ direction, there is a tendency for the magnetization to rotate towards the nearest easy axis. While $[1\bar{1}0]$ lies midway between the easy [100] and $[0\bar{1}0]$ directions, in practice, the applied field will never be exactly along the intended direction with the result that the magnetization vector rotates towards whichever easy direction is closer to that of the field ([100] in Fig. 2). Hence, in the remanent state, the sample is uniformly magnetized as a single domain along this "preferred" easy direction. Application of a field of the opposite polarity (namely one parallel to $[\bar{1}10]$) leaves the film in its single domain state until, at the critical field, 90° walls are nucleated and these sweep across

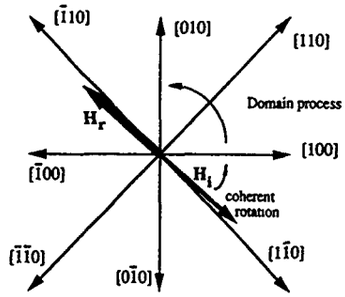

FIG. 2. Magnetization reversal process for applied fields near the ⟨110⟩.

the specimen introducing domains in which the magnetization is oriented along [010], the easy direction near to that of the applied field. Increasing the field strength by only a fraction of 1 Oe allows [010] oriented domains to grow through Barkhausen-like jumps, the jump distance observed being of the order of a few tens of microns. This part of the reversal process corresponds to the steep part of the MOKE loop. When it is complete the whole of the film is once again uniformly magnetized but the direction of magnetization has changed from the [100] direction to the [010] direction. Increasing the field strength further leads to the magnetization moving away from the $[01\bar{0}]$ direction towards that of the applied field. Very similar magnetization reversal behavior has also been observed for a 450 Å Fe film along the ⟨110⟩ hard axes.

2. ⟨100⟩ easy directions

Along the ⟨100⟩ easy directions, the Fe films exhibit a square hysteresis loop (the hysteresis loop is inset in Fig. 3). However, Barkhausen discontinuities are also observed at the transition field in the detailed minor hysteresis loop.

In the microscope, following a similar procedure to that used for the ⟨110⟩ direction, a single domain state was first induced, in this case by applying a field along $[0\bar{1}0]$. After removal of the field, no walls were observed in the sample, as is consistent with the square loop observed by MOKE. Magnetization reversal was then studied by applying successively greater fields parallel to [010]. No change was observed up to a field of H^e_{crit} = 7.8 Oe at which point domain walls suddenly appeared. A Foucault image, sensitive to the component of induction perpendicular to the field direction and recorded at the critical field strength is shown in Fig. 3(a). The evolution of the domain structure shown in Fig. 3(a) is shown for a field of 1.09 H^e_{crit} in Fig. 3(b). In both cases the domain structure is of the checkerboard type observed also in demagnetized Fe/MgO(001) films.[11,12] The magnetization distributions deduced from the images (the Foucault images, sensitive to the component of induction parallel to the field direction are not included in Fig. 3) are also shown in Fig. 3. Increasing the field above 1.13 H^e_{crit} led to a complete loss of domain walls with the sample returning to a single domain state, albeit with a reversed magnetization vector. A similar checkerboard domain pattern is also formed for reversal along the other easy axis.

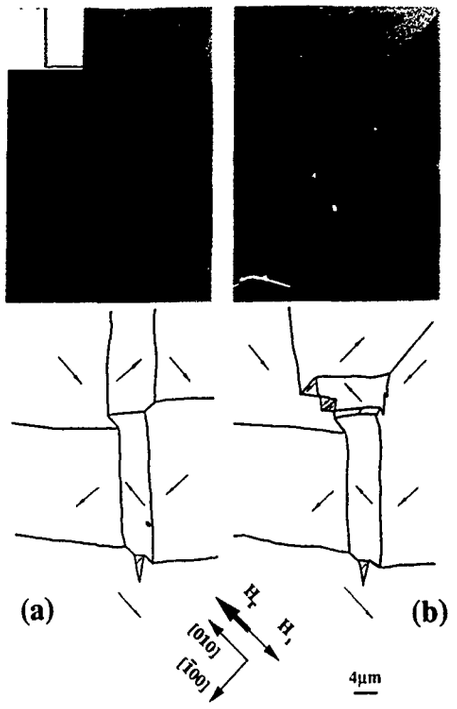

FIG. 3. Foucault images and magnetization distributions of the 150 Å Fe film for the field applied along the easy axis. The component of induction mapped in the images was perpendicular to the applied field direction for reverse field strengths (H_r||[010]) of (a) H^c_{crit}, (b) 1.09 H^c_{crit}. The MOKE hysteresis loop along this direction is inset.

While a pure checkerboard domain structure comprises only 90° domain walls, some (generally short) 180° walls are observed in our structures. It can be seen that the 90° and 180° domain walls are aligned almost along the ⟨110⟩ and ⟨100⟩ directions, respectively. The 180° domain walls are assumed to arise from the combined action of the applied field and pinning centers.

In Figs. 3, domain wall displacements and the nucleation of new domains are observed. A detailed study of Figs. 3 shows that the reversal of the magnetization which is initially antiparallel to the applied field tends to take place not by a single reversal, but by a combination of two 90° reorientations. This two-step reversal process appears to involve both domain nucleation and wall displacements.

It is immediately clear that magnetic domains again play a crucial role in the reversal mechanism when the field is applied along a ⟨100⟩ direction. The main steps in the reversal process are summarized as follows. Since ⟨100⟩ directions are the easy axes for an Fe film with cubic anisotropy it is entirely reasonable that the magnetization should remain oriented along is initial direction (say [0$\bar{1}$0]) when the field is reduced to zero. Even if the applied field is not exactly parallel to the [0$\bar{1}$0] direction, as mentioned in the previous section, during reduction of the field strength to zero, the magnetization will simply rotate to this [0$\bar{1}$0] direction leaving a single domain remanent state. Since the [0$\bar{1}$0] direction is the bisector of another two easy directions, [100] and [$\bar{1}$00], there should be comparable probabilities for the magnetization to jump into either of these two easy directions as the strength of the field in the [010] direction is increased. Thereafter, further 90° transitions take place to introduce domains in which the magnetization is parallel to the applied field and, over a small field range, all four easy magnetization directions are present in the sample simultaneously. This structure is the checkerboard pattern but it exists only within a narrow field range. It is destroyed by a combination of further domain nucleation and wall motion of the kinds discussed above. For the 450 Å Fe/GaAs(001) film an irregular checkerboard pattern also develops for reversal along the easy directions.

IV. DISCUSSION AND CONCLUSIONS

Since all the magnetic domains observed have sizes (>1 μm) much larger than the lateral length of surface features revealed by STM, one may conclude that the domain size is not affected by the topography of these Fe/GaAs(001) films. For demagnetized ultrathin fcc Co/Cu(100) films, the magnetizations of the domains lie along each of the four easy in-plane axes but the walls are extremely irregular, suggesting a vanishing magnetostatic energy. [13,14] In our films, the domain walls are fairly straight and have a defined orientation with respect to the crystal axes. Therefore, these results show that the 150 Å thickness is sufficient for the magnetostatic energy contribution to the wall energy to be important.[10] Nonetheless, the films are still thin enough to be considered as almost two dimensional from the viewpoint of domain formation. A simple estimate of the energy associated with the checkerboard domain structure shows that the checkerboard domain is driven by the Zeeman energy at the coercive field.[10]

Magnetic response of ultrathin Fe on MgO: A polarized neutron reflectometry study

S. Adenwalla, Yongsup Park, and G. P. Felcher
Argonne National Laboratory, Argonne, Illinois 60439

M. Teitelman
Russian Academy of Science, Nizhny Novgorod, Russia

The magnetization of ultrathin bcc Fe films (two and three monolayers) on MgO was measured and compared with the behavior predicted for a two-dimensional ferromagnet. The experiment indicated that no hysteresis was present in the magnetization. Instead, the magnetization at low temperature was affected by a marked field cooling effect. These observations lead to the conclusion that films of Fe on MgO of such thickness exhibit superparamagnetic behavior as if they were not entirely continuous. In contrast, films thicker than five monolayers exhibit a magnetic response close to that of bulk iron.

I. INTRODUCTION

A polarized neutron reflection (PNR) study of thin films of bcc iron on MgO recently published[1] showed some surprising features. Even the thinnest films (two monolayer thick) were found to be ferromagnetic. At low temperature a sizeable magnetic field (of the order of 1 kOe) was necessary to saturate the in-plane magnetization, while fields of a few oersted were sufficient to saturate thicker samples. The amplitude of the ferromagnetic moment was found to be 2.2 ± 0.2 μ_B/Fe atom regardless of the sample thickness, in contrast with a predicted enhancement[2] for the surface atoms close to 3 μ_B/Fe atom. In view of the unusual magnetization curve at low temperature the question was raised if these thin films of iron showed the elusive magnetic behavior expected for a two-dimensional ferromagnet.

A magnet in two dimensions differs in significant ways from its three-dimensional counterpart. The Mermin–Wagner theorem shows that in the absence of anisotropy there is no magnetic ordering at zero field.[3] At finite fields the field and temperature behavior of the magnetization is governed by the equation[4]

$$\frac{M}{M_0} = 1 + \frac{k_B T}{2\pi J} \ln[1 - \exp(-2\mu H/k_b T)]. \quad (1)$$

For $\mu H < kT$ the magnetization follows a loglike behavior. Over a large temperature range the magnetization induced at a given field decreases almost linearly with increasing temperature.

The technique used was PNR, the working of which has already been discussed in detail in the literature.[5] Here it was used to measure the magnetic moment, functioning as a sensitive magnetometer. The physical quantities observed by PNR, however, differ somewhat from those observed by regular magnetometry. In PNR it is assumed that the films are formed of uniform and flat layers. If the films are not entirely uniform, the mean amplitude has to be taken for each height in the film; the *roughness* also causes some of the neutrons to be scattered out of the specular beam. Second, only the component of the magnetization in the plane of the sample is measured. This component, however, can be obtained as an *absolute* value.

II. EXPERIMENT

The samples studied consisted of the equivalent of two, three, or eight monolayers of Fe evaporated onto the substrate at room temperature. The Fe was covered by a wedge-shaped coating of gold, with a mean thickness of 200 A. These samples had been used in a previous PNR experiment,[1] and they were similar to others used in extensive magneto-optical Kerr effect measurements.[6] However fresh samples, sputtered on MgO and covered with MgO as well, showed similar magnetic behavior. The measurements were taken at temperatures ranging from 25 to 300 K and magnetic fields from 20 to 7000 Oe at the reflectometer "POSY-I" at the Intense Pulsed Neutron Source at Argonne National Laboratory. Each data point presented here has been extracted from a measurement which took approximately 12 h.

Fitting the neutron reflectivity data, we obtain a saturated moment of $2.0 \pm 0.2 \mu_B$/Fe atom, showing no enhancement over the bulk value. Demagnetizing effects do not play a role since at this field the moment lies along the applied field direction.

Figure 1 shows the temperature variation of the magnetization of the three monolayers sample at 7 kOe. The magnetization decreases linearly with increasing temperature with a slope far greater than that of bulk iron. Is this the signature of a two-dimensional magnet? The low temperature magnetization curve (Fig. 2) shows saturation at about 1000 Oe and could not be fit to a log function. On the other hand, the magnetization had features not expected for a conventional ferromagnet. No evidence for hysteresis was found, as it was checked by reversing the field and then measuring the remnant magnetization. In addition, a very marked field cooling effect was present. On cooling from 275 K in a field of 7 kOe (FC), the remanent magnetization was about half the saturation value. The remanent magnetization dropped dramatically by cooling from room temperature in zero field. The two monolayers sample displayed essentially the same features as the three monolayer sample, but with worse statistics. The eight monolayer sample showed a clear hysteresis loop, with a H_c of 50 Oe at 35 K

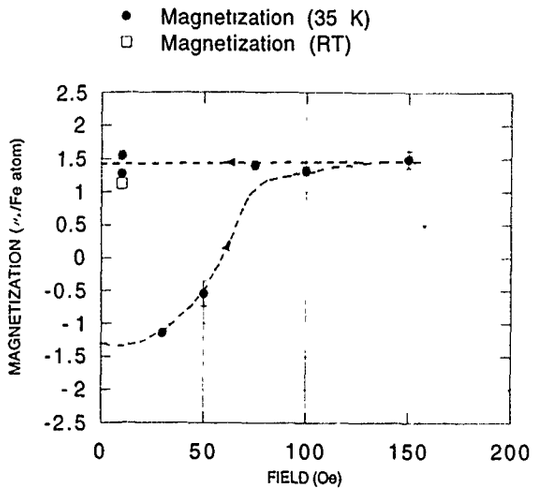

FIG. 3. Hysteresis loop at 35 K for the eight monolayer sample.

(see Fig. 3) and no appreciable variation with temperature of the magnetization at saturation.

III. DISCUSSION

The absence of hysteresis is indicative of superparamagnetism. Instead of a continuous thin film of Fe, the Fe forms islands on the surface of MgO. In a superparamagnetic material, in the absence of anisotropy, the component of magnetization in the field direction follows the Langevin function[4]

$$\frac{M}{M_0}=\coth\left(\frac{\mu H}{k_B T}\right)-\left(\frac{k_B T}{\mu H}\right), \tag{2}$$

where μ refers to the magnetization of the superparamagnetic particle, comprising a large number of atoms. Using the absolute value of the magnetization per Fe atom (obtained from fitting the neutron reflectivity data), we obtain the best fit to a Langevin function for islands of 1000 atoms in size. The calculated magnetization is presented in the form of dashed curves in Figs. 1 and 2; in Fig. 1 it is apparent that, even for superparamagnetic particles, the temperature variation of the magnetization is almost linear in a region not too close to the Curie temperature.

According to the Langevin function the magnetization is null at zero field. However it is well known[4] that below a blocking temperature field cooling effects are present, which are interpreted as due to anisotropy. The anisotropy energy provides an energy barrier against rotation of the magnetization. If the sample is cooled in a magnetic field, and the the magnetic field is turned off, the magnetization relaxes exponentially with a time constant that is large well below the blocking temperature. A naïve calculation starting from the crystalline anisotropy of Fe gives a relaxation rate at 25 K of $\sim 10^{-9}$ s—a value which is far too small. Published measurements by Xiao *et al.*[7] on granular films confirm that the crystalline anisotropy is only a small contribution to the anisotropy energy barrier in superparamagnetic systems. We know that other anisotropies are present in our system, for instance shape anisotropy. The iron clusters are in reality thin flat islands; if they were not so, their magnetic moment would not have contributed appreciably to the magnetic reflectivity. As corroborating evidence, the magnetization of the eight monolayer Fe coverage seems to be that expected of a *continuous* film. What is not known is the detailed nature of these islands, and for that reason it is not possible at present to do further modeling: the notion itself of superparamagnetism is qualitative (because no interaction is assumed between the islands) and based on a a limited amount of observations. However, transmission electron microscopy characterization may allow us to make a more quantitative analysis.

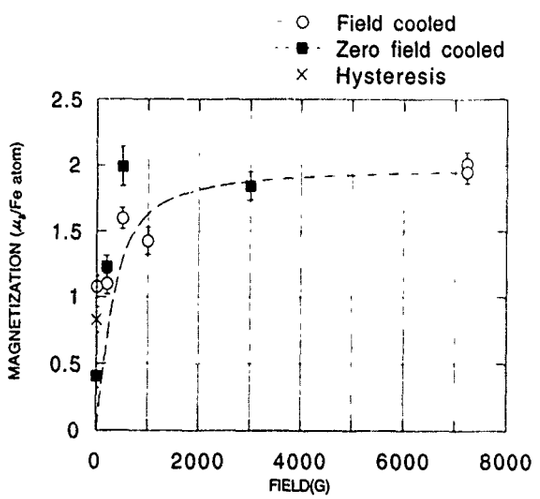

FIG. 2. Field dependence of the magnetization at 25 K of the three monolayer sample. The dashed line is the Langevin function for particles 1000 atoms in size.

The present study shows that films of Fe on MgO below a certain thickness do not have long range ferromagnetic ordering, such as has been observed for ultrathin Fe films on Cu,[8] Ag,[9] and Au.[10] The magnetic response can be explained in terms of superparamagnetism, which leads to the conclusion that, below a certain thickness, Fe on MgO aggregates in islands. This conclusion had been tentatively reached already by Liu *et al.*[6] on the basis of some magneto-optic measurements: below a thickness of four monolayers Fe films on MgO showed no Kerr effect signal. The lattice mismatch between MgO and Fe is only 4%; however, the difference in the surface energies (4010 nJ/mm^2 for Fe vs 1200 nJ/mm^2 for MgO) is large, which may account for the fact that at small thicknesses the Fe does not wet the MgO surface. Finally, the present measurements indicate that the magnetic moment of iron in these samples is not enhanced compared to the bulk value which is consistent with our conclusion that we have aggregates of particles in these samples.

Roughness dependent magnetic hysteresis of a few monolayer thick Fe films on Au(001)

Y.-L. He[a] and G.-C. Wang
Department of Physics, Rensselaer Polytechnic Institute, Troy, New York 12180-3590

We have studied quantitatively the surface and interface roughness of Fe films in a few monolayer regime on an Au(001) surface using the high-resolution low-energy electron diffraction technique. The hysteresis loops of those films were also measured *in situ* by the surface magneto-optical kerr effect technique. A correlation between the shape of hysteresis loops and the roughness of films was observed. The hysteresis loops are consistently squarelike for films with a two-dimensional (2D) smooth structure. For films with isolated three-dimensional (3D) islands structure, the hysteresis loops are typically stripelike. For films with a combination of 2D/3D structure, the loop shape is squarelike for longitudinal loops and stripelike for polar loops.

I. INTRODUCTION

The study of the relationship between ultrathin film morphology and magnetic properties on the atomic scale is a challenging subject. The magnetism is an electronically driven phenomenon. It depends not only on the arrangements of electrons in an atom but also on the structural arrangement of atoms in an ultrathin film. Advances in sample preparation techniques and availability of atomic scale characterization techniques have made it possible to prepare ultrathin films in a variety of structures.[1] If the magnetic property of films with known structure is measured, then the possibility of obtaining magnetic ultrathin films with desired characteristics increases.

Previous experimental studies on magnetic properties of ultrathin Fe films grown on an Au(001) surface under various growth conditions have been reported. For example, Liu and Bader[2] have observed perpendicular magnetic anisotropy in the Fe/Au(001) films grown at 100 K with thickness less than 2.8 monolayer (ML). In contrast, Fe/Au(001) films grown at room temperature have been shown to exhibit in-plane easy axes in the monolayer regime.[3,4] However, quantitative information on the roughness and structure of the as-grown films and their effects on magnetic properties are still lacking. In this article, we show there exists a strong dependence of magnetic hysteresis loops on the roughness of ultrathin Fe/Au(001) films in a few ML regime. There are three kinds of film roughness, two-dimensional (2D) smooth and continuous, three-dimensional (3D) isolated islands, and a mixture of 2D/3D, that can be prepared at room temperature by changing the deposition rate.

II. EXPERIMENT

All the experiments were performed in an ultrahigh vacuum chamber with a base pressure of 1×10^{-10} Torr. The chamber was equipped with surface magneto-optic kerr effect (SMOKE), high-resolution low-energy electron diffraction[5] (HRLEED), and Auger electron spectroscopy (AES) techniques. The details of our SMOKE setup have been presented elsewhere.[6] The magnetic field can be aligned either perpendicular or parallel to the sample surface by rotating the electromagnet 90° *in situ*. This allows the measurement of longitudinal and polar Kerr loops using the same electromagnet.

The perfection of the Au(001) substrate was characterized by angular profile measurements of diffraction beams from the surface. On a well-annealed surface, the size of ordered regions ranges from ~400 to ~600 Å. Ultrathin Fe films were prepared by thermal evaporation of Fe atoms from an Fe foil heated to ~1200 °C by electron bombardment. The growth rate and roughness of films were determined by analyzing the changes of angular profiles of the (00) diffraction beam measured from the Fe films/Au(001).

III. RESULTS AND DISCUSSION

A. Film growth and morphology

To monitor the growth morphology using HRLEED, we measure the change of angular profiles near an out-of-phase diffraction condition of film-substrate system during deposition. This is because the destructive interference of electrons is most sensitive to a surface or a film containing steps.[7] For example, if electrons scattered from adjacent terraces separated by a step of height d are out of phase, i.e., the electron path length is a half-integer number of the electron wavelength λ, then the diffraction intensity at the Bragg position decreases. The angular profile will broaden. This destructive interference condition is $d\cos\theta=\lambda/2$, where the θ is the angle of incidence and angle of diffraction for the specular diffraction beam and $\lambda=[150.4/E(\text{eV})]^{1/2}$. Reference 8 lists calculated and measured energies for the out-of-phase condition for the clean Au and Fe-Au systems.

The Fe films of a few ML thickness are prepared by the experience gained from the submonolayer growth.[8] Basically, the line shape of angular profiles broadens from that of the clean surface profile and then narrows with accumulated deposition time. At 110 s, the angular profile becomes nearly the same as that of the initial time. From the diffraction point of view, the Fe/Au(001) surface is virtually identical to the clean Au surface. We thus assign the Fe coverage as ~1 ML at 110 s, implying the growth rate is ~0.55 ML/min. The growth rate can be doubled by increasing the source temperature by 20 K. In this range of deposition rate, the growth mode is essentially layer-by-layer as evidenced by the full-

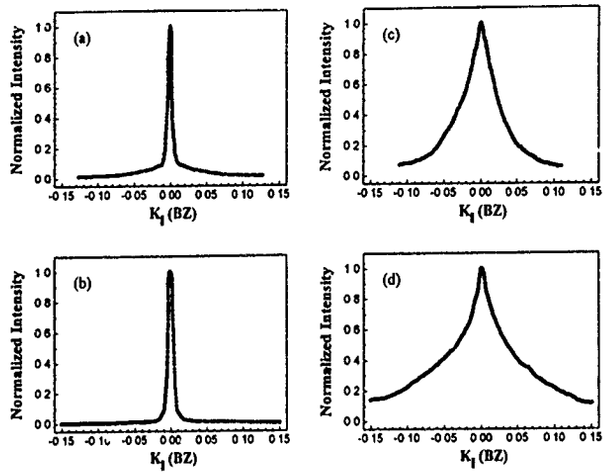

FIG. 1. Angular profiles of the (00) beam measured from Fe/Au(001) films: (a) and (b) 2D with ~2.0 ML coverage; (c) and (d) 3D film with ~2.1 MLE coverage. The energies of 27.5 eV (a) [28 eV for (c)] and 44 eV (b) [same for (d)] are near the out-of-phase conditions for Au-Fe and Fe-Fe steps, respectively. The $K_{\parallel}$ is the momentum transfer parallel to the surface and is in units of Brillouin zone [BZ=2π/(2.88 Å)].

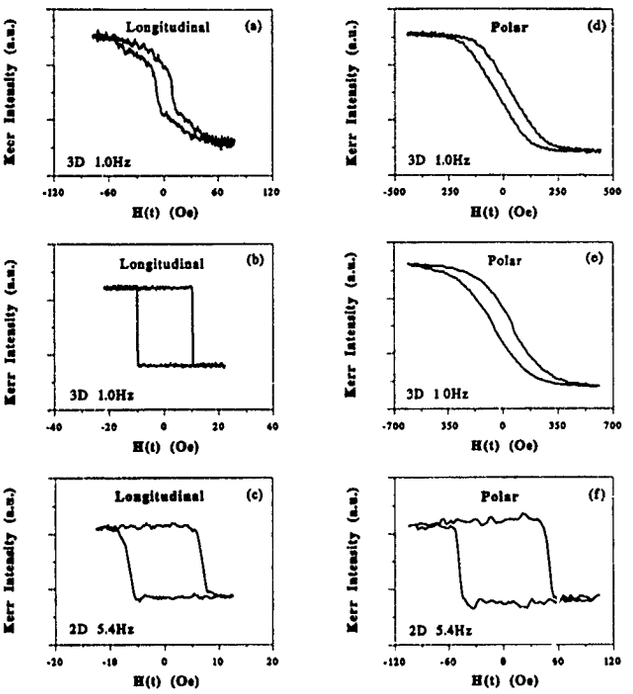

FIG. 3. Longitudinal and polar hysteresis loops measured from Fe films with various roughness as sketched in Fig. 2: (a) and (d) for 3D isolated islands, ~2.1 MLE; (b) and (e) for 3D islands on 2D smooth film, ~3.7 MLE; and (c) and (f) for 2D smooth film, ~2.0 ML. Note the arbitrary units in the Kerr intensity.

width-at-half-maximum (FWHM) oscillation and a smooth continuous film, denoted as 2D film, persists up to ~3 ML. It then crosses over to a 3D island growth mode. The angular profiles (raw data) near the out-of-phase conditions of Fe-Au (27.5 eV) and Fe-Fe (44 eV) from a 2D film of ~2 ML are shown in Figs. 1(a) and 1(b). Both profiles do not broaden significantly compared to that of the clean Au surface and indicate a relatively smooth and continuous film with low density of steps as sketched in Fig. 2(c).

If the growth rate was reduced below ~0.2 ML/min, 3D island growth occurs. There was no oscillatory behavior observed in the line shape of angular profiles with accumulated time as that observed in 2D layer-by-layer growth. Instead, the FWHM at the out-of-phase condition monotonically increases with time (not shown here). This is a characteristic of 3D growth. The rate dependence of growth mode is due to the growth kinetics and has been discussed elsewhere.[9] Figures 1(c) and 1(d) show the profiles measured near the out-of-phase conditions of Fe-Au (28 eV) and Fe-Fe (44 eV) from a film with ~2.1 ML equivalent (MLE) coverage. Comparing the profiles of Figs. 1(c) and 1(d) with that of Figs. 1(a) and 1(b), the profiles of Figs. 1(c) and 1(d) are considerably broader. A complete energy-dependent FWHM measurement shows maximum broadening peaks at ~28 and ~43 eV.[9,10] This result is consistent with the calculated destructive interference energy.[8] The coexistence of two types of steps (Fe-Au and Fe-Fe) supports that the film was grown in a 3D mode. The amount of broadening is inversely proportional to the average terrace width.[7] From the FWHM shown in Figs. 1(c) and 1(d), we estimate that the average terrace of isolated islands is ~60 Å. Also, the profile shape measured at the Fe-Fe out-of-phase is consistent with that from a multilayer thick film. A film with ~2.1 MLE coverage consisting of 3D islands isolated by nonmagnetic Au substrate is sketched in Fig. 2(a). The lateral size of the islands near the interface is smaller than the terrace of Au substrate (shaded area of ~400–600 Å). With sufficient amount of Fe deposits, e.g., ~3.7 MLE, the substrate is entirely covered by the film as sketched in Fig. 2(b).

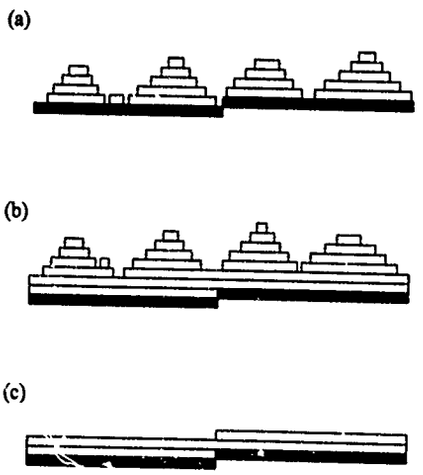

FIG. 2. Schematics of three ultrathin Fe/Au(001) films: (a) ~2.1 MLE, 3D isolated islands; (b) ~3.7 MLE, 3D continuous islands; and (c) ~2.0 ML, 2D continuous and smooth. The shaded area denotes the substrate (with a step), and the unshaded area denotes the films.

B. Magnetic hysteresis loops

Figure 3 shows hysteresis loops measured from two kinds of 3D films (~2.1 and ~3.7 MLE) and a 2D smooth film of ~2 ML. The polar loops measured from both 3D films are typically stripelike as shown in Figs. 3(d) and 3(e). However, the shape of longitudinal loops for the 3D films

depends on the film coverage. The longitudinal loop measured from ~2.1 MLE film is stripelike as shown in Fig. 3(a) but is square like for ~3.7 MLE film. In contrast there is no coverage-dependent loop shape for 2D films. The loops are squarelike in both directions as shown in Figs. 3(c) and 3(f).

Various shapes of hysteresis loops can be related to various film morphologies as follows. For a continuous and smooth film, the squarelike hysteresis loop shown in Fig. 3(c) is consistent with that of the dominant magnetization reversal process in the wall displacement and the easy axis is oriented in the surface plane. Due to the cubic symmetry observed in Fe film, the easy axis can also be oriented along the surface normal. Therefore, the polar hysteresis loop is also squarelike. See Fig. 3(f).

The stripelike shape of the hysteresis loops shown in Figs. 3(a) and 3(d) is consistent with the loop shape measured from single domains with various shapes and sizes. Note that from the 1×1 LEED pattern we learn that each Fe island has an epitaxial relation with respect to the Au(001) substrate, i.e., bulk bcc Fe lattice rotates 45° with respect to the fcc Au lattice. This rotation minimizes the lattice mismatch to less than 0.5%. The magnetization process involves rotation of spins in each single domain which requires larger applied field to reverse the spins and saturate the domains as compared with just domain wall movement. Each isolated ferromagnetic Fe island on the Au substrate may have its own demagnetization factor. The demagnetization factor depends on the structural shape and size of the Fe island. From the profile measurement we know the 3D film has a distribution of island size and height, therefore the demagnetizing field which is opposite to the applied field has various magnitude. When an external magnetic field is applied on the positive direction in either longitudinal or polar configuration, the domains magnetized in the opposite direction will be eliminated first. A further increase of the external field would rotate all domains into a saturation state at various external field strength.

The distinct shapes of hysteresis loops shown in Figs. 3(b) and 3(e) obtained in longitudinal and polar configurations result from a nearly in-plane magnetic anisotropy. The magnetic remanence is nearly the same as the saturation magnetization in the longitudinal direction which indicates that the easy axis is in the surface plane. In a polar configuration, the external field is perpendicular to the in-plane easy axis, which often leads to nearly linear hysteresis loop. However, for the 3D/2D film [Fig. 2(b)], there exist some isolated Fe islands which behave like the case of 3D islands sketched in Fig. 2(a) and contribute to the stripelike, or less linear loop shape. The conclusion of in-plane easy axis from our data is consistent with results from other experimental studies,[3,4] although the details of film morphologies were not presented.

Our result of anisotropy is not inconsistent with the prediction of perpendicular magnetic anisotropy for a free standing Fe ML.[11] At 1 ML, the easy axis is perpendicular to the surface. With increasing coverage (e.g., 2 ML), however, the demagnetization field tends to bring the easy axis to the surface plane. As a result, the hysteresis behavior in both polar and longitudinal configurations is similar to that observed in 2D flat films. That the easy axis is along the surface plane is also consistent with the smaller value of coercive field measured in the longitudinal direction compared with that in the polar direction. For 3D island films, the local variation of the demagnetization complicates the hysteresis behavior.

IV. CONCLUSIONS

Our study of both film morphology and hysteresis loop indicates that the shape of a loop is closely related to the roughness of a film. For a smooth film, one is most likely to observe squarelike loops [Figs. 3(c) and 3(f)]. For an isolated 3D islands film, one is likely to observe stripelike loops [Figs. 3(a) and 3(d)]. For films with continuous islands, the loops in the longitudinal configuration are squarelike. However, the loops in the polar configuration remain stripelike.

Fluctuation effects in ultrathin films

S. T. Chui
Bartol Research Institute, University of Delaware, Newark, Delaware 19716

We discuss finite temperature fluctuation of the domain walls and the magnetization **M** in ultrathin magnetic films where spins interact with short range exchange (J), anisotropy (K), and long range dipolar (g) couplings. Phase boundaries for a triangular lattice are obtained from Monte Carlo simulations as a function of J, g, and K. The transition temperature for the disappearance of the z magnetization as a function of the effective anisotropy field $K-g/0.1208$ is essentially unchanged as g becomes zero. This suggests a new physical picture that the change in the direction of **M** is closely connected with the Ising transition for $g=0$. Mean field calculation suggests *three* transitions where only M_z is finite at low temperature. As the temperature is increased (1) M_x becomes nonzero, (2) M_z becomes zero and eventually, (3) M_x becomes zero. To investigate fluctuation of domain walls their elastic energy are calculated. For Bloch walls perpendicular to the x axis separating spins along the z axis this energy is *negative* for a small enough wave vector. The competition of the stabilizing long range dipolar interaction and low dimensional fluctuation suggests the possibility of a finite temperature roughening of an array of one-dimensional Néel walls in the film.

I. MAGNETIZATION

In the ultrathin magnetic films, new physics occurs because of the competition between the stabilizing *long range* dipolar interaction and the *low dimensionality* fluctuation effects.[1] An example of this competition is provided for by the question of the existence of long range order. For two-dimensional (2D) systems, the fluctuation of the magnetization is of the order of $\int d^2qkT/\omega_q$. When the spins interact only with nearest neighbor exchange, $\omega_q \propto q^2$; the fluctuation is infinite and there is no long range order.[1] When the long range dipolar interaction is included, $\omega_q \propto q$ for some spin arrangements. The fluctuation becomes finite and long range order is restored.[2,3]

The interaction energy between the spins is $H=0.5\ \Sigma_{ij=xyz,RR'} V_{ij}(R-R')S_i(R)S_j(R')$ where $V=V_d+V_e+V_a$ is the sum of the dipolar energy $V_{dij}(R)=g(\delta_{ij}/R^3-3R_iR_j/R^5)$; the exchange energy $V_e=-J\delta(R=R'+d)\delta_{ij}$; and the anisotropy energy $V_a=-2K\delta(R=R')\delta_{iz}\delta_{jz}$. Here d denotes the nearest neighbors. For the experimental systems, J is much larger than g and K. However, without g and K there is no long-range order at any finite temperatures. We have studied the phase diagram (Fig. 1) as a function of the parameters J, K, and g for a triangular lattice with Monte Carlo simulations on a 60×60 lattice for 1.6×10^9 MC steps. The transition temperature is determined from the peak position of the magnetic susceptibility with a histogram technique.[4] We found that for small $K-g$, the transition temperature for the vanishing of M_z can be well approximated by $J/T_c=A+B\ \ln(\Delta/J)$ for constants A and B. Here Δ is the effective spin-wave gap energy given by $\Delta=K-g/0.12$. In the absence of the dipolar interaction ($g=0$), the magnetization disappears in the high temperature phase above T_c. $T_c=0$ for $K=0$ because of two-dimensional fluctuations. For $g\neq0$, there is an intermediate phase where the magnetization changes from perpendicular to in-plane above T_c, as is first observed experimentally.[5-8] *The constants A and B are unchanged to within the accuracy of the present calculation* (≈2%) *as g becomes nonzero.* This suggests a new physical picture, different from that of previous considerations,[9-11] that the driving force behind the change in the direction of the magnetization is the same as that causing the Ising transition for $g=0$ when the z magnetization disappears at a high enough temperature. After the z magnetization vanishes, the in-plane magnetization can still be stable in two-dimensional (2D) over a temperature range if the dipolar coupling is finite because of its long range nature. The temperature at which the x magnetization disappears depends mostly on only g and very little on K.

Allenspach and Bishof[8] observed that there are regions in temperature so that the in plane and the z-axis magnetization are both nonzero. We think that there are actually *two*

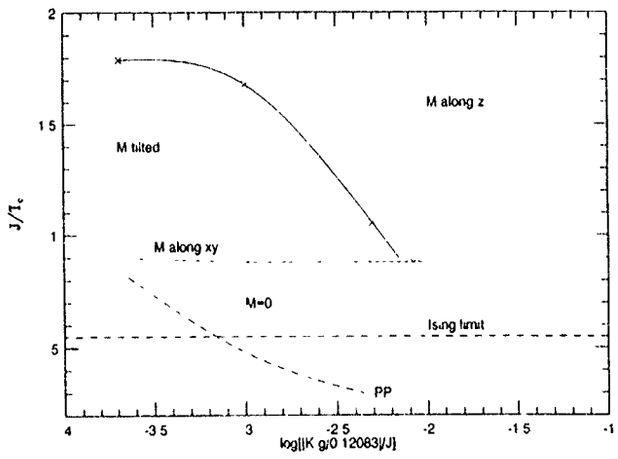

FIG. 1. Inverse transition temperatures for $g=0.12$ and different values of K. The different phases are as labelled. Lines are drawn connecting the points to guide the eye. The dotted line on the lower left corner is the theoretical results of Pescia and Prokrovsky; the horizontal line at the bottom is the asymptotic limit corresponding to the transition of the 2D triangular lattice.

transitions around T_c; one associated with the onset of the in-plane magnetization and the other one associated with the disappearance of the z-axis magnetization. The occurrence of a finite in plane magnetization depends on two issues. That the magnetization is not *completely* aligned along the z axis and that the fluctuation in the azimuthal direction is not infinite. These two transitions can be understood in more detail from a mean-field argument. Specifically, we assume the presence of two order parameters M_x and M_z and ask if these magnetizations can be self-consistently sustained. We get

$$M_x=\int_{-1}^{1} d\mu(1-\mu^2)^{0.5}\exp(-\beta E_z)I_1(\beta E_x)/Z';$$

$$M_z=\int_{-1}^{1} d\mu\ \mu\exp(-\beta E_z)I_0(\beta E_x)/Z';$$

$$Z'=\int_{-1}^{1} d\mu\exp(-\beta E_z)I_0(\beta E_x),$$

$$E_z=-K\mu^2-6J\mu M_z-g\mu M_z/0.75g_1,$$

$$E_x=(1-\mu^2)^{0\,5}(6J+0.5gc)M_x,$$

$\beta=1/kT$. When M_z is large, the spins are favored to align along the z axis with μ close to 1. A solution for M_x does not exist. When M_z is small *but not zero*, a solution for M_x is possible. The requirement that M_z be small restricts this onset of in-plane magnetization to close to T_c. In the limit of small M_x, the equation for M_z is similar to that in the 2D Ising model. Linearizing the equation for M_x we obtain the transition temperature T_2 for its onset as

$$T_2=(6J+0.5gc)\int d\mu\exp(-\beta E_z)(1-\mu^2)/2Z'',$$

where $Z''=\int d\mu\exp(-\beta E_z)$. A solution is possible even when M_z is nonzero. This implies that the onset of in-plane magnetization is distinct from the disappearance of the z axis magnetization. Detail numerical solutions of the mean field equations confirm the above argument.

Pescia and Pokrovsky[9] (PP) proposed that the spin-rotation transition temperature is given by $T_c=K^{-1}(K-g/g_1)12\pi J/\ln(3J/K)$. Their magnitude and functional dependence are very different from the Monte Carlo results. While no details of their calculation is available, we think the difference between their calculation and the present picture come from different assumptions of the fixed point Hamiltonian. More precisely, one can write the Hamiltonian in increasing power of q as

$$H=\Sigma_q-\Delta|S_z(q)|^2+\Sigma_{i,j=x,y}J_1q^2|S_q|^2+J_2q|S_z(q)|^2$$
$$+J_3\Sigma_{i,j=x,y}q_iq_jS_i(q)S_j(-q)/q$$

(Refs. 12 and 13) and follow the standard procedure[14,15] to derive renormalization group equations for the couplings Δ, J_i to first order in Δ/J_1, $J_{2,3}/J_1$. The bare dipolar coupling contributes to the initial values of Δ, J_1, and J_2, which possess different scaling trajectories ($n=3$):

$$d\Delta/dl=[2-(n-1)(T/2\pi J_1)]\Delta,$$

$$dJ_1/dl=-(n-2)T/2\pi-TJ_2/(32\pi J_1),$$

$$dJ_2/dl=[1-(n-1)T/J_12\pi]J_2/T,$$

$$dJ_3/dl=[1-(n-1)T/J_12\pi]J_3/T.$$

Thus it is not possible to have a single scaling equation for the dipolar coupling constant, as PP has assumed. Also, the functional form for the scaling equation for Δ does not depend on its initial value and thus, to first order in the small parameters g/J and K/J, remain the same whether the dipolar interaction is present or not; different from the conclusions of PP.

II. DOMAIN WALLS

Low-dimensional finite temperature fluctuation also affects domain walls. These effects are important in understanding domain formation, hysteresis and relaxation phenomena in the films. Whereas in three dimensional situations, domain walls are flat, recent experimental results[16–18] indicate that walls in ultra-thin films are not flat.

A magnetic domain wall is an interface between a spin-up region and a spin-down region. The statistical mechanics of interfaces have been actively studied over the last ten years. The movement of an interface usually proceeds not with the whole interface marching forward in unison but with part of the interface moving forward once at a time. This involves distorting the interface and thus the elastic energy and the roughness of the interface is an important consideration. The mobility of the interface in the presence of external pinning potentials is often discussed in terms of a roughening transition where the interfaces become rough and mobile if the temperature is higher than the roughening temperature. 2D interface in 3D systems roughens at a finite temperature.[19] 1D interfaces in 2D systems are always rough at any finite temperature. After the interface roughens, the free energy of steps becomes zero; the interface becomes mobile and the nature of the growth of domains becomes different. These studies assume that the interaction potential is short ranged.

The finite temperature statistical mechanics and dynamics of domain walls are often discussed in terms of a phenomenological model consisting of the elastic energy E_e to deform the wall and a pinning potential E_p that is due to the intrinsic periodic structure of the crystal lattice. For a deformation of wave vector q described by the displacement δr_q, the elastic energy is often assumed to be proportional to the strain squared, i.e., $E_e=A\Sigma_q q^2|\delta r_q|^2$. For magnetic domain walls in bulk materials, the physics is different. A Néel wall of width w located at position c is characterized by specifying the spin orientations at position $\mathbf{r}$ by the angles $\theta=\pi/2$, $\phi=\pi\tanh[(x-c)/w]/2$. The elastic energy is given by the domain wall energy change as c is changed by $\delta c=c_0[\cos(k.r)]$. In calculating this change, one ends up with the derivative of ϕ, which behaves like a δ function in the limit that the wave vector is less than the inverse domain wall width. We get $E_e=0.5\Sigma'_{RR'}V_{yy}(R-R')S_0^2(\delta c-\delta c')^2$. The prime on the summation indicates that we sum over those R,R' only at the $d-1$ dimensional undistorted wall position. V is proportional to the 2nd derivative of the $1/r$ Coulomb potential and is identical in form to the dynami-

cal matrix of the Wigner crystal in two dimensions, the Fourier transform of which can be summed with the Ewald sum technique.[20]

In the long wavelength limit the elastic energy is not proportional to q^2 but, because of the long range nature of the dipolar forces, is instead proportional to $|q|$ in 3D. In 2D, for magnetization in the plane, it is proportional to $q \ln(q)$ for a single 1D wall and to q/d for arrays of 1D domain walls separated by distances d. *Bloch walls perpendicular to the x axis separating domains with spins along the z axis are unstable against distortion in the long wavelength limit.*

Because of the different elastic behavior a 2D magnetic domain wall in 3D bulk systems is never rough at any temperature. On the other hand, in 2D films, a single wall in an n-layer system roughens at any finite temperature even when the dipolar interaction is included. For spins oriented along the y-axis separated by an *array* of Néels walls running perpendicular to the x axis a distance d apart, the problem can be related to the Knodo problem[21,22] via a Coulomb gas mapping.[19] The walls are flat for length scales less than d. There exist a temperature T_R above which the walls become rough. $T_R \approx 8\pi^2 g^2 \mu_B^2 n^2 a/d$ as the pinning strength approaches zero.

In conclusion, we presented in this article Monte Carlo results for the phase boundaries for ultrathin films as a function of the dipolar, z-axis anisotropy and exchange interactions. Our result suggests a new way of looking at the transition when the spins rotate into the plane. Renormalization group and mean field scenarios are discussed. We propose that there are three transitions associated with the disappearance of M_z and the onset and disappearance of M_x. We investigated finite temperature fluctuation of magnetic domain walls. For Bloch walls perpendicular to the x axis separating spins along the z axis this energy is *negative* for a small enough wave vector. The competition of the stabilizing long range dipolar interaction and low dimensional fluctuation suggests the possibility of a finite temperature roughening of an array of one dimensional Néel walls in the film.

Magnetic studies of fcc Co films grown on diamond (abstract)

J. A. Wolf,[a] J. J. Krebs, Y. U. Idzerda, and G. A. Prinz
Naval Research Laboratory, Code 6345, Washington, DC 20375

We report the first growth and characterization of fcc Co epitaxial films (t=10–130 nm) on diamond. Growth was carried out under UHV conditions in a commercial MBE machine and monitored during growth using RHEED which showed single crystal growth oriented with $\langle 100\rangle_{Co}\|\langle 100\rangle_{C}$. X-ray diffraction studies of the 130 nm sample demonstrated the single crystal fcc growth throughout the entire sample. Separate studies to determine growth mode and structure were carried out using angle-resolved Auger forward scattering. Vibrating sample and SQUID magnetometry yields a magnetic moment of $(1.05\pm0.1)\ 10^3$ emu/cm^3. Ferromagnetic resonance measurements carried out at 35 GHz yield a large cubic anisotropy K_1/M_S=(480±30)Oe and linewidth of only ΔH=100 Oe. Spin waves were observed in the thicker samples and the exchange constant determined to be $A_{Co}=1.09\times10^{-6}$ erg/cm. This work has been supported by the Office of Naval Research.

We have used Ising-model Monte Carlo calculations to study the magnetic order near cubic ferromagnetic and antiferromagnetic surfaces. The antiferromagnets were studied with and without frustrated next-nearest-neighbor interactions. Intralayer and interlayer spin-spin correlation functions have been calculated as a function of the relative coupling strength in the surface layer. If this coupling strength is more than a few times the bulk value, a distinct surface phase transition is observed at temperatures $T_{C,surf}$ or $T_{N,surf}$ that can be significantly above the corresponding bulk values, $T_{C,bulk}$ or $T_{N,bulk}$. These calculations suggest that previous spin-polarized photoelectron diffraction measurements on antiferromagnetic $KMnF_3(110)$[1] and $MnO(001)$[2] could in fact have been observing such surface transitions at $T_{N,surf}$ values of 2.7 and 4.5 times $T_{N,bulk}$, respectively.

Magnetic circular dichroism (MCD) studies at K and L edges using hard and soft x rays are presented. The relation of this universal phenomenon in the x-ray absorption near-edge structure (XANES) and extended x-ray absorption fine structure (EXAFS) regions to local magnetic structures in the case of $3d$ and $4f$ elements is illustrated. The validity of atomic and band-structure pictures to describe the MCD in the XANES range are outlined and the applicability of sum rules and two-step vector coupling models to deduce spin and orbital moments of the absorbing atom as well as spin-density profiles from the experimental data are critically discussed. The correlation of the dichroic contribution in the EXAFS to the magnetic moments and spin densities of the neighboring atoms are addressed by systematic studies which provide new insights into the exchange phenomena of the interaction of spin-polarized electrons with ferromagnetic media. The potential but also the limitations of this new spectroscopy is demonstrated.

I. INTRODUCTION

X-ray circular magnetic dichroism (X-MCD) in core-to-valence transitions is a new powerful method to study in an element- and symmetry-selective manner the magnetic aspects of local electronic structures in magnetic media. The possibility of extracting local spin and orbital moments using "sum rules" deduced on the basis of an atomic approach[1,2] or in the local spin-density (LSD) formalism[3,4] by a comparison of the magnetic L_2- and L_3-dichroic spectra is one of the dominant subjects of interest. To date a correct interpretation of experimental spectra seems to be restricted to cases with either a localized character of the involved final states as, e.g., $3d$-$4f$ transitions in rare earth (RE) systems,[5,6] where an atomic picture[7] is adequate or to those with a delocalized behavior as, e.g., $1s$-$4p$ transitions in $3d$ elements and $2s$-$6p$ transitions in $4f/5d$ systems[8,9] and $2p$-$5d$ transitions in $5d$ elements,[3] where the band-structure approach has been adopted successfully.[10] For intermediate cases, however, as the $L_{2,3}$ edges in transition elements[5,11] and in REs,[9,12] a closed theoretical description is still a problem.

Although the occurrence of a dichroic contribution to the extended (EXAFS) [spin-polarized EXAFS (SPEXAFS)] has been proven to be a universal phenomenon,[4,13] theoretical calculations of the experimental spectra are not available but are on the way.[14] However, as demonstrated in the second part of this article, the systematics observed in several systems show that on the basis of simple two-step models interesting correlations of the SPEXAFS to the local magnetic short-range order can be found, which demonstrate the potential of this method to study magnetic structures on an atomic scale.

II. NEAR-EDGE MCD

A. Theoretical models

Large MCD effects (in some cases more than 20%) are found in the near-edge region within 20 eV above an absorption threshold. In this energy range the absorption cross section can be described by Fermi's golden rule.[15] In the case of bandlike final states, the single-particle density-of-states model describes the experimental spectra successfully. The energy dependence of the absorption cross section is given by the density profile of the final states with selected symmetry determined by dipole-selection rules times a nearly energy-independent matrix element. If the final states are well localized, two-particle interactions have to be included. These can be calculated explicitly using atomic multiplet[16] approaches. Here it is also possible to include solid state effects by adding crystal field terms to the Hamiltonian and hybridization of ligand character by an admixture of extra-atomic configurations such as in charge-transfer states.

In both cases, polarization effects and exchange splittings can be taken into account. Using fully relativistic spin-polarized Korringa–Kohn–Rostoker (KKR)–GF and linear muffin-tin orbital[10] band-structure approaches or spin-polarized versions of the linear augmented plane wave (LAPW) method,[7] the MCD L spectra of various heavier

 0021-8979/94/76(10)/6453/6/$6.00 © 1994 American Institute of Physics

transition metals such as magnetic $5d$ elements and Gd-metal have been successfully described in the single-particle picture, while on the other hand the experimental $M_{4,5}$-MCD spectra in RE systems are excellently reproduced by atomic calculations.[6]

On the basis of the atomic description sum rules have been developed recently,[1,2] which relate the difference and the sum of the dichroic signals ($\mu^{\pm}$) for reversed photon polarization $\mu_c := (\mu^+ - \mu^-)/2$ for the two spin-orbit initial states directly to the local spin and orbital moments of the partially filled final valence shell.

Based on a simple vector-coupling version of the band-structure approach, a similar relation between the normalized MCD spectra μ_c/μ_0 at the L_2 and L_3 edges times the unoccupied final state density and the local magnetic moments can be deduced.[4,9] Based on the Fano effect[8] the sensitivity of the dichroic signal to the spin and orbital moment originates from finite spin $\langle \sigma_z \rangle$ and orbital polarization $\langle l_z \rangle$ of the outgoing photoelectron in the propagation direction z of the circularly polarized photon. The photoelectron emitted from an unpolarized core state is thus considered as a polarized probe for the spin and orbital moment of the final states. The polarization values for a free electron wave are $\langle l_z \rangle = +3/4$ in an initial p state and $\langle \sigma_z \rangle = -1/2$ and $+1/4$ for the corresponding $p_{1/2}$ and $p_{3/2}$ spin-orbit partners.

In a simple spin-polarized version of Fermi's golden rule for pure spin-ferromagnetic systems,[8,9] the MCD signal is directly correlated to the spin density $\Delta\rho = \rho^+ - \rho^-$ of the final state by $[\mu_c/\mu_0](E) = \langle \sigma_z \rangle [\Delta\rho/\rho](E)$, which corresponds to $\mu_c(E) \sim -\Delta\rho(E)$ at the L_2 and $\mu_c(E) \sim +\Delta\rho(E)$ at the L_3 edges for $\mu_0(L_3) = 2\mu_0(L_2)$.[9]

Within the vector-coupling model the relation between the normalized MCD spectra μ_c/μ_0 and the spin and orbital moments is deduced to

$$\mu_S/\mu_B \sim -\tfrac{4}{3} \int \{[\mu_c/\mu_0]_{L_3}(E) - [\mu_c/\mu_0]_{L_2}(E)\} \rho(E) dE, \tag{1}$$

$$\mu_L/\mu_B \sim -\tfrac{4}{9} \int \{[\mu_c/\mu_0]_{L_3}(E) + 2[\mu_c/\mu_0]_{L_2}(E)\} \rho(E) dE. \tag{2}$$

Under the condition $\mu_0(L_3) = 2\ \mu_0(L_2)$ Eqs. (1) and (2) are equivalent to the sum rules, which are more appropriate in case of (nearly) isolated absorption profiles (white lines =WL) as, e.g., the $M_{4,5}$ edges in RE, while Eqs. (1) and (2) can be more easily applied in the case of more steplike absorption edges, e.g., the $L_{2,3}$ edges in heavier elements, without or with weakly indicated WL structure as in some RE and Pt and Au systems.

For K edges $\langle l_z \rangle$ amounts -1 and $\langle \sigma_z \rangle$ has the very small value of $\sim 10^{-2}$. Thus only weak MCD effects of less than 1% are expected for outer, bandlike final states with nearly quenched orbital moments, as, e.g., the $(4)p$ states in $3d$ elements or $(6)p$ in $4f/5d$ systems and no simple relation of the MCD profile and the local p moment exists.

B. Fe-metal layers

To demonstrate the reliability of the sum rules Eqs. (1) and (2), they are applied to $L_{2,3}$ MCD spectra of Fe-metal layers (cf. Fig. 1). The exact thicknesses of the 9.25 Å (A) and 24 Å (B) Fe layers (deposited on 300 Å Au on a glass substrate and protected by a 30 Å Al coverlayer) and the magnetic moments per atom of 2.07(3) μ_B for the thin (A) and 2.14(3) μ_B for the thicker sample (B) were determined via XFA and super conducting quantum interference device (SQUID) measurements, respectively.[20] The μ_c profiles are shown in Fig. 1(a) in addition to the spin-averaged μ_0 profile for the 9.25 Å (dashed line) and the 24 Å Fe layers (solid line). Corresponding theoretical spectra from fully relativistic spin polarized KKR calculation for iron metal are presented in Fig. 1(b).[10] The experimental data measured by total-yield detection in an applied external field of 0.2 T were taken at the DRAGON beamline (NSLS).

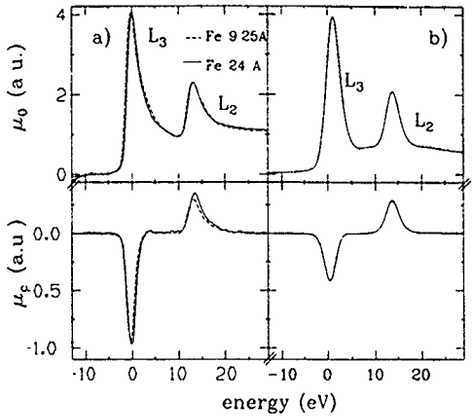

FIG. 1. Experimental absorption and dichroic profiles (a) at the Fe $L_{2,3}$ edges of Fe metal layers with thicknesses of 9.25 Å (dashed) and 24 Å (solid) in comparison with theoretical profiles from band-structure calculations (b). The experimental spectra correspond to raw and unsmoothed data with subtracted linear background.

Figure 1(a) shows, that the dichroic L_2 signal is significantly reduced relative to the L_3 signal causing a strong deviation from the ratio $\mu_c(L_2)/\mu_c(L_3) = -1$ expected for pure spin moments. This indicates the existence of an orbital moment coupled parallel to the spin moment [Eq. (4)]. Applying the sum rules one deduces a spin and orbital moment of $m_S \sim 2.19\mu_B$ $(2.29\mu_B)$ and $m_L \sim 0.25\mu_B$ $(0.21\mu_B)$ for samples A (B) taking into account $n = 4$ holes in the $3d$ level. The errors of these numbers due to the uncertainties of estimating the white line areas amounts to 20%. Very similar, somewhat smaller values of $m_S \sim 2.02\mu_B$ $(2.08\mu_B)$ and $m_L \sim 0.20\mu_B$ $(0.15\mu_B)$ (uncertainty about 5%) are found by applying Eqs. (3) and (4) using theoretical density of states profiles with an integrated value of $\int \rho(E) = 3.1$. These results are in excellent agreement with the results of the macroscopic measurements and confirm the expected increase of m_L with decreasing layer thickness.

Only the absolute values of m_L are larger than expected from theory and other measurements.[21] The spin polarized KKR calculation of the μ_0 and μ_c spectra seems to underestimate the values of μ_c and μ_0 at the L_2 edges, which could be an indication for the breakdown of the single-particle approach, as has been found for the $L_{2,3}$ MCD in the lighter $3d$ transition metals.

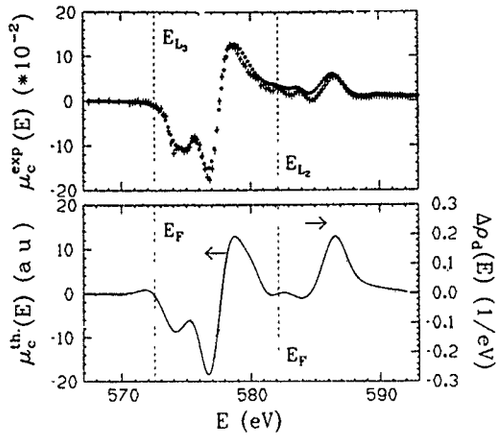

FIG. 2. Top: experimental dichroic absorption of CrO_2 at the L_3 and L_2 edges of chromium, measured at the SX700/3 (BESSY) (O) and DRAGON beamlines (NSLS) (+) with energy resolutions of about 900 and 500 meV, respectively. From the raw data only a constant offset has been subtracted. Bottom: theoretical dichroic absorption at the L_3 and L_2 edge of CrO_2, given by LMTO calculation (—) and the spin density of the $3d$ band above the Fermi level, given by LAPW band-structure calculations. The L_2 edge is rescaled by (-1) due to the negative photoelectron polarization. The vertical lines (···) mark the energy of the L_2 and L_3 edges, which are identical to the Fermi levels of the plotted spin densities.

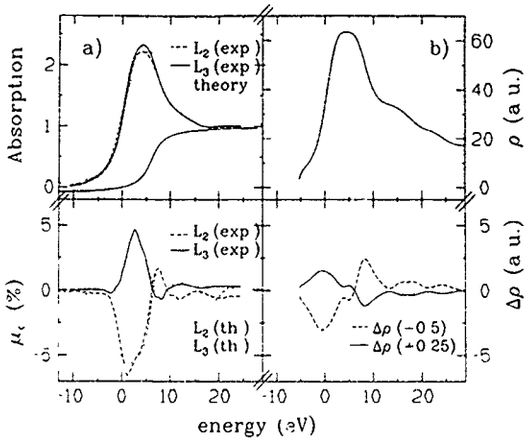

FIG. 3. (a) Experimental L_2 (dashed) and L_3 (solid) absorption (μ_0) (top) and corresponding dichroic profiles (μ_c) (bottom) of Gd-metal in comparison with theoretical unpolarized (dash-dotted) (top) and L_2 (dash-dotted), L_3 (dots) polarized profiles (bottom). The first inflection point of the absorption onset is chosen as the origin of the energy scale. The experimental absorption step is fitted by an arctan function (width 4 eV). (b) Theoretical total d spin-density profiles ($\rho=\rho^+ + \rho^-$) (top) and corresponding difference (b) ($\Delta\rho=\rho^+ - \rho^-$) broadened by core hole lifetime and experimental resolution and rescaled by -0.5 and $+.25$ at the $L_{2,3}$ edges, respectively. The dash-dotted line represents the theoretical MCD profile.

C. Cr $L_{2,3}$ MCD spectra

Going to lower Z within the $3d$ series due to the decrease of the $2p$ spin-orbit splitting below 10 eV it is difficult to separate the corresponding L_2 and L_3 parts in the spectra as seen in case of the Cr MCD in the half-metallic ferromagnet CrO_2 presented in Fig. 2. The dichroic profile is much more complex than in the heavier transition metals and even changes sign within the L_3 contribution. A comparison with the calculation of the dichroic effects for transition metal ions in the atomic approach[22] suggests that these models are more appropriate to reproduce the experimental findings and thus we have used a ligand field multiplet model (LFM), which includes the influence of the cubic crystal field on the local wave functions.[23] Setting the spin-orbit splitting to zero gives a reasonably good agreement between theory indicating the validity of the theoretical concept for the description of the MCD effects. The vanishing influence of an orbital momentum and correlated spin-orbit effects can also be verified by the application of the sum rules, which gives an upper limit of m_L of less than $10^{-2}\mu_B$. It can also be seen from the MCD spectra that it is difficult to deduce the corresponding spin moment in case of too close, i.e., not well resolved, $L_{2,3}$ absorption edges. That the LSD approach and the model Eqs. (1) and (2) are based on fails can be demonstrated by a comparison of the local unoccupied spin density of states $\Delta\rho$ shifted to the absorption edge with the μ_c profile, which show only rather poor similarities.

D. $L_{2,3}$ MCD in Gd-metal and $Eu_3Fe_5O_{12}$

Dichroic $L_{2,3}$ effects of several percent in REs have been found in all systems investigated up to now. Theoretical descriptions, however, have concentrated on Gd, as the fully relativistic band-structure approach by Ebert[10] and the calculations carried out by Carra *et al.*[17] which were also extrapolated to heavier RE metals.

However the description of the REs with nonzero $4f$ angular momentum is still an open problem. In particular the structures at the L_3 edges at negative energies, characteristic for all systems except Gd, have been proven to exhibit an atomic character.[24]

Although the ratios of the normalized Gd $L_{2,3}$ MCD profiles (both peak values and integrated areas) as seen in Fig. 3 are close to -2, i.e., the ratio of the spin-polarization factors, applying the sum rules Eqs. (1) and (2) leads to a spin moment of $-0.24\mu_B$ having the opposite sign compared to the theoretical calculations, which predict $\mu_S=+0.47\mu_B$ for the spin and $\mu_L=-0.04\mu_B$ for the orbital d moment.[25] The sum rules yield for the orbital moment a value of $-0.004\mu_B$ which is a factor of 10 too small compared with the theoretical prediction. Similar results are obtained even in the naive vector-coupling model ($\mu_S=-0.19\mu_B$ and $\mu_L=-0.002\mu_B$).

A direct comparison of the unbroadened theoretical Gd MCD profiles with unbroadened spin densities (Fig. 4) explains the breakdown of the validity of the basic assumptions Eqs. (1)–(2) are based on. Though the fine structures of the profiles coincide roughly, indicating a direct correlation between μ_c/μ_0 and $\Delta\rho/\rho$, the value of $\langle\sigma_z\rangle$ obviously becomes strongly energy dependent, amounting, e.g., to a value twice as high at the Fermi energy. Hence the small positive spin density leads to a strong line in the $L_{2,3}$ MCD spectrum at E_F and a negative spin moment.

The physical origin is a strong energy and spin dependence of the matrix element, since close to E_F the overlap of initial and final spin-up wave functions is much larger for the

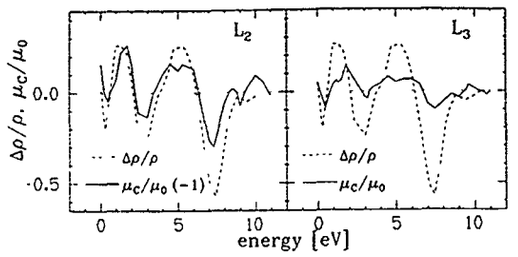

FIG. 4. Unbroadened theoretical $\Delta\rho/\rho$ profiles (dashed) and unbroadened theoretical μ_c/μ_0 profiles (solid) at the L_2 (left) and L_3 (right) edges in Gd-metal. The ratio $(\Delta\rho/\rho)/(\mu_c/\mu_0)$ is not constant with energy.

corresponding states of minority character, a fact, which has to be neglected in the models. But the MCD calculations (shown in Fig. 3) using the single particle band-structure approach reproduces this behavior exactly.

Applying the sum rules in the case of Eu $L_{2,3}$ MCD spectra (Fig. 5) in $Eu_3Fe_5O_{12}$ yields a spin moment of $-0.03\mu_B$ and an orbital moment of $+0.005\mu_B$. The moments obtained in the naive vector-coupling model amount to $-0.03\mu_B$ for the spin and $+0.007\mu_B$ for the orbital contribution. However, similar to Gd, these values lead to the wrong sign for the spin, which can again be drawn back to matrix-element effects. On the other hand, the expected opposite signs of μ_L and μ_S, induced in the $5d$ state by the intra-atomic $4f$-$5d$ coupling in lighter REs, seems to be directly manifested in the collapse of the L_3 MCD to the credit of a strong L_2 dichroic signal.

III. MAGNETIC EXAFS

A. Theoretical aspects

A phenomenological description of the measured effects is presented based on the simple vector-coupling "two-step" model, which has successfully been used to describe the near-edge MCD in the "spin-only" limit. In the first step, we assume that a free electron wave is going out with a spin

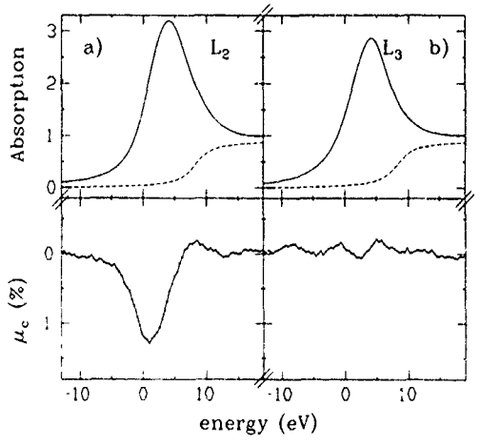

FIG. 5. (a) Experimental L_2 (a), L_3 (b) absorption (μ_0) (top) and dichroic profiles (μ_c) (bottom) of Eu in $Eu_3Fe_5O_{12}$. The absorption step is fitted by an arctan function (width 4 eV).

projection $\langle\sigma_z\rangle$ in photon-beam direction. If the magnetic moment of the neighboring atom, i.e., the spin of its majoritylike electrons, is also polarized in z direction, an exchange contribution to the Coulomb scattering potential is present in the scattering processes of the outgoing photoelectron. This should result in a magnetic contribution to the backscattering amplitude, which changes its sign with reversing the relative orientation of the photoelectron spins and the spins of the magnetic neighbors in the absorption process. In the conventional EXAFS formula the effect of exchange interaction in the scattering process is described by an additive exchange contribution (with index c) to the Coulomb-interaction parameters, i.e., the backscattering amplitude $F=F_0\pm F_c$, the phase shift $\phi=\phi_0\pm\phi_c$ and the mean free path $\lambda=\lambda_0\pm\lambda_c$. The strengths of the exchange contribution are within this simple model expected to scale directly with the spin-polarization parameter, i.e., $\langle\sigma_z\rangle\sim F_c, \phi_c, \lambda_c$.

Thus the conventional EXAFS (χ_0)[41] as function of the photoelectron de-Broglie wave-number k, which are described by a summation over the coordination shells located at distances r_j with N_j neighboring atoms and including the Debye–Waller factor D_j and "shake-off/on" processes at the central atom i (S_i), is transferred into a spin-polarized expression $\chi_c=\chi^+-\chi^-$ by

$$\chi_c(k)=\sum_j N_j S_i(k) D_j(k)\frac{e^{-2r_j/\lambda_{jo}}}{kr_j}\left(F_{jc}\sin(2kr_j+\varphi_{ijo})+\varphi_{ijc}F_{jo}\cos(2kr_j+\varphi_{ijo})+\frac{2r_j\lambda_{jc}}{\lambda_{jo}^2}F_{jo}\sin(2kr_j+\varphi_{ijo})\right). \quad (5)$$

B. Experimental results

1. $L_{2,3}$ SPEXAFS

SPEXAFS studies in the hard x-ray range have been performed in the transmission mode at HASYLAB (Hamburg) in various magnetic systems at the L edges in REs and $5d$ elements and at the K edges of $3d$ systems.[4]

For an analysis of the EXAFS and accordingly of the SPEXAFS to deduce structural information as, e.g., the distances r_j of next atoms and the coordination numbers N_j a sufficiently extended range of the $\chi_{0/c}$ spectra is Fourier transformed. Thus, this method is often not well practicable for energetically close following $L_{2,3}$ edges in $3d$ elements. This holds especially for the SPEXAFS analysis, since according to the simple picture the magnetic oscillation at the L_2 and L_3 edges should show identical structures but with opposite sign, which is found in all systems studied up to now as demonstrated in Fig. 6 at the Eu $L_{2,3}$ edges in the ferromagnetic Eu iron garnet ($Eu_3Fe_5O_{12}$).

If one takes into account a ratio of the amplitudes of -2, the χ_c profiles at the L_2 and L_3 edges are identical. The corresponding near-edges MCD signals (Fig. 5), behave completely different due to their dependence on the orbital moment. This proves that similar effects of the orbital polarizations can be neglected in the SPEXAFS interpretation. Only an additional contribution due to the small near-edge MCD at the iron K edge causes some deviation at the L_3

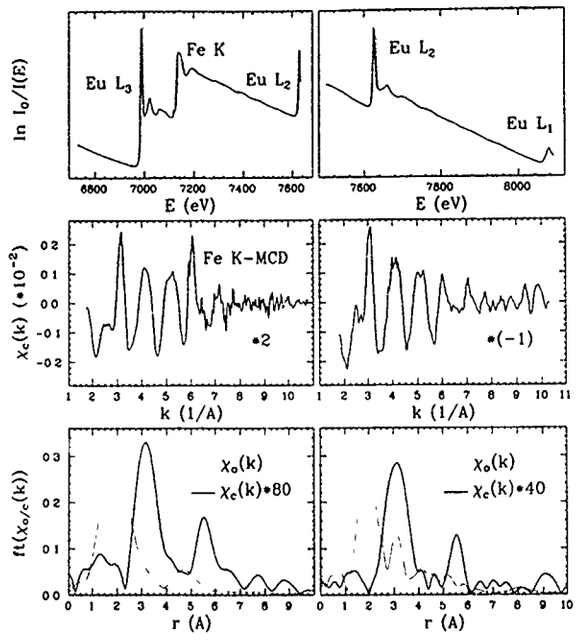

FIG. 6. Top: the absorption of $Eu_3Fe_5O_{12}$ between 6700 and 7680 eV (left) and between 7480 and 8120 eV (right), displaying the Fe K and the Eu L_3, L_2, and L_1 edges. Center: the SPEXAFS at the Eu L_3 (left) and L_2 edge (right) follow the same profile with a ratio of (-2). Bottom: the Fourier transform of the spin-averaged EXAFS (···) and SPEXAFS (—) of the Eu L_3 (left) and L_2 edge (right).

edge ($k=6$ Å^{-1}). Since in the simple picture the corresponding K-edge SPEXAFS are more than one order of magnitude smaller, they are nearly invisible in the L_3 SPEXAFS.

The Fourier transform (FT) of the polarization averaged EXAFS spectrum $f(\chi_0)$ (dashed line) and the corresponding SPEXAFS FT (solid line) $f(\chi_c)$ are significantly different. The FT of the L_3 EXAFS show very broad features due to the small transformation range limited by the Fe K edge. The prominent maximum in $f(\chi_o)$ resulting from the strong backscattering at the next oxygen neighbors has vanished in the SPEXAFS to the credit of an increase of the peaks at higher r values, which mark the positions of the next and over next iron Fe neighbors. They are small or almost invisible in the EXAFS FT. The $f(\chi_c)$ at the L_2 and L_3 edges are very similar demonstrating that the occurrence of the Fe K edge does not limit the k range in the magnetic spectra.

These studies show, that (nearly) nonmagnetic neighbors as the oxygen components on magnetic oxides do not contribute to the SPEXAFS and a clear distinction between magnetic and nonmagnetic neighborhood is possible. From the systematics observed by studies in various systems,[4,13] we have observed that the relative strength of the SPEXAFS rescaled by the photoelectron spin polarization

$$[\chi_c/\chi_0]/\langle\sigma_z\rangle=[f(\chi_c)/f(\chi_o)]\langle\sigma_z\rangle=2.4(3)\%\mu_S(\mu_B) \tag{6}$$

is directly proportional to the magnetic spin moment of the neighboring atoms. Thus, we expect, that the SPEXAFS spectroscopy gives even quantitatively new element-specific insights into the magnetic short-range order.

2. K-edge SPEXAFS

The highly precise measurements, which are possible in the transmission mode, allow us also to address $3d$ elements by K-edge SPEXAFS studies as demonstrated in case of Co-(fcc) and Ni-metal. As shown in Fig. 7, the χ_c oscillation at the K edges follow roughly the χ_0 structure except an additional contribution at a k region of 4–5 Å^{-1}. In this range multielectron contributions ($3p\rightarrow 3d$ transition) result in an additional line in the dichroic K spectra, which decreases strongly by going from Fe to Ni.[13] Following Eq. (6), we deduce a value of $\langle\sigma_z\rangle=+3.5(5)\%$ for the K SPEXAFS, which is somewhat larger than expected from the near-edge MCD effects.

Due to the small value of $\langle\sigma_z\rangle$ the statistics of the K SPEXAFS can be poor. But a more detailed analysis by an extraction of the exchange parameter from the experimental data allows also in this case a sufficiently quantitative analysis. Hereby the values F_{jo}, ϕ_{ijo}, and λ_{jo} are calculated by the FEFF code of Rehr[17] and the D_j and S_i values can be deduced by fitting the χ_o profiles. The F_c profile for Co and Ni indicate a significant different k dependence of the magnetic and Coulomb backscattering amplitude F_o, which seems to be correlated to the differences of the distribution of spin and charge density in the neighboring atom. The ratio of the Co and Ni F_c amplitudes scale directly with the ratio of the magnetic moments per atom. Thus the described analysis allows the determination of the average magnetic moment carried by a coordination shell with good accuracy even for noisy SPEXAFS data.

The amplitudes of F_c correspond to relatively large exchange contributions of the *elastic* scattering cross section of more than 20% per magnetic electron. On the other hand the

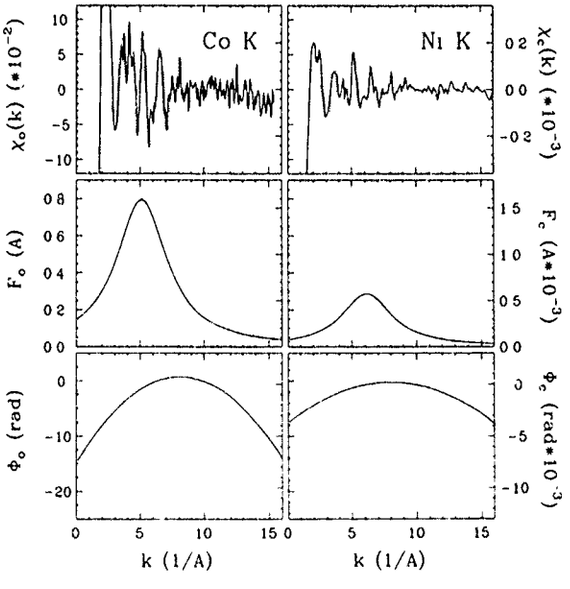

FIG. 7. Top: the EXAFS (···) and SPEXAFS (—), measured at the Co K (left) and Ni K edge (right) of Co fcc and Ni fcc metal. Center: the calculated spin-independent (···) and fitted spin-dependent part (—) of the backscattering amplitude of the first neighbor of Co fcc (left) and Ni fcc (right). Bottom: the corresponding calculated spin-independent (···) and fitted spin-dependent (—) phase shift.

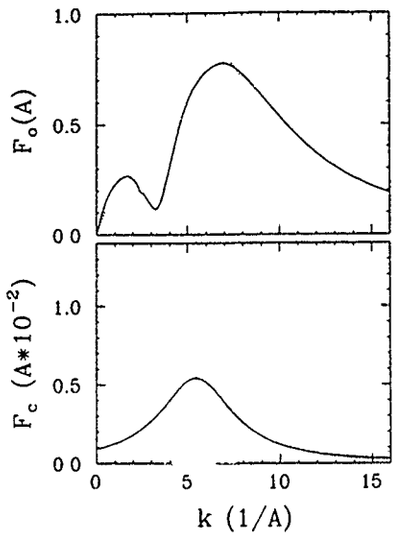

FIG. 8. The calculated spin-independent part F_0 (top) and fitted spin-dependent part F_c (bottom) of the backscattering amplitude for Co (···) and Cu (—) of a Co(5) Cu(4) multilayer.

exchange contributions to the phase shift, as seen from Fig. 7, are much smaller and the spin-dependent mean-free path of the order of less than 10^{-3} is found to be negligible. This demonstrates that the SPEXAFS analysis can also provide useful new information on the exchange phenomena in the interaction of spin-polarized electrons directly inside a solid and especially in comparison with corresponding results from surface-sensitive electron spectroscopies.

SPEXAFS studies can be applied even for multilayered systems (ML) to get information on the interface structures, as shown for Co/Cu systems. Our calculated distribution of the magnetic moments of 5Co/4Cu ML (Fig. 9) indicates a small Cu polarization corresponding to an average spin and orbital moment of $m_S(\mathrm{Cu})=0.0137\mu_B$ and $m_L=0.001\mu_B$, which agree well to our near-edge MCD studies at the NSLS, where we observed for the first time an induced Cu moment in this ML of $m_S(\mathrm{Cu})=0.014\mu_B$ and $m_L<0.002\mu_B$.[4]

In MLs with strongly different magnetic moments of both components as the Co/Cu systems the average magnetic moments of the *neighboring* Co and Cu atoms depend very sensitively on the sharpness of the interface. The ratio between the Co and Cu SPEXAFS amplitudes resulting from the exchange scattering at the first coordination shell should be about 7.3 for a sharp interface and reduced to ~1.9 for a complete intermixing of two adjacent atomic layers. Thus a comparison of the strengths of F_c deduced from the Co and Cu SPEXAFS in the ML (see Fig. 8) gives quantitative information on the quality of the interface. Their ratio of the amplitudes of ~2.0 are significantly smaller than the value of 7.3 estimated for an ideal structure and can be explained by an intermixing of close to 50% in the first Co and Cu at the interface.

Discussion of the magnetic dichroism in the x-ray resonance scattering

Peter Rennert
Physics Department, Martin-Luther-University, Halle-Wittenberg, D-06099 Halle, Germany

The cross section for the x-ray resonance scattering is evaluated at the K edge for a transition metal like Ni. The Green function is calculated analytically from a model system. The differences in the spectra measured with different polarization can be explained from these results. The examples show that the shape of magnetic dichroism is very sensitive to the spin polarized p part of the Green function.

I. INTRODUCTION

The x-ray-resonance scattering or the anomalous scattering involves the variation of the intensity of a Bragg peak if the photon energy crosses an edge. Magnetic dichroism can be observed considering magnetic systems and using polarized x-ray sources. Recently magnetic dichroism at the K and L edge was analyzed theoretically for ferromagnetic $3d$ transition metals where the main source of dichroism is the spin polarization of the valence electrons.[1] The cross section

$$d\sigma/d\Omega' = r_0^2 |S(\mathbf{K})|^2 |M(\mathbf{q}'\boldsymbol{\epsilon}';\mathbf{q}\boldsymbol{\epsilon})|^2 \tag{1}$$

can be calculated by second order perturbation theory.[1-4] The order of magnitude is given by the square of the classical electron radius r_0.

The matrix element M [Eq. (30) of Ref. 1 with terms I to VII] depends on the photon wave vectors $\mathbf{q}$, $\mathbf{q}'$ and on the polarizations $\boldsymbol{\epsilon}$, $\boldsymbol{\epsilon}'$ of the incoming and outgoing photon, respectively. It contains terms which describe the Thomson scattering (I), the magnetic scattering (II), and the resonance scattering (III–VII). The terms VI and VII are neglected in the following discussion. The resonance terms depend on the structure of the unoccupied electron energy bands. It can be expressed by the Green function.

Experimental results for nickel were presented by Namikawa *et al.*[5] and Schütz *et al.*[6] Namikawa *et al.* observed magnetic dichroism for the (220) reflex with linear polarized light. The polarization was chosen in the scattering plane and the magnetization perpendicular to the scattering plane. Schütz *et al.* observed magnetic dichroism for the (222) reflex with circular polarized light. The magnetization was in the scattering plane. The results of both experiments differ from each other, and it is one aim of the paper to discuss the magnetic dichroism for different experimental conditions.

II. MODEL OF THE BAND STRUCTURE

In Eq. (30) of Ref. 1 the electron states of the unoccupied part of the electron energy bands are included in the Green function. The Green function is expanded into lattice harmonics, angular momentum parts in our example. The total Green function $G = G_\uparrow + G_\downarrow$ and the spin polarized part $G_s = G_\uparrow - G_\downarrow$ appear separately. Different parts of the Green function appear in the expressions III–VII. They are multiplied with factors containing the photon wave vectors and the polarizations. To discuss the influence of the different factors we use a simplified picture of the band structure with degenerate parabolic energy bands characterized by the position of the bottom $E_{l\sigma}^0$ and the width $W_{l\sigma}$ of the bands for the different angular momentum parts ($l = s,p,d$) and spin ($\sigma = \uparrow,\downarrow$). These values are taken from the band structure of nickel in the numerical discussion of the following chapters. In this model the Green function of the unoccupied states can be calculated analytically

$$G(E) = -\frac{3}{W}\left[1 - x_F + \frac{\alpha}{2}\ln\left(\frac{(1-\alpha)(x_F+\alpha)}{(x_F-\alpha)(1+\alpha)}\right)\right] \tag{2}$$

with

$$x_{Fl\sigma}^2 = (E_F - E_{l\sigma}^0)/W_{l\sigma} = n_{l\sigma}^{2/3}/(2l+1),$$
$$\alpha_{l\sigma}^2 = (E - E_{l\sigma}^0)/W_{l\sigma}. \tag{3}$$

$n_{l\sigma}$ is the number of l electrons with spin σ. The behavior of this function is shown in Figs. 1 and 2 for the p and d part, respectively. In our example the unoccupied part of the $p_\uparrow$ band lies in the range from the Fermi energy ($E_F = 0$) up to 17.4 eV. Thus, in Fig. 1 $D_\uparrow(E)$ is restricted to this range. The real part of the Green function $G_\uparrow$ has long tails below the Fermi energy. It changes the sign within the unoccupied region. Figure 2 shows the d part of the Green function. In our example the top of the majority band lies at 0.11 eV and the top of the minority band at 0.43, respectively. The spin density $\mathrm{Im}(-G_s/\pi)$ is positive in the range from the Fermi energy up to the top of the majority d band and then it

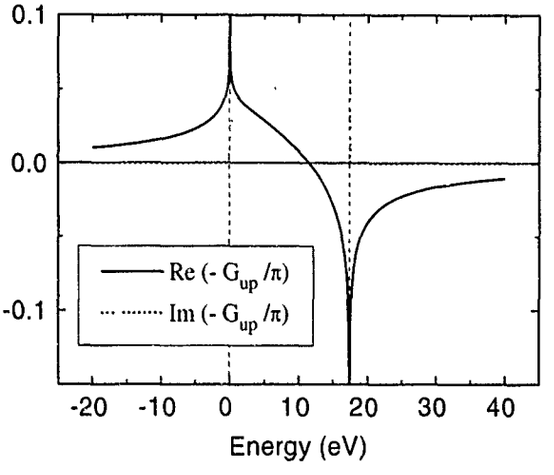

FIG. 1. The p part of the Green function $G_\uparrow$ multiplied with $-1/\pi$. $\mathrm{Im}(-G/\pi)$ is the density of states $D(E)$. The dashed lines indicate the Fermi energy ($E_F = 0$) and the top of the p band, respectively

becomes negative up to the top of the minority d band. Again the real part of the Green function has a long tail below the Fermi energy.

III. LINEAR POLARIZED LIGHT

The polarization is given by

$$\epsilon=\mathbf{u}_1 \sin\psi+\mathbf{u}_2 \cos\psi\, e^{i\xi}, \tag{4}$$

where $\mathbf{u}_1$ is chosen to be in the scattering plane (say yz plane) and $\mathbf{u}_2$ perpendicular to it. $\xi=0$ describes linear polarized light, $\xi=\pm\pi/2$ and $\psi=\pi/4$ circular polarized light. At first we choose $\xi=0$ and $\psi=\pi/2$ which corresponds to the experimental conditions of Namikawa *et al.*[5] We consider the two opposite ($\pm x$) directions of the magnetization and we get

$$\begin{aligned}|M^+|^2-|M^-|^2=&-2\sin(2\Theta)\Big[\cos(2\Theta)n(\mathbf{K})-\cos(2\Theta)\frac{2\pi}{3}\frac{\hbar\omega}{W_{p\uparrow}}N_p^2\,\mathrm{Re}\Big(-\frac{1}{\pi}W_{p\uparrow}G_p(E)\Big)\\&-\cos(4\Theta)\frac{2\pi}{15}\Big(\frac{\hbar\omega}{mc^2}\Big)^2\frac{\hbar\omega}{W_{d\uparrow}}(Z\alpha)^{-2}R_d^2\,\mathrm{Re}\Big(-\frac{1}{\pi}W_{d\uparrow}G_d(E)\Big)\Big]\Big(\frac{\pi}{3}\frac{\hbar\omega}{mc^2}\frac{\hbar\omega}{W_{p\uparrow}}R_pN_p[W_{p\uparrow}D_{ps}(E)]\Big)\\&-2\sin(2\Theta)\Big[\frac{\hbar\omega}{2mc^2}n_s(\mathbf{K})+\frac{\pi}{3}\frac{\hbar\omega}{mc^2}\frac{\hbar\omega}{W_{p\uparrow}}R_pN_p\,\mathrm{Re}\Big(-\frac{1}{\pi}W_{p\uparrow}G_{ps}(E)\Big)\Big]\\&\times\Big[\cos(2\Theta)\frac{2\pi}{3}\frac{\hbar\omega}{W_{p\uparrow}}N_p^2[W_{p\uparrow}D_p(E)]+\cos(4\Theta)\frac{2\pi}{15}\Big(\frac{\hbar\omega}{mc^2}\Big)^2\frac{\hbar\omega}{W_{d\uparrow}}(Z\alpha)^{-2}R_d^2[W_{d\uparrow}D_d(E)]\Big]\end{aligned} \tag{5}$$

for the difference of the intensities. R and N are radial integrals as listed in Table III of Ref. 1. The leading terms correspond to Eqs. (2) and (4) of Ref. 5. The notation follows Ref. 1.

Values for the charge formfactor $n(\mathbf{K})$ and for the magnetic formfactor $n_s(\mathbf{K})$ can be taken from Zukowski *et al.*[7] They are measured for the Bragg angle $2\Theta=90°$ which corresponds to $\hbar\omega=8.62$ keV for the (222) reflex. The K edge energy is 8333 eV. We have $2\Theta=94°$ for the (222) reflex and $2\Theta=73°$ for the (220) reflex. This is an important point, too. For the (222) reflex the charge form factor contributes with a small weight $\cos 2\Theta=-0.07$ whereas for the (220) reflex this weight is larger (0.28) and of opposite sign.

It should be noticed that the terms in Eq. (5) contain the factor $D(E)$. Therefore the spectrum of Namikawa *et al.* is restricted to the energy region of the unoccupied states. Furthermore there is no contribution to the dichroism from pure magnetic scattering. Figure 3 shows the results. The dichroism in the x-ray resonance spectrum is determined by the behavior of the p part of the Green function. We find negative values near the edge and positive values up to the top of the band. The shape of the curve is determined by the shape of density of states of the model. The spin polarization of the p band determines for the negative values near the edge. As known from Compton profiles[8,9] there is a negative spin po-

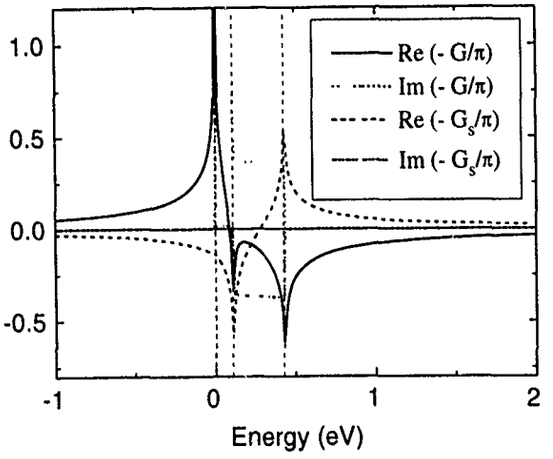

FIG. 2. The d part of the total Green function G and of the spin-polarized Green function G_s multiplied with $-1/\pi$. The dashed lines indicate the Fermi energy ($E_F=0$), the top of the majority d band, and the top of the minority d band, respectively.

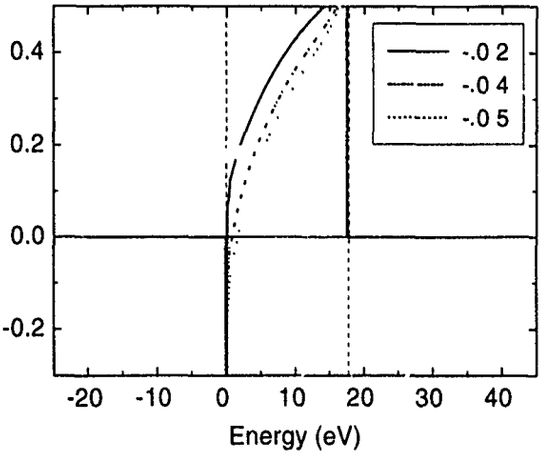

FIG. 3. Dichroism $\Delta I/(I_+ + I_-)$ for the scattering of linear polarized x rays near to the K edge. The spectrum is restricted to the energy range of the unoccupied part of p band. The numbers indicate the assumed value for the contribution of the p electrons to the magnetic moment per atom. The values are scaled by a factor 10^4.

larization of the p band in Ni with a contribution of $\approx -0.2\mu_B$. Figure 3 shows results for different values of the spin polarization. If we neglect this spin polarization at all then we do not get negative values near the edge. Thus, to discuss measured spectra it is important to calculate the spin polarization of the p band in detail.

The calculated values are smaller than the experimental one for Ni.[5,6] This is due to the simple model of the band structure. In the real band structure of Ni the spin polarization of the p band is larger near the Fermi energy whereas in the model it is uniform over the whole band.

IV. CIRCULAR POLARIZED LIGHT

Now we consider the polarization (4) which corresponds to the experiment of Schütz *et al.*[6] instead of Eq. (5) we get

$$
\begin{aligned}
|M^+|^2-|M^-|^2=\cos\Theta\Bigg[&[\cos(2\Theta)+1]n(\mathbf{K})-[\cos(2\Theta)+1]\frac{2\pi}{3}\frac{\hbar\omega}{W_{p\uparrow}}N_p^2\,\mathrm{Re}\left(-\frac{1}{\pi}W_{p\uparrow}G_p(E)\right)\\
&-[\cos(4\Theta)+\cos(2\Theta)]\frac{2\pi}{15}\left(\frac{\hbar\omega}{mc^2}\right)^2\frac{\hbar\omega}{W_{d\uparrow}}(Z\alpha)^{-2}R_d^2\,\mathrm{Re}\left(-\frac{1}{\pi}W_{d\uparrow}G_d(E)\right)\Bigg]\\
\times\Bigg[&\frac{\hbar\omega}{2mc^2}n_s(\mathbf{K})+\sin^2\Theta\,\frac{\pi}{3}\frac{\hbar\omega}{mc^2}\frac{\hbar\omega}{W_{p\uparrow}}R_pN_p\,\mathrm{Re}\left(-\frac{1}{\pi}W_{p\uparrow}G_{ps}(E)\right)\Bigg]\\
-2\cos\Theta\Bigg(&\sin^2\Theta\,\frac{\pi}{3}\frac{\hbar\omega}{mc^2}\frac{\hbar\omega}{W_{p\uparrow}}R_pN_p[W_{p\uparrow}D_{ps}(E)]\Bigg)\Bigg[[\cos(2\Theta)+1]\frac{\pi}{3}\frac{\hbar\omega}{W_{p\uparrow}}N_p^2[W_{p\uparrow}D_p(E)]\\
+[\cos(4\Theta)+\cos(2\Theta)]&\frac{\pi}{15}\left(\frac{\hbar\omega}{mc^2}\right)^2\frac{\hbar\omega}{W_{d\uparrow}}(Z\alpha)^{-2}R_d^2[W_{d\uparrow}D_d(E)]\Bigg],
\end{aligned}
\tag{6}
$$

which has a quite different structure than Eq. (5). At first we find an essential contribution from the magnetic scattering—a term proportional to $n(\mathbf{K})\cdot n_s(\mathbf{K})$. Furthermore the contributions from the resonance scattering contain the real part of the Green function. As shown in Fig. 1 it has a long tail below the edge. This behavior explains the observation of Schütz *et al.* who found essential contributions below the edge in contrast to Namikawa *et al.*

Figure 3 shows the dichroism for our example. The constant contribution from the pure magnetic scattering was subtracted and only the resonance contribution is shown. In contrast to Fig. 4 we find a finite intensity below the Fermi energy, thus below the edge. Furthermore the range of negative values is much broader and the shape is similar to the behavior of the real part of the Green function in Fig. 1.

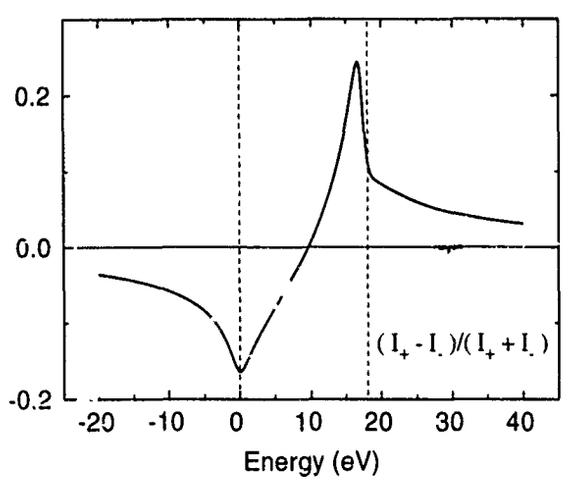

FIG. 4. Dichroism $\Delta I/(I_+ + I_-)$ for the scattering of circular polarized x rays near the K edge. The contribution of the pure magnetic scattering was subtracted. The dashed lines indicate the Fermi energy ($E_F=0$) and the top of the p band, respectively. The values are scaled by a factor 10^4.

V. CONCLUSIONS

We have calculated the magnetic dichroism in the x-ray resonance scattering in a model for the band structure, which can be evaluated analytically. The formulas and the numerical evaluation show what features of the band structure determine the characteristic peaks found in the experimental spectra. Clearly, the Green function has to be determined by a full band structure calculation to get consistence in respect to peak position and the order of magnitude with the experimental spectra in detail. Especially measurements with linear polarized light seems to more suitable, because the influence of the pure magnetic scattering is suppressed. In this case the spectrum sensitively depends on the spin-polarized part of the Green function.

Uncertainties in the application of the $\langle L_z\rangle/\langle S_z\rangle$ sum rule to experimental spectra of V, Cr, Mn, Fe, Co, and Ni are discussed. An important contribution to these uncertainties is the possible presence of dichroism due to diffuse magnetic moments, which are known to exist in Fe, Co, and Ni.

X-ray magnetic circular dichroism (XMCD) is the difference in the absorption cross section for photons with spin parallel and antiparallel to the sample magnetization. The $L_{2,3}$ absorption edges of the magnetically interesting $3d$ transition metals have readily measurable dichroism signals, making XMCD an excellent technique for the study of magnetism in ultrathin films and multilayers. Theoretical understanding of XMCD can be traced to work by Erskine and Stern[1] who predicted that the XMCD L_3/L_2 intensity ratio is equal to -1 for a simple atomiclike model. Early measurements on Ni by Chen *et al.*[2] found values substantially different than -1. Later, Smith *et al.*[3] showed that agreement with experiment could be improved by including the d-band spin-orbit interaction in the calculation. More recently, Thole *et al.*[4] and Carra *et al.*[5] have derived sum rules which relate the ground state expectation values $\langle L_z\rangle$ and $\langle S_z\rangle$ to the dichroism spectra of atoms. The derivation of these sum rules assumes excitations into d levels only and their application to solids is still controversial.[6] In this article we examine the details of the V, Cr, Mn, Fe, Co, and Ni $L_{2,3}$ XMCD spectra. We point out a number of trends in the spectra, some of which affect the application of the sum rules We also discuss dichroism due to diffuse magnetic moments and its effect on the application of the dichroism sum rules.

The experiments were performed on the 10M toroidal grating monochromator at the Synchrotron Radiation Center of the University of Wisconsin.[7] The samples were magnetized *in situ* by a 2 kG electromagnet. Absorption spectra, $\sigma(\hbar\omega)$, were obtained by measuring the total electron yield, $Y(\hbar\omega)$, by monitoring the sample drain current. All XMCD measurements were made on the remanent magnetization by reversing the sample magnetization and using a fixed incident polarization. We have completed several extensive tests of this technique[8] and have identified experimental conditions where the approximation $Y(\hbar\omega)\propto\hbar\omega\sigma(\hbar\omega)$ is valid.

In Fig. 1 we show the XMCD spectra of V, Cr, Mn, Fe, Co, and Ni. Samples were a V-Fe multilayer, a submonolayer film of Cr on Fe, a submonolayer film of Mn on Co, and Fe, Co, and Ni thin films grown on Cu(001), respectively. The energy of the maximum L_3 peak intensity in the linear absorption spectra is defined as the zero of the energy scale. We make the following observations of the results in Fig. 1. The separation between the L_3 and L_2 peaks decreases in going from Ni to V. For V and Cr the L_3 and L_2 features are not clearly separated. The L_3 peaks are predominantly of negative intensity and the L_2 peaks of positive intensity. The vanadium L_2 peak is the only exception to this. Ni and Co have negative shoulders, B, on the high energy side of the L_3 peak. For Ni, the main peak and shoulder are due to d^9 and d^8 initial state configurations, respectively.[9] We propose a similar identification for the shoulder in the Co spectra. There is also a nearly constant negative intensity feature between the shoulders B and the L_2 peaks in the Ni and Co spectra, gray arrows. The Fe L_3 peak is nearly symmetrical, having a small positive intensity shoulder. The Mn,

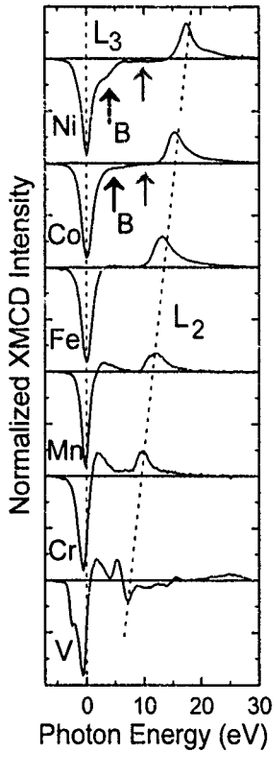

FIG. 1. V, Cr, Mn, Fe, Co, and Ni XMCD spectra shown normalized to constant L_3 peak height The shoulders labeled B are due to multiple initial state configurations. We identify the constant negative intensity features between B and L_2 in the Ni and Co spectra, gray arrows, as due to diffuse-magnetic moments

TABLE I. Diffuse moment, μ_{diff}, and ratio of diffuse moment to total moment, μ_{diff} (%), for Ni, Co, and Fe determined by calculation, Ref. 13, and by neutron diffraction (ND), Ref. 12. Values are given in μ_B/atom.

	Ni		Co		Fe	
	Theory	ND	Theory	ND	Theory	ND
μ_{diff}	−0.04	−0.105	−0.07	−0.28	−0.04	−0.21
μ_{diff}(%)	−7%	−17%	−4%	−16%	−2%	−10%

Cr, and V L_3 peaks have more pronounced positive intensity shoulders. These shoulders are present in atomic calculations for Mn, d^5, Cr d^4, and V d^2.[10] The asymmetry introduced by these shoulders shifts the peak maximum in the L_3 XMCD signal to −0.2, −0.6, and −0.8 eV relative to the maximum in the linear absorption spectra for Mn, Cr, and V, respectively.

We now discuss the application of the $\langle L_z\rangle/\langle S_z\rangle$, sum rule to our experimental results. From Carra *et al.*,[5]

$$\frac{\langle L_z\rangle}{\langle S_z\rangle}=\frac{4}{3}\frac{R_M+1}{R_M-2},$$

where $R_M=I(L_3)/I(L_2)$, the ratio of the integrated dichroism intensities. The only uncertainties involved in applying this sum rule are in the experimental separation of $I(L_3)$ and $I(L_2)$ and in the identification of dichroism intensities due to non-3d orbitals. We immediately see difficulties in applying this sum rule to the Cr and V data, since the L_3 and L_2 peaks are not clearly separated. In the Ni and Co spectra the constant negative intensity feature between the shoulder B and the L_2 peak must be identified. These features are present in other published spectra but have not been previously interpreted.[2,11] It is important to know whether or not this intensity is due to excitations into 3d orbitals. If it is not, then its intensity should not be included in the value for R_M. If this is the case, accurate models must be used to distinguish the non-3d contributions to the XMCD spectra.

A possible source of these constant negative intensity features is from diffuse magnetic moments. Polarized neutron diffraction studies have shown that diffuse magnetic moments are present in Fe, Co, and Ni.[12] This background magnetism is assumed to be caused by 4s electrons, whose spin is oppositely polarized to the 3d electrons. Recent band structure calculations on Fe, Co, and Ni[13] also predict a negative diffuse magnetic moment due to the sp-projected and interstitial moments. The results from these calculations and the neutron scattering experiments are summarized in Table I. Since $L_{2,3}$ absorption spectra are sensitive to both s- and d-electron levels, it is expected that diffuse magnetic moments will affect the XMCD spectra.

To show that the dichroism signal due to diffuse magnetic moments is consistent with the experiment we use a model similar to that developed by Erskine and Stern.[1] We assume that the empty d levels have minority spin character (↓) and that the diffuse magnetic moment is described by empty s levels which have majority spin character (↑). This simple model predicts an R_M of −1 for excitation into both the 3d(↓) and s(↑) levels. Note that the sign of the dichroism signal is the same for excitations into these oppositely polarized states. The sign at the L_3 edge for both 3d(↓) and s(↑) excitations is negative and the sign at the L_2 edge is positive for both excitations. Since there is no spin-orbit coupling in the s levels we expect $R_M=-1$ for transitions into s orbitals. Based on a comparison of radial matrix elements the diffuse XMCD should be small compared to the 3d XMCD.

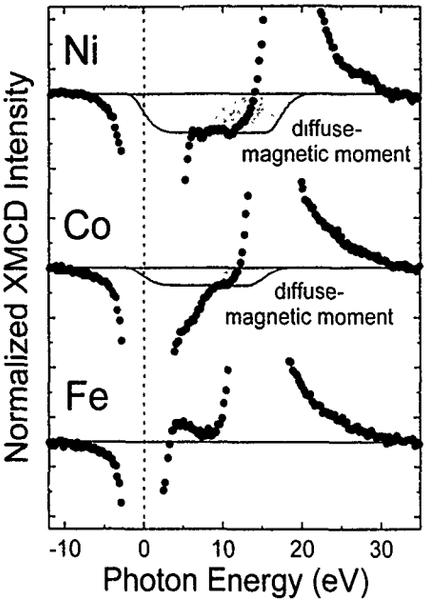

FIG. 2. Fe, Co, and Ni XMCD spectra from Fig. 1 shown on an expanded scale. XMCD signal due to diffuse-magnetic moments in Ni and Co, shaded area.

In Fig. 2 we show the same Ni, Co, and Fe spectra from Fig. 1 on an expanded scale together with the predicted XMCD signal due to diffuse magnetism for both Ni and Co. We observe no effects of diffuse magnetic moments in the Fe XMCD spectra. The positive going shoulder on the Fe L_3 may obscure such a feature, or the separation between the Fe L_2 and L_3 peaks may be too small. We also note that for Fe, Co, and Ni, the relative diffuse moment is smallest for Fe (Table I). The model we have used predicts a step-function line shape, which reflects a broad s band with nearly constant density of state. We have assumed that $R_M=-1$ so that the diffuse XMCD signal goes to zero above the L_2 edge. While the XMCD line shape due to diffuse magnetic moments is undoubtedly more complicated, this simple model serves to illustrate the importance of considering diffuse magnetism in XMCD.

We have determined $\langle L_z\rangle/\langle S_z\rangle$ for V, Cr, Mn, Fe, Co, and Ni, from our XMCD spectra both before and after subtracting contributions from diffuse moments. These values are given in Table II along with values determined by neutron diffraction[12] and band structure calculations[14] for Fe, Co, and Ni. Values of $\langle L_z\rangle/\langle S_z\rangle$ determined from XMCD are larger than values determined by neutron scattering and band structure calculations, but including diffuse moments improves the comparison for Co and Ni. The results in Table II show how different interpretations of weak features in the XMCD spectra greatly affect the application of the $\langle L_z\rangle/\langle S_z\rangle$

TABLE II. $\langle L_z\rangle/\langle S_z\rangle$ values obtained from results in Fig.1 and dichroism sum rules, compared to theoretical values, Ref. 14, and neutron diffraction (ND), Ref. 12. Values for Co and Ni were obtained both before and after subtracting the diffuse-XMCD signal. The calculated value for Co is for the fcc phase which is present in this experiment. Errors given for Cr are due to overlap of L_3 and L_2 dichroism signal.

The first observation of spin-dependent photoelectron diffraction using circularly polarized x rays is reported for monolayer ferromagnetic fcc Fe films on Cu(001). Circularly polarized x rays are used to produce spin-polarized photoelectrons from the Fe2p spin-orbit split doublet, and intensity asymmetries in the $2p3/2$ level of $\approx 3\%$ are observed. The asymmetry is dependent on the relative orientation of the x-ray polarization vector and the Fe magnetic moment. This spin-dependent technique promises the direct, element-specific determination not only of local atomic structure, but magnetic structure as well.

The last several years have witnessed a massive growth in the research and development of nanoscale magnetic materials. Perhaps the best review is provided by the Falicov report[1] on "Surface, Interface, and Thin-Film Magnetism." Three general lessons can be derived from this report. (1) Magnetism is one of those special cases where fundamental research can directly lead to technological applications; (2) the key to understanding and manipulation of magnetic properties is the subtle yet overwhelming interplay of atomic geometric structure and local magnetic properties. For example, the giant magnetoresistance effect (GMR), which is already being explored for technological exploitation,[2–4] appears to be intimately coupled to interfacial and thin film effects and probably will require elementally specific probes for an explicit determination of the underlying causes.[5–7] This also appears to be the case for spin valves,[8–10] another source of device miniaturization in read heads and magnetic sensors. [While it may eventually be found that these two effects are fundamentally connected, for now it appears that the GMR effect (up to 60%) is dependent upon an antiferromagnetic coupling through a nonferromagnetic layer while the spin valve effect ($\leqslant 10\%$) is associated with a loosely coupled ferromagnetic layer,[9] which can be controlled externally.] (3) The importance of probes with a direct spin dependence. A very recent illustration of this is the development of the magnetic x-ray circular dichroism using x-ray absorption[11–15] and photoemission[16,17] as a probe of surface, monolayer, and multilayer magnetism. It is this advantage that we propose to utilize, as will be described. However, before beginning that discussion, it is useful to summarize the state of of core-level photoelectron spectroscopy and diffraction at this point.

In the case of photoelectron spectroscopy and diffraction, there have been some significant strides recently. High resolution core-level spectroscopy has been demonstrated by Himpsel,[18] to be a sensitive measure of oxidation state of surface silicon. Photoelectron diffraction[19–21] has been shown to be a powerful probe of metal overlayer structure. Using the internal spin polarization of the 3s state of Mn, Fadley *et al.* have reported observation of spin-specific photoelectron diffraction in bulk systems,[22] and used it to study short range magnetic order. In attempting to extend such measurements to metal overlayer systems,[23] limitations to this method became apparent. The small 3s cross section, the overlap of the split peaks, the large background on which the peaks rode, and the generally unknown spin composition of the peaks all militate for a better defined approach. This approach must possess some sort of independent spin sensitivity or selectivity, such as that shown in Fig. 1, and a more rigorous analysis based upon multiple scattering theory. One avenue to better spin sensitivity is the utilization of spin detectors, which unfortunately carry with them a concomitant loss. (Efficiencies of 10^{-2}–10^{-4} are common, relative to unpolarized detection.) Despite this handicap to spin-polarized, core-level, photoelectron spectroscopy, the first results were reported by Kisker *et al.* and Carbone *et al.* looking at the shallow 3p (Ref. 24) and 3s (Refs. 25 and 26) levels of bulk Fe. Subsequently, the measurements have been extended to include magnetic overlayers, demonstrating effects such as antiferromagnetic coupling between substrate and overlayer.[27] (In parallel with this, spin-polarized photoemission studies of valence band structure have also been pursued. Recent examples include the investigations of quantum well state, by Johnson *et al.*[28] and Carbone *et al.*,[29] which suggest that these states are connected to oscillatory interlayer coupling. Johnson has also led the effort at NSLS to extend their spin-resolved measurements to include shallow core levels.)[30] Finally, Roth *et al.*[31] reported the observation of strong dichroism effects in the Fe 3p spectra using linear polarization, with and without spin detection, by using specific high symmetry geometries. These first studies were invariably done using *linearly* polarized soft x rays, and the spin sensitivity was provided by electron spin polarizers coupled to energy-analyzers. An alternative means to extract spin-specific information from core levels is to use circularly polarized x rays and the strong dipole selection rules that govern these transitions. The observation of photoemission circular dichroism was first demonstrated using the Fe 2p

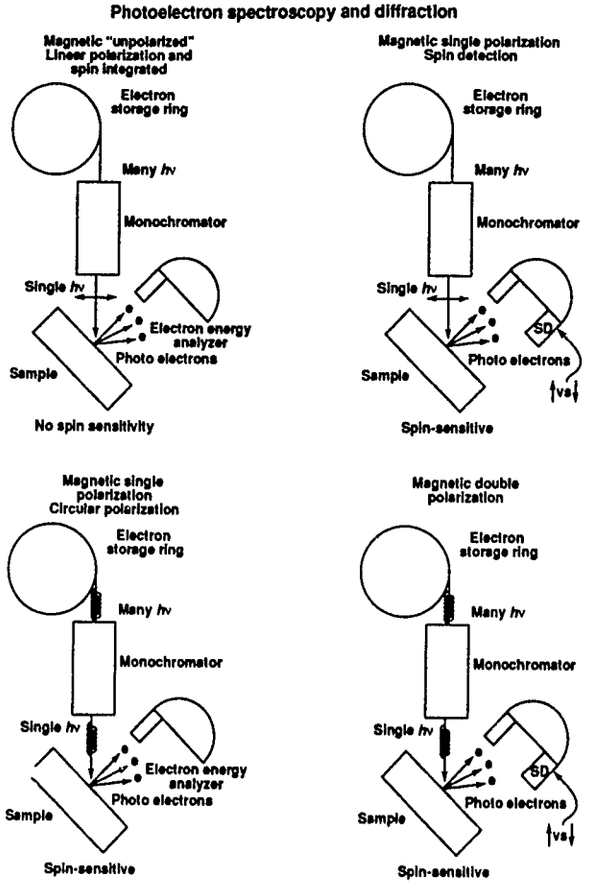

FIG. 1. This figure shows schematically the experimental setup. A single energy ($h\nu$) of electromagnetic radiation is selected from the broad continuum of synchrotron radiation using a monochromator. The photons cause the ejection of photoelectron, which are then collected by the angle ($\pm 3°$) and energy resolving detector. The photons can be linearly or circularly polarized. The electron energy analyzer can be coupled to a spin detector (SD).

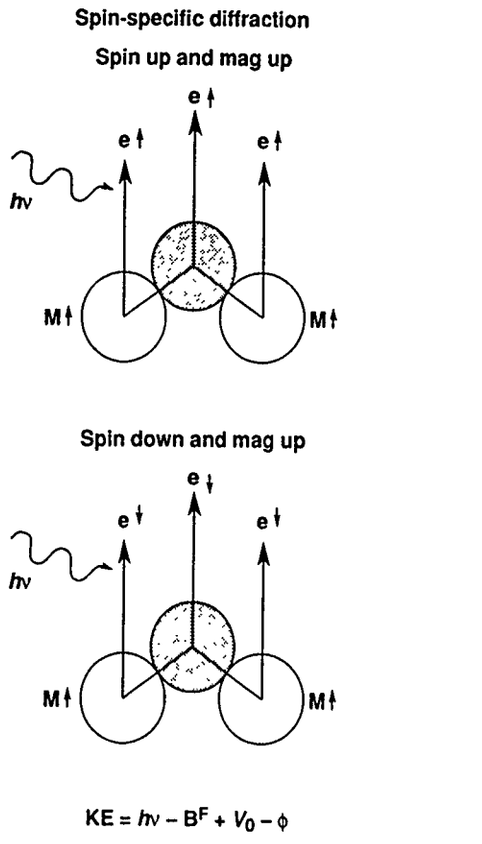

FIG. 2. This schematic illustrates the underlying cause of photoelectron diffraction: interference between the direct and scattered waves. The interference is dependent upon the details of the local geometry and the emission angles, the kinetic energy (KE), and the spin of the outgoing electron, as well as the sample magnetization. The kinetic energy is varied by scanning the photon energy, $h\nu$. The binding energy (B^F), the work function ($\varnothing$), and inner potential (V_0) are constant for a given state and material system.

states of bulk Fe by Baumgarten *et al.*[16] and then ultrathin films of Fe/Cu(001) by Waddill *et al.*[17] Subsequently, Kaindl *et al.* extended this work to rare-earth systems, with the observation of very strong effects.[32] More recently, a large circular dichroism in the Fe $3p$ emission from Fe/Cu(001) has been observed and quantitatively simulated,[33] using a spin-specific, fully relativistic, multiple scattering theory that can also explain the large linear dichroism that was previously observed.[31] It is this spin selectivity, based upon circular polarization of soft x rays, that we have used to perform spin-specific photoelectron diffraction.

In photoelectron diffraction, an electron is ejected from a core level and can scatter or diffract off of its nearest neighbors. In the usual experiments a small solid angle of electrons is collected and linearly polarized x rays are used as the excitation. From the energy or angular variations of the partial cross section, the local geometrical structure can be obtained. To gain sensitivity to local magnetic structure, the spin of the electron must come into play (Fig. 2). One way to do this is to use circularly polarized x rays as the excitation: In this case the $2p$ peaks will be intrinsically spin polarized. A naive atomic picture would predict that the $2p_{3/2}$ would be

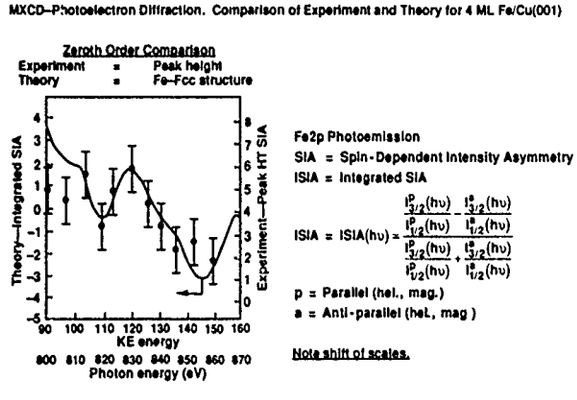

FIG 3. Spin-specific photoelectron diffraction using magnetic circular dichroism, for emission along the Cu[111] direction. Because the sample was perpendicularly magnetized, the x rays were incident normal to the surface. Experimental results are shown as data points with error bars. The theoretical results are from a spin-specific, multiple scattering calculation using an unrelaxed fcc model (a=3.6 Å) for the Fe

$\pm 25\%$ polarized and the $2p_{1/2}$ would be $\mp 50\%$ polarized. These spin-polarized electrons can then be used to determine local atomic magnetic structure, for example, to distinguish local antiferromagnetic ordering versus local ferromagnetic ordering.

In fact, we have already done the first such experiment. In Fig. 3 is an example of our data collected using ferromagnetic Fe/Cu(001) and circularly polarized x rays without spin detection. It should be noted that our measurements were done in mirror planes and with variation of both the magnetization and helicity, to remove other extraneous effects and as a cross-check upon our analysis. It is obvious from our spectra that there is a fundamental intensity asymmetry that is independent of exchange-induced peak shifting. A more thorough discussion is provided elsewhere.[34] Thus, spin-dependent photoelectron diffraction can provide a sensitivity to local magnetic order, similar to that demonstrated for spin-polarized extended x-ray-absorption fine structure.[35]

Work was performed under the auspices of the U.S. Department of Energy by the Lawrence Livermore National Laboratory under Contract No. W-7405-ENG-48. Work at Wisconsin was supported by the U.S. Department of Energy. The authors wish to thank Karen Clark for her clerical support. Discussions with James Brug were enlightening and enjoyable.

Two-dimensional, ordered surface alloys of MnCu and MnNi were grown on Cu(001) and Ni(001) substrates. These surface alloys, which have structures that are not present in the bulk phase diagram, are highly corrugated with a $c(2\times2)$ periodicity. The stability of these surfaces has been predicted theoretically to be due to a gain in magnetic energy of the Mn atoms. Using a combination of soft x-ray absorption spectroscopy and x-ray magnetic circular dichroism we find that Mn is in a high-spin state and is ferromagnetically ordered in the MnNi surface alloy. MnNi surface alloys have been grown with an easy axis of magnetization perpendicular to the surface.

Ultrathin films of Mn on Cu(001) and Ni(001) have received much attention recently due to the existence of stable surface alloys which form at 1/2 monolayer (ML) coverage.[1–4] These surface alloys form at room temperature and are characterized by $c(2\times2)$ low energy electron diffraction (LEED) patterns. LEED $I-V$ analysis,[1,2] shows that these surface alloys are highly corrugated with the Mn relaxing outwards by 0.3 Å on the Cu surface and 0.25 Å on the Ni surface, Fig. 1. This large outward relaxation results in a reduction of screening at the Mn sites, observable as large binding energy shifts in the Mn $3s$, $3p$, and $2p$ photoemission.[4] The stability of these highly corrugated surfaces has been attributed to a gain in magnetic energy of the Mn atoms and ferromagnetic ordering of the Mn atoms has been predicted.[1] Calculated magnetic moments for Mn in the surface alloys are high $\sim 4\mu_B$.[1]

In this article we investigate the magnetic properties of the MnCu and MnNi $c(2\times2)$ surface alloys using soft x-ray absorption spectroscopy[5] and x-ray magnetic circular dichroism (XMCD).[6,7] Both these techniques give element specific magnetic information. The line shape of the Mn $L_{2,3}$ absorption spectra has been shown to be sensitive to the ground state spin moment of the Mn atoms.[5] The XMCD signal, $\sigma_M = (\sigma_+ - \sigma_-)$, is the difference between the absorption spectra with the photon spin parallel (σ_+) and antiparallel (σ_-) to the sample magnetization, **M**. The average of the two spectra, $\sigma_0 = 1/2(\sigma_+ + \sigma_-)$, is in most circumstances considered to be identical to the linearly polarized absorption spectra. The intensity and sign of σ_M depends on the relative orientation of **M** and the photon spin, Σ, that is $\sigma_M \sim \Sigma \cdot \mathbf{M}$. This is an important property of XMCD since it allows the direction of **M** to be determined, allowing antiferromagnetic coupling to be distinguished from ferromagnetic coupling.[6,7] We present our XMCD spectra normalized to σ_0 at the L_3 peak, $\sigma_M(\hbar\omega)/\sigma_0(L_3)$, in order to discuss relative degrees of magnetic ordering.

The experiments were performed on the 10M toroidal grating monochromator at the Synchrotron Radiation Center of the University of Wisconsin. The beamline is equipped with a water-cooled copper aperture which allows the selection of either linear, left-handed or right-handed elliptically polarized photons in the energy range 200–900 eV. The degree of circular polarization for this instrument has been calculated to be $85\pm5\%$.[8] The samples were magnetized *in situ* by a 2 kG magnet and all XMCD measurements were made on the remanent magnetization at room temperature. All absorption measurements were made using the total electron yield by monitoring the sample drain current.[6] For perpendicular magnetization the photons were incident normal to the surface. For in-plane magnetization measurements the photon angle of incidence was 65° off normal (25° grazing). This reduces the in-plane σ_M signal by a factor of 0.9 (cos 25°) when compared to σ_M signals for perpendicular magnetization. We have corrected our measurements for this geometrical factor by multiplying the normalized in-plane σ_M spectra by 1/cos (25°).

Samples were made and measured in an ultrahigh vacuum system equipped with cryo-shrouded evaporation sources. Manganese was evaporated from an Al_2O_3 crucible at a rate of 1 ML in 5 min. The MnCu $c(2\times2)$ surface alloy was prepared by evaporation onto a clean Cu(001) single crystal at room temperature. A sharp $c(2\times2)$ pattern, as viewed by LEED, was formed at 1/2 ML coverage. The

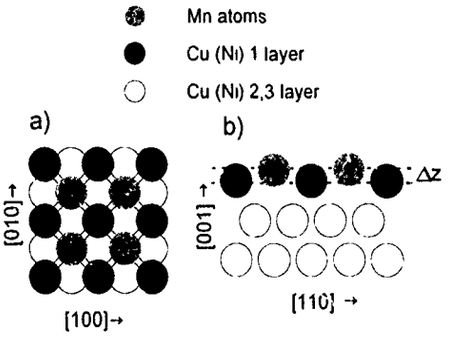

FIG. 1. Structural model of $c(2\times2)$ surface alloy (a) top view, (b) side view. Corrugation, Δz, is 0.3 Å for MnCu and 0.25 Å for MnNi.

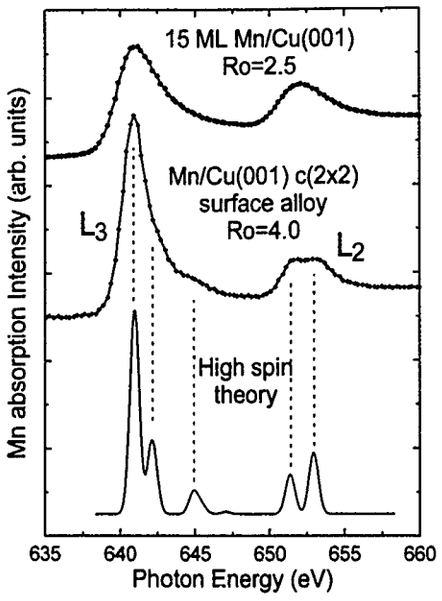

FIG. 2. (Top) Mn $L_{2,3}$ absorption spectrum, σ_0, for 15 ML of Mn on Cu(001), (middle) Mn $L_{2,3}\sigma_0$ for the Mn/Cu(001)$c(2\times2)$ surface alloy. (Bottom) Theoretical spectrum for high spin Hund's rule ground state, $S=5/2$, of d^5 Mn^{+2} from Ref. 11.

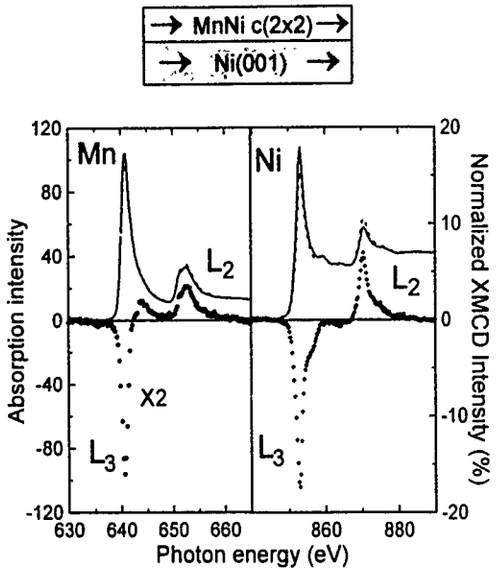

FIG. 3. (Top) Mn and Ni $L_{2,3}$ absorption spectra, σ_-, solid line, and σ_+, dashed line, for the MnNi $c(2\times2)$ surface alloy grown on Ni(001). (Bottom) Mn and Ni normalized XMCD spectrum, $\sigma_M(\hbar\omega)/\sigma_0(L_3)$, showing ferromagnetic ordering in both Mn and Ni and ferromagnetic alignment of Mn to Ni. The film was magnetized in plane along the [110] axis. The spectra have been multiplied by 1/cos(25)=1.1 to account for the photon angle of incidence.

MnNi surface alloy was grown on two types of fcc Ni(001) substrate: a Ni(001) single crystal and a 20 ML Ni(001) film grown on Cu(001). The ultrathin Ni films are known to have a perpendicular easy axis of magnetization, while the Ni(001) single crystal has an in-plane easy axis.[9] For both Ni(001) substrates a $c(2\times2)$ LEED pattern was formed after deposition of 1/2 ML of Mn. This pattern became much sharper after annealing to 400 K. The base pressure of the vacuum chamber was 5×10^{-11} Torr and the pressure during evaporation was 2×10^{-10} Torr.

In Fig. 2 we show the Mn $L_{2,3}$ absorption spectra, σ_0, for the MnCu surface alloy and a 15 ML film of Mn grown on Cu(001). The two spectra are shown normalized to the integrated L_2 intensity and are quite different. The spectrum for the surface alloy has two shoulders on the main L_3 peak and the L_2 feature appears as a doublet. The spectrum for the 15 ML film is comparatively featureless consisting of a single broad peak at both the L_3 and L_2 edges. Also the L_3/L_2 intensity ratio, R_0, is smaller than the 15 ML spectrum. The spectrum for the 15 ML film is very similar to the absorption spectra for bulk Mn.[10]

Also shown in Fig. 2 is the theoretical spectrum for high spin atomic Mn^{+2} d^5, $S=5/2$. This calculated spectrum is from Fig. 1(e) of Ref. 11 and includes spin-orbit coupling in the d levels. The only solid state effect included in the calculation is an 80% scaling of the electrostatic terms in the Hamiltonian to account for solid state screening. The calculated high spin spectrum is in good agreement with the experimental spectrum of the surface alloy. Each of the major features in the experimental spectrum are reproduced in the theoretical spectrum. The relative intensity ratios of the different features also agree well. A similar agreement is found for the Mn absorption spectrum in the MnNi surface alloy. These comparisons show that Mn in the MnNi and MnCu surface alloys are nearly atomiclike and have high spin moments.

It is informative to consider why the atomic calculation describes so well the Mn absorption spectra for these surface alloys. We first note that atomic calculations have been more successful than band structure calculations in explaining the nonstatistical behavior of the L_3/L_2 intensity ratio in the absorption spectra of first row transition metals.[10] This is due to the localization of the d orbitals involved in the transitions and the importance of many-body excitations. At the surface, d orbitals are further localized due to lower coordination. This leads to an enhanced surface moment in magnetic materials. The outward buckling of Mn in the surface alloys causes even more localization of the d orbitals resulting in an almost atomiclike Mn. The Hund's rule ground state for Mn d^5 is an $S=5/2$ state. Therefore, both the atomiclike σ_0 spectra and the high spin moment are due to the surface corrugation.

In Fig. 3 we show the Mn $L_{2,3}$ absorption spectra σ_+ and σ_- and their difference σ_M for the MnNi surface alloy grown on a Ni(001) single crystal. Mn is found to be ferromagnetically ordered with an in-plane easy axis of magnetization. Also shown in Fig. 3 is the Ni σ_+, σ_-, and σ_M spectra for the same sample. Both the Mn σ_M spectrum and the Ni σ_M spectrum are negative at the L_3 edge and positive at the L_2 edge. Mn is ferromagnetically aligned with the Ni substrate. This is unusual since bulk MnNi is antiferromagnetic at room temperature.[12] No remanent magnetization was found for either Mn or Ni for magnetization perpendicular to the surface. No remanent magnetization was found in any direction for the MnCu surface alloy.

The MnNi surface alloy was also grown on a 20 ML film

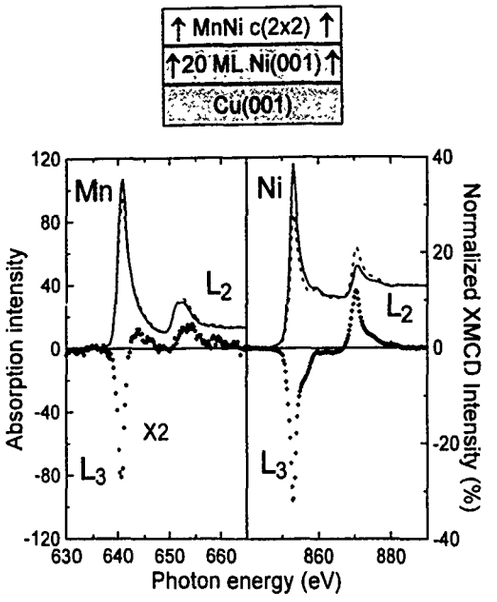

FIG. 4. (Top) Mn and Ni $L_{2,3}$ absorption spectra, σ_-, solid line, and σ_+, dashed line, for the MnNi $c(2\times2)$ surface alloy grown on a 20 ML film of Ni/Cu(001). (Bottom) Mn and Ni normalized XMCD spectrum, $\sigma_M(\hbar\omega)/\sigma_0(L_3)$ showing ferromagnetic ordering in both Mn and Ni and ferromagnetic alignment of Mn to Ni. The film was magnetized perpendicular to the surface. The intensities of the normalized XMCD spectrum are ~2 times greater than those for MnNi grown on Ni(001), Fig. 3.

of Ni deposited on Cu(001). These Ni films are known to have an easy axis of magnetization which is perpendicular to the surface.[9] XMCD studies of these films show they have a similar σ_M line shape as bulk Ni but that the normalized intensity is increased by almost a factor of 2.[9] This increase has been attributed to magnetic domains in the bulk sample, which are apparently absent in the thin films.[9] In Fig. 4 we show the Mn and Ni $L_{2,3}$ absorption spectra σ_+ and σ_- and their difference σ_M for the MnNi surface alloy grown on a 20 ML film and magnetized perpendicular to the surface. Once again the Mn is ferromagnetically ordered and aligned with the Ni substrate. No remanent magnetization was found for either Mn or Ni for magnetization parallel to the surface. The Mn σ_M line shape is similar for the surface alloy grown on the single crystal and the thin film. The normalized intensity of the Mn σ_M spectra is increased by a factor of ~2 for growth on the Ni thin film, consistent with the Ni σ_M results and the idea of magnetic domains in the bulk sample.

In conclusion, we have shown that Mn has a high spin moment in the MnCu and MnNi $c(2\times2)$ surface alloys. This high moment results from the corrugation of the surface which localizes the Mn d orbitals. We find Mn to be ferromagnetically ordered in the MnNi surface alloy but not in the MnCu surface alloy. Long range magnetic ordering does not affect the stability of these surface alloys. We believe that it is the formation of atomiclike Mn in the Hund's rule ground state which stabilizes the surface alloy. For the MnNi surface alloy we find that the Mn is ferromagnetically coupled to the Ni for substrates with in-plane and perpendicular easy axis of magnetization. This is unusual since bulk MnNi is antiferromagnetic at room temperature.

It is also possible to grow thicker compositionally ordered MnNi alloys with the $c(2\times2)$ surface structure.[3] We have measured the magnetism in these films using XMCD and have found ferromagnetic ordering for film thickness up to 4 ML. These results will be discussed in detail in a separate publication.[13]

The $M_{2,3}$ edge of Rh in Co-Rh alloys shows measurable x-ray magnetic circular dichroism. Such dichroism is not present, however, for analogous alloys of Co-Ru. The induced Ru magnetic moment, if any, is thus demonstrated to be significantly smaller than the induced Rh moment in otherwise similar Co alloys.

X-ray magnetic circular dichroism (XMCD) is a useful technique for the study of magnetic systems. In XMCD, the absorption coefficient of circularly polarized x rays is measured as a function of photon energy. Near a core level absorption edge, the absorption coefficient is seen to vary depending on the cosine of the angle between the x-ray polarization and the sample magnetization. XMCD can be used to determine the net magnetization, projected onto the x-ray polarization axis, of the individual elemental species in a complex sample.

Published studies using XMCD have considered diverse systems, including the K_1 edge[1] and $L_{2,3}$ edge[2] of the $3d$ transition metals, the $L_{2,3}$ edge of the $5d$ transition metals,[3] and the $L_{2,3}$ earth of the rare-earth transition metals.[4]

Absent from this list are the $4d$ transition metals. The reason for this omission is that for the transition metals, the $L_{2,3}$ edge is preferred for XMCD because (a) it allows the study of the d-like valence electrons, and (b) because it has a high signal to background ratio for x-ray absorption.[5] However, the angle of incidence required in the energy range of the $4d$ $L_{2,3}$ absorption edges (2–3 kV), is typically close to Brewster's angle for most crystal monochromators (≈45°).[6] That is, the monochromators produce only linearly polarized x rays, independent of the polarization of the incident radiation. For example, with 100% circularly polarized incident radiation at the Rh L_2 edge (3146 eV), a Si(111) monochromator crystal would be held at 39° incident angle, and would reflect only 8% circularly polarized x rays. Given that the XMCD signal from Rh is only 4% using 85% polarized x rays (see below), systematic errors in, e.g., spectrum normalization make measurements at the Rh L edge unfeasible. Another approach toward the measurement of Rh XMCD is therefore indicated.

In this study, we evaluate the feasibility of XMCD measurements of $4d$ transition metal elements at the $M_{2,3}$ absorption edge. Although the estimated signal/background ratios are low, such experiments may be possible with currently available grating monochromators which produce x rays approaching 90% circular polarization in the energy range of interest for the M edges (300–600 eV). We present measurements made on intermetallic alloys close to the $Co_{75}Ru_{25}$, $Co_{75}Rh_{25}$, and $Co_{50}Rh_{50}$ compositions. The particular alloys were chosen based on their miscibility, remanent moment, and energy position of their respective absorption edges (e.g., Pd was omitted due to a conflict with the O $1s$ grating absorption edge).

The measurements were made at the Synchrotron Radiation Center in Stoughton, WI, on a 10 m toroidal grating monochromator. The alloys samples were prepared as 500–1000 Å thin films on fused quartz wafers by codeposition using magnetron sputtering at 500 °C. Alloy compositions were measured by electron microprobe analysis and absolute magnetizations were measured by superconducting quantum interference device magnetometry. The samples were transported to the synchrotron in air. To remove the resulting surface impurity layer, the films were sputtered in vacuum and annealed to ~300 °C prior to measurement. Residual oxygen impurity levels were small (less than 1 equivalent monolayer) as determined from the oxygen $1s$ core absorption peak. The samples were magnetized in-plane prior to the XMCD measurements, and were measured in remanence (zero applied field). We estimate the x rays had about 85%±5% circular polarization[7] and they were incident at ±65° from the surface normal upon the sample, with consecutive spectra taken at alternating angles. Absorption spectra were measured using a total electron yield technique. For more information on the measurement technique, see Ref. 7.

Figure 1 displays the XMCD data from the Co $L_{2,3}$ and Ru $M_{2,3}$ edges of a $Co_{75}Ru_{25}$ alloy. Here the solid and dashed curves are the absorption coefficients, $\alpha_{\pm 65°}$, taken in the two sample positions (magnetization 25° or 155° with respect to polarization, respectively), and the dotted curve their difference. Regarding this data, we wish to make several points: in the Co spectrum the signal to background ratio at the L_3 absorption edge is 4, while at the Ru M_3 edge it is 0.15, or about 25 times smaller. As a result, the Ru spectrum took much longer to collect (about 8 h) than the Co spectrum (about 40 min). The peak XMCD signal, χ_p, defined as $\chi_p = \max\,[(\alpha_{+65}-\alpha_{-65})/(\alpha_{+65}+\alpha_{-65})]$, is 0.032 at the Co edge, compared with 0.21 for a saturated epitaxial Co film.

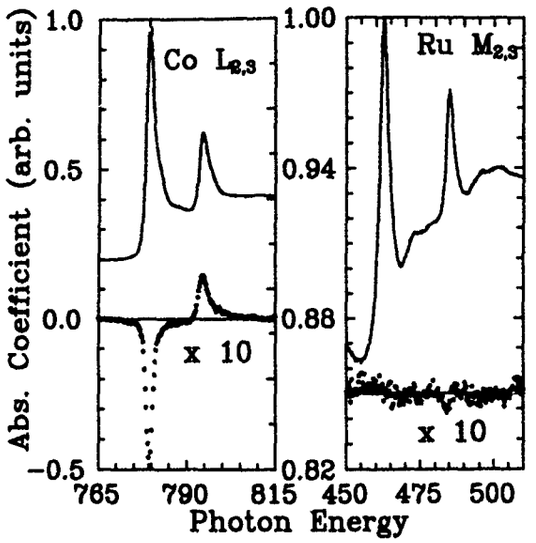

FIG. 1. Circularly polarized x-ray absorption spectra (solid and dashed curves) and their difference or dichroism (dotted curve) from a $Co_{75}Ru_{25}$ alloy. The Co $L_{2,3}$ edge shows significant dichroism but the Ru $M_{2,3}$ edge does not.

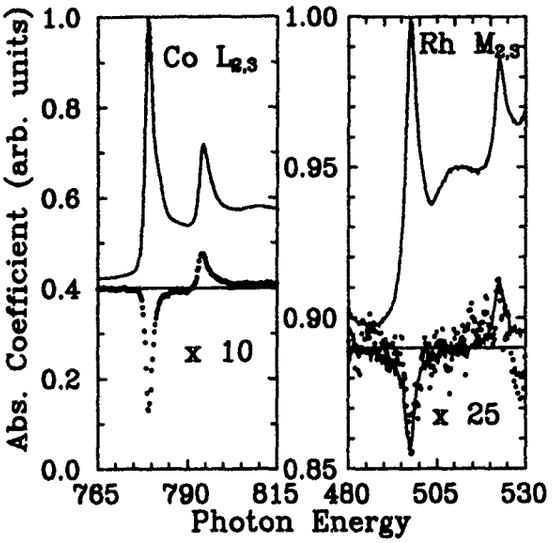

FIG. 3. Spectra analogous to Figs. 1 and 2, except for a $Co_{49}Rh_{51}$ alloy. The Rh atoms develop measurable magnetic moments in this alloy.

The low XMCD signal is caused by the low saturation magnetization in this alloy and by its low remanence (52%). At the Ru edge, however, no XMCD signal is seen. We conservatively place an upper bound on χ_p to be ≤ 0.005 at the Ru L_3 edge.

The data from the $Co_{75}Ru_{25}$ alloy can be compared with Fig. 2 showing spectra from a $Co_{77}Rh_{23}$ alloy. Here $\chi_p=0.12$ at the Co edge. At the Rh $M_{2,3}$ edge definite XMCD is seen, with $\chi_p=0.04$. The induced Rh moment is parallel to the Co moment. This alloy had 66% remanence, and we can extrapolate the XMCD measurement to determine that the saturation Rh χ_p for this alloy is 0.06. Mössbauer measurements of the Rh moment in $Fe_{75}Rh_{25}$ alloys indicate an induced Rh moment of $\sim 1\ \mu_B$.[8] If we assume that Rh develops a similar moment in Co alloys, we may deduce an approximate proportionality constant between χ_p for Rh and its moment, i.e., $\chi_p=0.06/\mu_B$.

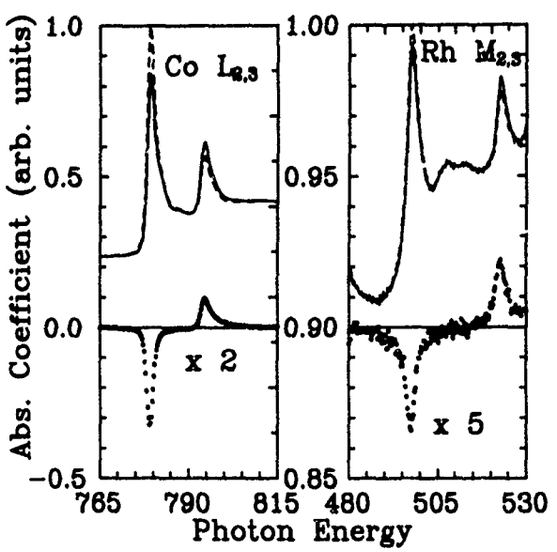

FIG. 2. Spectra analogous to Fig. 1, except for a $Co_{77}Rh_{23}$ alloy. Here significant dichroism is seen at the Rh $M_{2,3}$ edge, indicating that the Rh develops a significant magnetic moment.

Figure 3 shows spectra from a $Co_{49}Rh_{51}$ alloy. The Co edge has $\chi_p=0.025$. The Rh dichroism signal is only about 3 times the noise level, yet still measurable with $\chi_p=0.006$. This sample had 40% remanence, and based on the results from the previous paragraph, we find the saturation Rh moment in this alloy to be 0.25 μ_B. As a guide to the eye, we have superimposed a scaled version of the $Co_{77}Rh_{23}$ XMCD spectrum as a dashed curve.

This last result has particular significance to our understanding of the $Co_{75}Ru_{25}$ alloy (Fig. 1). Although the Ru alloy possessed remanent Co moments 1.3 times higher than in the $Co_{49}Rh_{51}$ alloy, no detectable Ru moment was found. If we assume the same proportionality constant between magnetic moment and χ_p for Ru as for Rh, we can place an upper bound on the saturation Ru moment in the $Co_{75}Ru_{25}$ alloy of approximately 0.16 μ_B. Thus we find that Ru and Rh behave qualitatively quite differently when alloyed with Co.

In summary, we have demonstrated the feasibility of XMCD measurements in the $4d$ transition metals using photon energies below 1000 eV. We find that the signal/background ratio at the $4d$ $M_{2,3}$ edge is about 25 times smaller than at the $3d$ $L_{2,3}$ edge, but that this edge can be effectively used to study XMCD in the $4d$ transition metals.

Circular magnetic x-ray dichroism is a promising new tool for the study of spin and orbital moments in ferromagnetically ordered materials. For rare-earth systems the L_2 and L_3 edge dichroic spectra give information about the magnetic properties of the $5d$ conduction electrons. This article addresses a few of the key issues concerning the interpretation of the spectra. In particular, the quadrupole nature of the dichroic spectra below the L absorption edges and its angular dependence is discussed. The important role of the $4f$-$5d$ exchange in causing a large and important spin dependence in the $2p-5d$ matrix elements is likewise examined.

Because of the strong electronic correlations associated with the ground state of magnetic materials, there is an old but continuing problem on how to best formulate a model capable of quantitative analysis. With the advent of dedicated synchrotron sources a new tool, circular magnetic x-ray dichroism (CMXD), has become available and may eventually prove as valuable as magnetic neutron scattering in helping to sort out the microscopic details of the magnetic ground state. An attractive feature of CMXD is its ability to yield element and shell specific information about the separate spin *and* orbital magnetic moments, even in complicated magnetic materials. In this article we concentrate on several issues which arise when trying to interpret features of the observed spectra for the L edges in rare-earth materials. Although the first CMXD measurements on rare-earth materials (Gd and Th) were reported in 1988,[1] there already exists a fairly large literature on the subject, which we cannot adequately review in this short paper.

In the analysis of the L edge x-ray dichroism experiments on Gd a simple model was used to compare the experimental spectra with a theoretical spin difference d density of states.[1] The obvious disagreement was noted. The question arose whether when dealing with high energy photons and the creation of a core hole the single particle picture is valid. Certainly an atomic picture with full multiplet considerations is required for the M_4 and M_5 spectra of the rare earths (involving dipole transitions from the $3d$ core states to the highly local $4f$ states).[2] However a self-consistent, relativistic, spin-polarized band structure calculation was extremely successful in reproducing the dichroic spectra of Gd for the L_2 and L_3 edges,[3] thus indicating the single particle picture may be adequate for the very itinerant $5d$ states. The experimental data also exhibit some structure below the L_2 and L_3 absorption edges, and these features were quantitatively accounted for by using an atomic model to evaluate the $2p-4f$ quadrupole transitions.[3] Similar atomic calculations were carried out to explain the variation of these below edge features in the dichroic spectra across the entire heavy rare-earth series.[4] There is good agreement with experiment.[5] The reason these quadrupole features appear below the L edges is that the core hole is more attractive for the localized $4f$ states than for the itinerant $5d$ states.

These first calculations also included a quantitative prediction for confirming the quadrupolar character of the below edge structure. There is an expected difference in the angular dependence of the dipole and quadrupole spectra as one varies the direction of the magnetization relative to the wave vector of the incoming light.[3] For some rare earths (e.g., Ho and Er) the angular difference is expected to be large and was looked for experimentally, with no success.[6–8] We have speculated on possible explanations for the negative results of these experiments.[9] We believe the simplest explanation which should be checked first involves the lack of complete magnetic alignment that has been obtained so far in the experiments. There are two causes for the lack of alignment: (1) experiments done on powders that have the easy axis of grains misaligned (not the case for samples with grain alignment or with very small anisotropy), and (2) the misalignment caused by thermal fluctuations (not a problem at temperatures that are very low compared with the magnetic ordering temperature). To demonstrate the rather large sensitivity of the difference between dipole and quadrupole angular dependence to temperature, we consider an isolated ion of holmium. We neglect crystal field effects (which can also reduce the expected difference). The integrated spectra for the $2p-4f$ quadrupole transitions can be decomposed into two terms, one with a $P_1(\theta)=\cos(\theta)$ dependence, and the other with a $P_3(\theta)=[5\cos^2(\theta)-3]\cos(\theta)/2$ dependence.[10,11] The first term has an angular dependence identical to the $2p-5d$ dipolar transitions, so it is only the second term that gives the quadrupolar transitions at different angular dependence. If we take the $|JM\rangle$ $4f$ states as equally spaced in energy (no crystal field effects) and evaluate the magnitude of the factor multiplying the P_3 term for Ho, we get the dependence shown in Fig. 1. This figure indicates under ideal conditions, that if the experimental $4f$ moment is at 70% of its zero temperature saturated value, then the P_3 term is already reduced by a factor of 6! We are not aware of any experiments that have been done in such a way that the magnetic alignment was sufficient to make a definitive statement about the quadrupolar angular dependence, although several groups are planning such measurements in the near future.

Another interesting aspect of the L dichroic spectra for rare earths is the sign. It was a surprise when the first spectra for Gd were analyzed and interpreted as indicating more spin up than spin down unoccupied $5d$ states. This is inconsistent

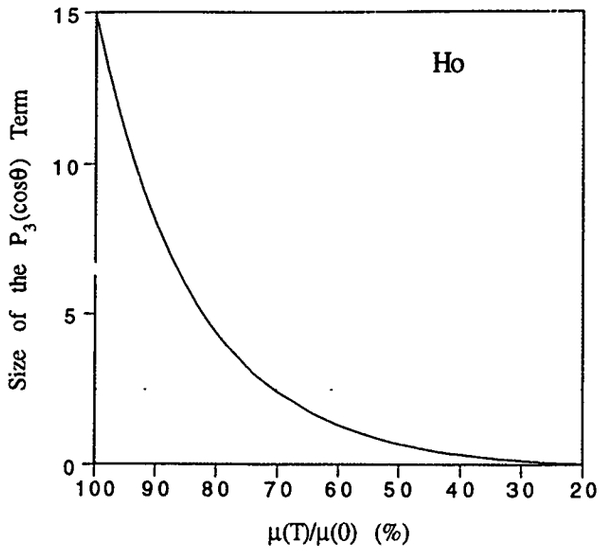

FIG. 1. The P_3 term for the quadrupolar part of the dichroic spectra of Ho as a function of the magnetic moment (relative to the zero temperature saturated moment).

with there being a net spin up conduction electron moment of 0.63 μ_B/atom moment. Figure 11 of Ref. 1 compares the difference in the $5d$ spin density of states (DOS) from a band structure calculation with that derived from the measured dichroic spectra. Based on a simple model the experimental spectra indicate a dominant positive spin DOS above E_F, while the theory has a dominant negative spin DOS. These authors comment "This obvious disagreement may indicate a modification of the $5d$ spin density spectrum by the polarized core hole created by absorption of a circularly polarized photon." This same sign problem has also recently been discussed for rare-earth intermetallic compounds by Giorgetti *et al.*[12] who suppose that it is due to an open $4f$ shell. As mentioned earlier, the full band structure calculations *with dipole matrix elements* are able to accurately reproduce the dipolar part of the experimental dichroic spectra above the L_2 and L_3 edges; so that it is not necessary to invoke core hole or many body interactions to explain the sign. In a previous publication we briefly discussed the resolution.[4] The $5d$ radial functions in rare earths with open $4f$ shells have a strong spin dependence. This is illustrated in Fig. 2 for the Gd atom. The $5d$ orbitals by themselves are too spread out and the $5d$ band too broad to support a magnetic ground state, and it is the $5d$ exchange interaction with the localized $4f$ orbitals (which have a peak in probability well within 1.0 au) that is responsible for inducing the magnetism in the conduction electron bands. The observed conduction electron moment scales with the total spin of the $4f$ states across the rare-earth series. The $2p$ radial function has its peak in probability just inside 0.1 au and the dipole matrix elements between the $2p$ and $5d$ orbitals are very spin dependent, with the matrix elements for the majority spin up $5d$ states being 20%–30% larger than the corresponding $5d$ spin down states at the same energy. The effect of the matrix elements is demonstrated in Figs. 3 and 4. In the first we plot the (up–down) difference in the DOS for Gd calculated with the linear aug-

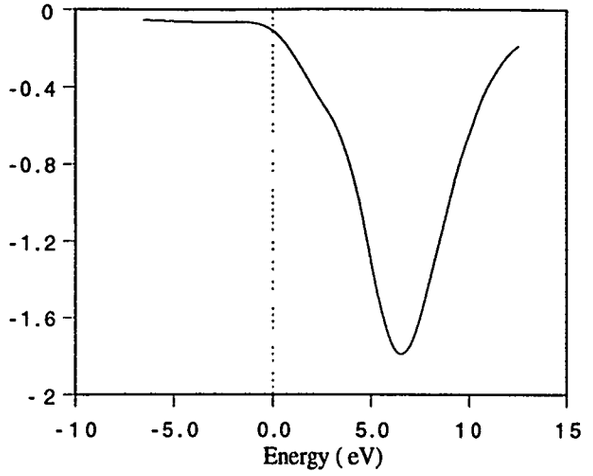

FIG. 3. The unoccupied spin up minus the spin down $5d$ DOS of Gd. The theoretical curve has been Lorentzian broadened by 6 eV.

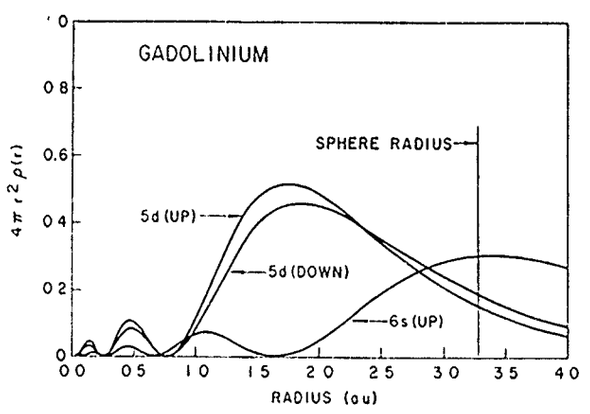

FIG 2 The spin up and spin down $5d$ radial functions for a neutral gadolinium atom.

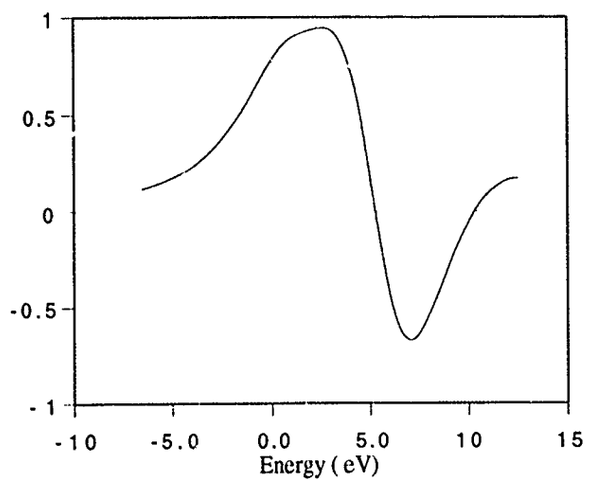

FIG. 4. The same as Fig 3 except the spin up density of states has been multiplied by 1.25 to approximate the spin-dependent matrix element effect for the dichroic spectra

mented plane waves (LAPW) method, using several energy panels above E_F. The DOS has been set to zero below E_F and broadened with a 6 eV Lorentzian. The broadening represents the large (~3.5 eV) core hole and final state lifetime and the experimental resolution. It can be seen that the spin down DOS dominates. Now we take the same data set and multiply the spin up DOS by 1.25 before making the subtraction. The results shown in Fig. 4 show that it is now the spin up spectrum that "wins." There is sufficient spin up d character to the bands extending to high energies that the integrated spectrum never switches sign to indicate a net spin down moment. This means that a recently derived sum rule[13] involving the net spin is invalid for the case of L edge spectra involving rare-earth $5d$ bands. It is interesting however that a related sum rule for the net orbital moment[14] yielded reasonable estimates when applied to the amorphous and crystalline $GdFe_2$ dichroic spectra.[15] It is still unclear if the orbital moment sum rule will retain its usefulness in all cases, and why.

We have benefited from conversations with Dr. V. P. Antropov and Dr. B. T. Thole, and with Professor A. I. Goldman and Professor G. Schütz. Magnetic circular dichroism (MCD) in x-ray absorption represents an exciting new technique for studying and imaging magnetic systems. However, there are to date relatively few studies of dichroism in the inherent process involved: photoelectron emission. We will here illustrate that photoelectron diffraction (PD) theory provides a fruitful way of analyzing dichroism data for both nonmagnetic and magnetic systems. Circular dichroism (CD) has been observed in core-level photoemission from nonmagnetic systems: C 1s from CO/Pd(111)[1] and Si $2p$ from Si(100)[2]. For CO/PD(111), chirality in the experimental geometry is readily discernible, but for Si(100), it is more difficult to define the chirality with simple vector relationships. PD effects implicitly contain all information on such core-level dichroism, and we will present multiple-scattering simulations of the observations to date. We will also discuss the role of such CD effects in core-level MCD measurements, using Fe $2p$ emission from magnetically aligned Fe(110)[3] as an example. The analysis of such MCD data has so far been qualitative.[3] We will present a more quantitative analysis including final-state effects such as the interference of $l\pm1$ photoelectron channels and spin-dependent scattering and diffraction.

Recently, we have shown that magnetic circular dichroism (MCD) can be used to obtain element specific magnetic hysteresis (ESMH) loops of heteromagnetic systems.[1] By using magnetic circular dichroism (MCD) we map the three orthogonal components of the magnetic moment vector of each element of a strongly (90°) coupled $Fe_{30}Co_{70}$/Mn/$Fe_{30}Co_{70}$ single crystal trilayer heterostructure as a function of applied magnetic field. The intensity of the MCD of the Mn $L_{2,3}$ absorption edges clearly shows that the Mn possesses a ferromagnetically aligned net magnetic moment. Furthermore, the individual element specific hystersis curves, when followed through the magnetic reversal process, reveals a detailed description of the magnetization reversal in the presence of both cubic anisotropy and strong exchange. This vividly demonstrates the capability of this technique to analyze the magnetic moment reversal process in the presence of strongly competing interactions.

Hybrid NiFeCo-Ag/Cu multilayers: Giant magnetoresistance, structure, and magnetic studies

J. D. Jarratt and J. A. Barnard
Department of Metallurgical and Materials Engineering, The University of Alabama, Tuscaloosa, Alabama 35487-0202

Giant magnetoresistance (GMR), crystal structure, and magnetic properties have been investigated in sputtered $Ni_{66}Fe_{16}Co_{18}$-Ag/Cu hybrid granular multilayer thin films. High angle x-ray diffraction (HXRD) was used to reveal the overall film structure and growth texture and low angle XRD was used to investigate the periodicity and flatness of the multilayer structures. Hysteresis loops for the as-deposited Ag-rich films show superparamagnetic behavior (and conventional granular GMR) which does not saturate in 14 kOe. Very NiFeCo-rich films are magnetically soft and exhibit induced in-plane uniaxial anisotropy.

I. INTRODUCTION

Giant magnetoresistance (GMR) in magnetic/nonmagnetic multilayer thin films,[1] discontinuous multilayer films,[2,3] and in granular phase separated alloys[4–6] has been the subject of much recent study. We have recently investigated the composition dependence of GMR and structure in "thick" (>1000 Å) $Ni_{66}Fe_{16}Co_{18}$-Ag single layer phase separating films.[7] In this article we analyze the effect of layering and reduced dimensions on the same alloy in a multilayer geometry using Cu spacers.

II. EXPERIMENTAL METHODS

These films were computer-controlled dc magnetron sputter deposited at 100 W and two different sputtering pressures (2 and 15 mTorr) with ultrahigh purity argon in a Vac-Tec model 250 side sputtering system with a base pressure of 3×10^{-7} Torr onto Corning 7059 glass substrates. A permanent magnet was positioned behind each substrate providing a 90 Oe field parallel to the substrate. The granular layer was cosputtered from a $Ni_{66}Fe_{16}Co_{18}$ target partially covered with Ag foil. This resulted in a composition gradient that was perpendicular to the induced easy axis in the films. The composition of the granular layers ranged from $Ag_{20}FM_{80}$ to $Ag_{48}FM_{52}$ (at. %) for films deposited at 2 mTorr and from $Ag_{28}FM_{72}$ to $Ag_{72}FM_{28}$ for films deposited at 15 mTorr, where FM stands for the NiFeCo ferromagnetic portion of the film. The granular layer thickness was varied from 25 to 55 Å and the Cu spacer layer thicknesses investigated were 20 and 24 Å. The granular layers have a thickness gradient (the Ag-rich end is ~25% thicker than the Ag-poor end due to the faster sputtering rate of the Ag foil). The granular film thicknesses reported are the average thicknesses. Slightly better MR magnitudes were observed throughout in samples with a Cu spacer thickness of 20 Å rather than 24 Å. The sputtering rates were determined from reference film steps measured on a Dek-Tak IIA surface profilometer.

Composition was determined with a JEOL 8600 Electron Probe Microanalyzer. Magnetic properties were measured on a Digital Measurement Systems vibrating sample magnetometer model 880. X-ray diffraction (XRD) was performed on a Rigaku D/Max-2BX XRD System with thin film attachment. The MR measurements were made at room temperature using a four-point probe assembly with the applied current and easy axis of the film both perpendicular to the applied magnetic field except where designated on anisotropic magnetoresistance (AMR) results. The annealing (300 °C for 30 and 60 min) was done in a quartz tube wrapped in heating tape with an overpressure of flowing purified argon. A magnetic field of 50 Oe was maintained in the films' easy axis direction during the anneal using magnetic coils outside the tube.

III. EXPERIMENTAL RESULTS

Broadly speaking, two different as-deposited MR (dR/R_{max} with a maximum applied field of 12.5 kOe) behaviors were seen, where dR is the change in resistivity of the film from zero applied magnetic field to the maximum field and R_{max} is the resistivity of the film in the maximum applied field. In the Ag-rich compositions a very rounded MR profile was observed. As the NiFeCo component is increased the MR profile sharpens. A small low field AMR component (~0.2%) was observed in the most NiFeCo-rich samples. We were unable to saturate the GMR in the available field. The granular composition giving the largest GMR magnitudes for the samples prepared at 2 mTorr was $\sim Ag_{44}FM_{56}$ and for the 15 mTorr samples it was $Ag_{50}FM_{50}$, both being ~4%. The evolution of the GMR profile versus FM fraction for (NiFeCo-Ag 35 and 55 Å/Cu 24 Å)×10 appears in Fig. 1 (the profiles are offset for clarity). We note two important differences between the GMR observed in these hybrid structures and single layer films of the same granular alloy: the GMR magnitude is reduced by ~50% and the composition at

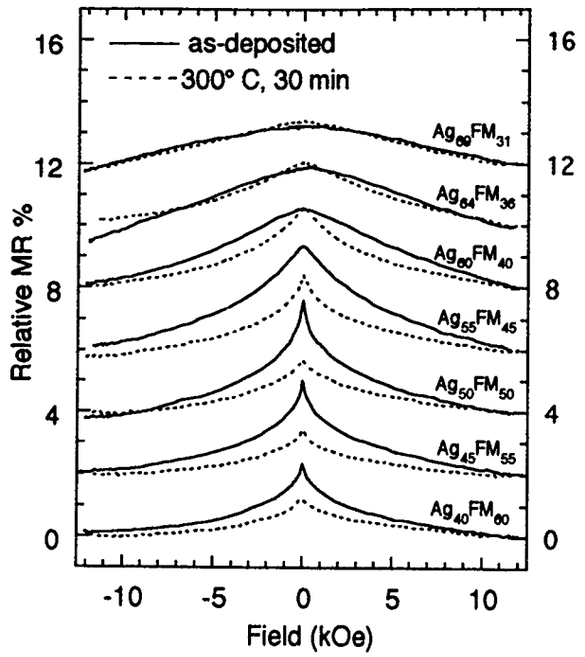

FIG. 1. MR loops for a series of granular layer compositions for as-deposited and annealed (300 °C, 30 min) hybrid granular multilayer films (NiFeCo-Ag 35 Å/Cu 24 Å)×10.

the maximum GMR is much more FM rich (~50% vs 30%) in the layered structures.[7] A significant reduction in MR ratio with film thickness has recently been reported in Co-Ag alloy films.[8] The same study also reported a slight increase in the Co composition corresponding to the maximum MR ratio in 200- vs 2000-Å-thick films. The composition shift we report is much larger, but our individual granular layers are also much thinner than 200 Å. This phenomenon may be associated with a transition from three-dimensional to quasi-two-dimensional behavior. The percolation threshold is much higher in a two-dimensional lattice than the corresponding three-dimensional lattice.[9]

Annealing caused a decrease in MR magnitude for the FM-rich samples while the overall profile was maintained.

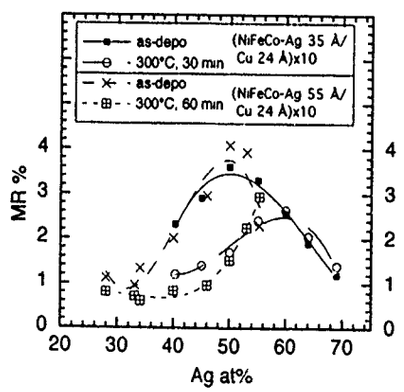

FIG 2. MR magnitude vs granular layer composition for as-deposited and annealed hybrid granular multilayer films (NiFeCo-Ag 35 Å/Cu 24 Å)×10 and (NiFeCo-Ag 55 Å/Cu 24 Å)×10. (The curves are guides for the eye.)

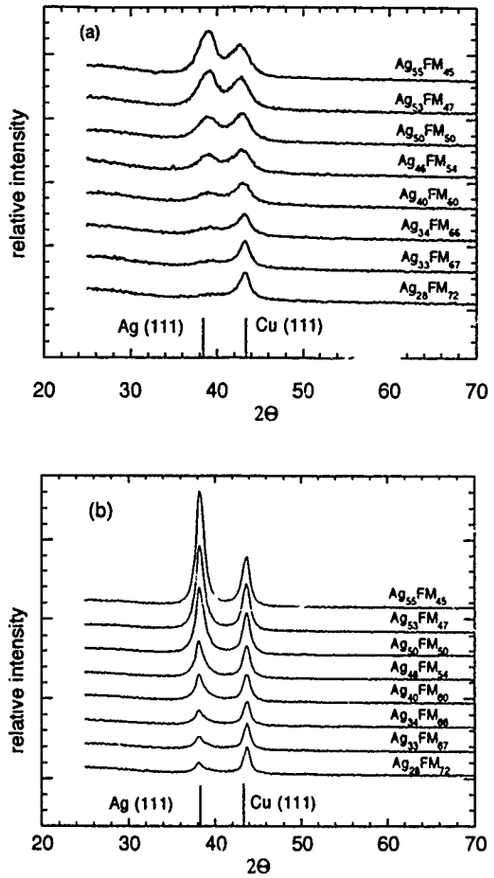

FIG. 3. High angle θ-2θ XRD scans for (a) as-deposited and (b) annealed (300 °C, 60 min) hybrid granular multilayer films (NiFeCo-Ag 55 Å/Cu 24 Å)×10.

Ag-rich films displaying an as-deposited broad profile experienced an increase in MR magnitude upon annealing along with a distinct sharpening of the MR peak. Beyond a critical Ag concentration, (~$Ag_{55}FM_{45}$ for 15 mTorr) the GMR magnitude increases with annealing (Fig. 2). A similar trend with a critical composition of $Ag_{50}FM_{50}$ was seen for samples prepared at 2 mTorr. This transition was previously

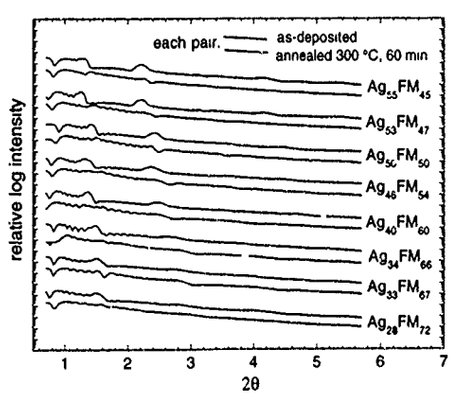

FIG. 4. Low angle θ-2θ XRD scans for an as-deposited and annealed (300 °C, 60 min) hybrid granular multilayer film [$Ag_{50}(NiFeCo)_{50}$ 55 Å/Cu 24 Å]×10.

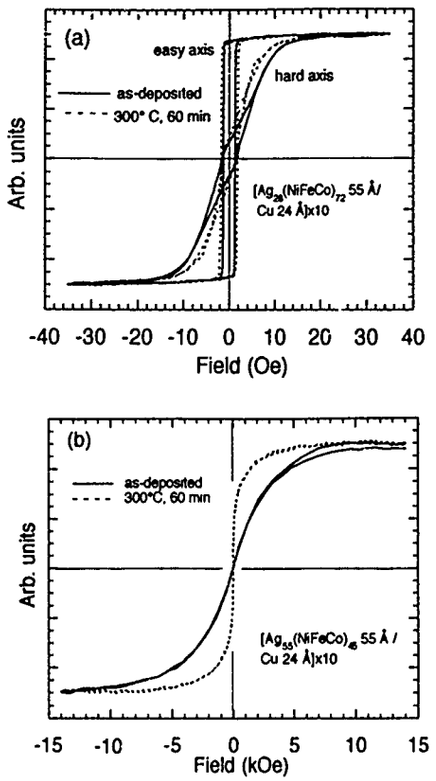

FIG. 5. *M-H* hysteresis loops for as-deposited and annealed (300 °C, 60 min) hybrid granular multilayer films with (a) both easy and hard axes shown for $[Ag_{28}(NiFeCo)_{72}$ 55 Å/Cu 24 Å$]\times 10$ and (b) easy-axis (this sample was nearly isotropic) loops for $[Ag_{55}(NiFeCo)_{45}$ 55 Å/Cu 24 Å$]\times 10$.

reported for single layer NiFeCo-Ag granular films grown at 15 mTorr with a more Ag-rich critical composition of $\sim Ag_{68}FM_{32}$.[7] Because the average FM particle size is expected to increase with the FM fraction, the critical concentration is naturally also associated with a critical FM particle size. Annealing shifts the maximum GMR composition to the more Ag-rich films (this is also found in single layer films).[7]

As-deposited high-angle XRD data revealed Cu(111) peaks consistently and increasing Ag(111) peak intensities with increasing percentage of Ag; the films are strongly (111) textured [Fig. 3(a)]. A systematic shift in the Cu(111) peak to lower angles with increasing Ag content is noted in the as-deposited films. The Cu(111) peaks are observed at angles lower than bulk values. Explicit NiFeCo peaks are not observed. Upon annealing, both the Cu and Ag(111) peaks sharpened and intensified with the Ag peak increase more pronounced [Fig. 3(b)]. Interestingly, following the anneal, the Cu(111) peak position is now independent of Ag content and its position is now at a slightly higher angle than bulk. The asymmetry of the Ag(111) peaks for annealed FM-rich samples may be associated with the growth of NiFeCo particles. The *d* spacing derived from Ag(111) peaks from the as-deposited films is smaller than the bulk Ag(111) value. Annealing causes an increase in the *d* spacing up to nearly the bulk value, in agreement with the single layer results.[7] The low-angle XRD (LXRD) peaks (Fig. 4) indicate reasonably good periodicity in the multilayer structure in the as-deposited state which allows for a calculation of the bilayer thickness, Λ, that agrees well with the calibrated sputtering rate data. Annealing has a small, nonsystematic effect on the LXRD spectra.

M-H hysteresis loops from very FM-rich (e.g., $Ag_{28}FM_{72}$) samples display induced uniaxial anisotropy that decreases slightly with annealing while the coercivity slightly increases [Fig. 5(a)]. These surprisingly soft loops, which display no further increase in *M* at higher fields, indicate that very FM-rich granular layers are behaving much like simple NiFeCo alloy layers. The NiFeCo alloy in the NiFeCo-Ag layer most likely forms a physically continuous matrix with the Ag existing as particles (an "inverted" granular layer). As the Ag concentration in the granular layer increased (ferromagnetic concentration decrease) the *M-H* loops tend toward superparamagnetism associated with a small FM component particle size [Fig. 5(b)]. Annealing of this Ag-rich sample results in a more easily saturated *M-H* loop probably resulting from an increase in FM component particle size.

IV. CONCLUSIONS

Layering of NiFeCo-Ag granular alloys with Cu spacers does not improve either the GMR magnitude or field sensitivity when compared with thick single layers of the same alloy. However, the composition dependence of GMR is strongly affected by the multilayer geometry with thin layers of NiFeCo-Ag separated by Cu behaving similar to thick single layers of much higher Ag content. We also find that very soft uniaxial multilayers can be grown with Ag compositions as high as 22% in the FM layer.

Some FeNi-Ag granular films of composition $Fe_{11.43}Ni_{6.35}Ag_{82.22}$ (sample A) and $Fe_{7.62}Ni_{16.4}Ag_{75.98}$ (B) were prepared by using rf magnetron sputtering, and once deposited were rapidly annealed at 600, 650, and 750 °C. All samples displayed giant magnetoresistance. The zero-field-cooled and field-cooled processes evidence the segregation of ferromagnetic particles with a broad size distribution. The temperature and magnetic field dependence of the resistance is analyzed. The magnetoresistance follows a H^n law at high fields and it decays from its maximum value with a T^m behavior, with m approaching 1 at high fields.

I. INTRODUCTION

The discovery of giant magnetoresistance (GMR) effects in a variety of antiferromagnetically coupled transition-metal multilayers[1] has opened a new amazing research field not only from the fundamental point of view but also from the technological one. Recently, this extraordinary effect has also been found in granular alloys[2] consisting of a distribution of nonaligned nanocrystalline ferromagnetic particles embedded in a nonmagnetic metallic matrix. In both kinds of systems, the resistivity strongly drops as the magnetic field orients the magnetic moments. Concerning theoretical explanations, both the existence of a spin-dependent potential scattering either at the interfaces or in the bulk of ferromagnetic layers (or particles) and the role of the unfilled d bands of the transition metal constituent (through an asymmetric density of states for majority- and minority-spin d bands)[3,4] have been taken into account in order to correlate GMR with the microscopic parameters. The magnitude of GMR has been found to be a sensitive function of both the size of the ferromagnetic particles and the concentration of the ferromagnetic material in the alloy. The former effect is postulated to be due to the existence of an optimum particle size, determined by the conduction electron mean free path or spin diffusion length. Larger particles result in a reduction of GMR as a result of the decrease in particle surface-to-volume ratio.[3] The latter effect is believed to be due to the onset of percolation, which acts to couple the particles ferromagnetically.[1-3] We present in this article the temperature and magnetic field dependence of the resistance of NiFe-Ag granular alloys presenting GMR.[5]

II. EXPERIMENT

Ag-Ni-Fe films of thickness 200–300 nm were rf sputtered onto glass microscope slides using a Nordico 2000 sputtering system. The base pressure was less than 2×10^{-7} Torr, the sputtering pressure was 8 mTorr of argon and the sputtering power was 300 W. The target used consisted of a 4 in. Ag (99.999%) disc onto which were placed $Ni_{80}Fe_{20}$ and Fe 0.25 cm^2 squares arranged in a mosaic pattern. In order to promote post-deposition phase segregation and magnetic particle growth, strips of about 7 mm wide were rapidly thermally annealed in a custom built vacuum system. Three annealing temperatures were investigated: 600, 650, and 750 °C, and these were reached in 20 s, 2 min, and 3 min, respectively. Resistance and magnetoresistance (MR) of all samples were measured by an ac four-point probe technique in the temperature range 20–300 K and in magnetic fields up to 12 kOe. The relative geometry among the film plane, the electrical current, and the magnetic field was set by three ways: (a) the electrical current and the magnetic field are parallel to the film plane (parallel geometry); (b) the in-plane magnetic field is perpendicular to the electrical current (transversal geometry); and (c) the magnetic field is perpendicular to both the electrical current and the film plane (perpendicular geometry). The zero-field-cooled (ZFC) and field-cooled (FC) processes at low fields and the magnetization curves at 5 K up to 55 kOe were carried out by applying the magnetic field along the film plane using a superconducting quantum interference device magnetometer.

III. RESULTS AND DISCUSSION

The structure of some of the thin films ($d\approx50$ nm) were investigated by transmission electron microscopy (TEM) in a modified JEOL 2000 electron microscope. Films were deposited onto Si substrates into which a SiN covered window had been etched and were found to have a strong ⟨111⟩ texture. A number of films were also investigated by using a Philips x-ray diffraction (XRD) system. This confirmed the strong ⟨111⟩ texturing but in neither the TEM nor the XRD was any clear evidence of phase segregation of the Ni or Fe from the Ag matrix. Magnetic and transport properties were measured on films which had composition $Fe_{11.43}Ni_{6.35}Ag_{82.22}$ (sample A) and $Fe_{7.62}Ni_{16.4}Ag_{75.98}$ (sample B). As both samples were rapidly annealed at 600, 650, and 750 °C, we will refer to them as A(as cast), A(600), A(650), A(750), B(as cast), B(600), B(650), and B(750), respectively.

Figure 1 shows the ZFC-FC processes for sample A(650) measured at 100 Oe. The ZFC displays a broad maximum at $T_M\approx22$ K, suggesting the existence of a broad size distribution of ferromagnetic particles. As magnetic irreversibility persists up to high temperature, we expect very large particles to be present in the sample. We plot in Fig. 2 the magnetization curve of the same sample at 5 K. A detail of

the hysteresis circle is displayed in the inset, showing that the coercive field is small (about 150 Oe).

The temperature dependence of the ratio $-R_M(T,H)/R(T,H=0)$ [with $R_M(T,H)=R(T,H=0)-R(T,H)$] in the parallel geometry for samples A(650) and B(650) are plotted in Figs. 3 and 4, respectively. All the rest of the samples display very similar experimental features. The maximum MR values are obtained for samples B(650) and A(650), suggesting that the optimum annealing temperature is about 650 °C in this Ag compositional range. MR is larger for sample B(650) than for sample A(650) because of the larger amount of ferromagnetic entities. As-cast samples display smaller MR than annealed samples due to the segregation of ferromagnetic particles in the latter. Results concerning the rest of annealing temperatures and other Ag compositions will be published elsewhere. Figures 3 and 4 evidence that MR is largely susceptible at low fields. We have also detected that MR is more susceptible in the in-plane geometries than in the perpendicular geometry, which is only due to the demagnetizing field (and it is not associated with an intrinsic in-plane magnetocrystalline anisotropy) because there is no difference between the MR in the parallel and transversal geometry. All measurements have been recorded with increasing and decreasing field, and we observe a slight irreversibility at low temperatures below the coercive field.

We have analyzed the temperature dependence of the MR as Mattson *et al.*[6] by defining the MR as $R_M(T,H)=R(T,H=0)-R(T,H)$, where $R(T,H)$ is the resistance measured at a temperature T and in an applied field H. The total resistance at T and H is assumed to be given by $R(T,H)=R_0+R_{sd}(T)+R_M(T,H)$, where R_0 is the resistance due to defects, $R_{sd}(T)$ is the temperature dependent resistance due to phonons and magnons. We show in Fig. 5 the temperature dependence of $R_M(T,H)$ at different fields for sample A(650). $R_M(T,H)$ displays a monotonic increase

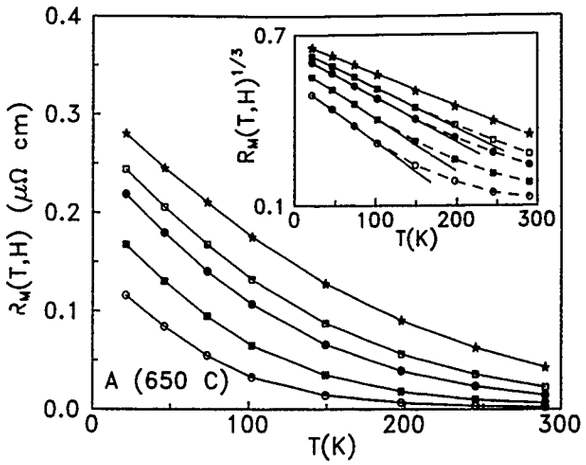

FIG. 5. $R_M(T,H)$ vs T at various fields for sample A(650). Magnetic fields: (○) 1 kOe; (■) 2 kOe; (●) 4 kOe; (□) 6 kOe; (☆) 12.1 kOe. Inset: $R_M(T,H)^{1/3}$ vs T at the same fields for the same sample.

as temperature goes down, which is in agreement with the progressive blocking of the ferromagnetic particles (Fig. 1). We plot in the inset of Fig. 5 the temperature dependence of $R_M(T,H)^{1/3}$ at various fields for the same sample. We notice that $R_M(T,H)^{1/3}$ is perfectly linear with T in the whole temperature range 20–290 K when the magnetic field is the maximum available in our experimental setup (H_{max}=12 kOe), and that the linear law $R_M(T,H)^{1/3}$ versus T is followed in a smaller temperature range as we reduce the magnetic field. The same 1/3 exponent and temperature dependence of $R_M(T,H)$ is found for sample B(650). If we extrapolate the data at T=0, we obtain the $R_M(T=0,H)$ and we may define $\Delta R_M = R_M(T=0,H) - R_M(T,H)$. The log-log plot of ΔR_M versus T is displayed in Fig. 6 for sample A(650) at 2 and 12.1 kOe. The slope of the plot yields the exponent m in the relationship $\Delta R_M \approx T^m$, and this power law gives us an idea of the underlying scattering mechanism. It is evidenced that the temperature range in which the power law is accomplished increases with magnetic field (as expected, since the MR saturates at large fields). The exponent m slightly increases with H and seems to tend to about 1, which is smaller than the $T^{3/2}$ and T^2 laws found by Mattson *et al.*[6] in Fe/Cr multilayers. These behaviors are attributed to the thermal excitation of magnons. The temperature dependence of the MR of granular materials is complicated by there being a distribution of particle sizes and therefore blocking processes. We might tentatively attribute the temperature dependence of ΔR_M at high fields to the thermal excitation of magnons with a smaller exponent in the T^m law due to the reduction of the magnetic system dimensionality.

Concerning the field dependence of the MR, we have observed that $R_M(T,H)/R(T,0)$ follows a H^n behavior at high fields (above about 6000 Oe), as was found by Nigam *et al.*[7] in $Au_{87}Fe_{13}$ cluster glass. Solids lines in Figs. 3 and 4 indicate the best fit of the data to the H^n law. The n-exponent monotonically increases with temperature, ranging from 0.18 at 21.6 K to 0.86 at 290 K for samples A(650), and from 0.13 at 21.5 K to 0.76 at 282.1 K for sample B(650). The error in n is about 0.02. This monotonic temperature behavior evidences the progressive blocking of the ferromagnetic particles, without being a freezing state corresponding to a spin glass behavior. Also, n is always smaller than the n=2 value expected for a pure paramagnetic state,[7] signaling that magnetic correlations persist even at room temperature and/or larger particles are still blocked at this temperature, since the size distribution of ferromagnetic particles seems to be very broad (see Fig. 1).

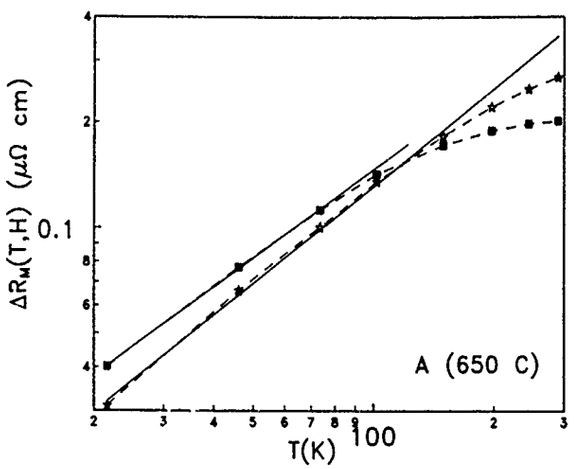

FIG. 6. Log-log plot of the temperature dependence of $\Delta R_M = R_M(T=0,H) - R_M(T,H)$, at (■) 2 kOe and at (☆) 12.1 kOe for the sample A(650). Solid lines correspond to the best fit of the data to a T^m law.

Anisotropic giant magnetoresistance induced by magnetoannealing in Fe-Ag granular films

J. G. Na
Korea Institute of Science and Technology, Sungbuk, Seoul 136-791, Korea

State Key Laboratory of Magnetism, Institute of Physics, CAS, Beijing 100080, China

The effects of magnetoannealing on the giant magnetoresistance (GMR) in Fe_xAg_{100-x} granular films (X= 15, 26, 29, 33, 37, and 60) were investigated. The thin films were annealed in a presence of magnetic field of 3 kOe at different temperatures of 300, 400, and 500 °C using various annealing times. It is found that the anisotropic GMR characteristics were developed when Fe-Ag granular thin films were annealed in the presence of a magnetic field. The anisotropic GMR characteristics of the thin films were closely related to the magnetic anisotropy developed along the field direction during magnetoannealing.

I. INTRODUCTION

A considerable number of studies have been conducted on the giant magnetoresistance (GMR) effect in magnetic multilayers with antiferromagnetic interlayer coupling[1,2] and magnetic granular films with nonconnecting ferromagnetic particles embedded in a paramagnetic matrix,[3,4] due to their high potential for application for various kinds of sensors, i.e., a magnetic head for high recording density. Among these materials, the magnetic granular thin films are investigated by many researchers because they can be easily fabricated over large areas using usual thin film processes. Most of the work, however, is confined to the isotropic GMR in a microscopic point of view.

Traditionally it has been well known that the anisotropic properties of magnetic materials are used to maximize the required magnetic properties and magnetoannealing is one of the most convenient methods to develop the magnetic anisotropy in magnetic materials.

In this article, Fe_xAg_{100-x} (X=15, 26, 29, 33, 37, and 60) granular thin films were deposited on slide glasses (Qing Huang Dao Medical Glasses Co., 1.2 mm×26 mm×76 mm) and annealed in a presence of magnetic field of 3 kOe at different temperatures of 300, 400, and 500 °C in a vacuum of 5×10^{-3} Pa or a high purity nitrogen atmosphere to develop an anisotropic GMR. The effects of magnetoannealing on the GMR and magnetic properties of Fe-Ag granular thin films were investigated.

II. EXPERIMENTAL PROCEDURES

Ag-Fe granular thin films were prepared by dc magnetron sputtering. The target was composed of 6-cm-diam Ag disk (99.9 at. % purity) and iron chips (99.9 at. % purity). The composition of the granular thin films was controlled by adjusting the number of iron chips attached on the Ag disk. Prior to deposition, the target was presputtered at 0.5 Pa for 30 min. The sputter conditions are summarized in Table I.

The magnetic annealing of thin films was carried out at different temperatures of 300, 400, and 500 °C in a vacuum of 5×10^{-3} Pa or a high purity nitrogen (99.99%) atmosphere. There was no difference in the electrical and magnetic properties between vacuum and N_2-atmosphere annealed samples in this annealing temperature range. A magnetic field of 3 kOe was applied in an in-plane direction of the films.

The magnetoresistance was measured by using a conventional four-point configuration on a specimen of 3 mm×8 mm with the magnetic field of 20 kOe perpendicular to current within the film plane at room temperature. Two directions, i.e., parallel and perpendicular to the magnetic field direction of annealing were measured to compare the magnetic annealing effect of the thin films.

An x-ray diffractometer and a vibrating sample magnetometer were used to analyze the microstructure and magnetic properties of the films, respectively. A scanning electron microscope was used to analyze the composition of the thin films.

III. RESULTS AND DISCUSSION

Figure 1 shows the change of GMR as a function of Fe content in the as-sputtered Ag-Fe granular films. The GMR reported here is referenced to the maximum resistivity at zero magnetic field and it is defined as $\Delta\rho/\rho_{H=0}=(\rho_H-\rho_{H=0})/\rho_{H=0}$, where $\rho_{H=0}$ and ρ_H denote the resistivity at zero magnetic field and field H, respectively. One can see that the GMR value is very sensitively dependent upon the chemical composition of thin films. There is a narrow optimum composition range around $Fe_{29}Ag_{71}$, and in both the Fe-poor and Ag-poor regime the GMR decreases rapidly, which is in agreement with the result of Xiao *et al.*[5]

As-sputtered Fe-Ag thin films were annealed in a presence of magnetic field of 3 kOe at different temperatures of 300, 400, and 500 °C for various times. The structural change of the samples was characterized by x-ray diffraction.

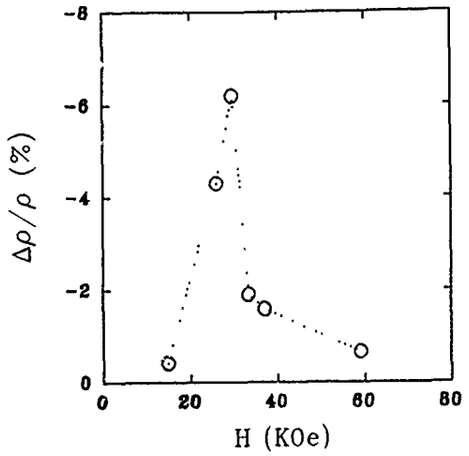

FIG. 1. The change of GMR as a function of Fe content in the as-sputtered Ag-Fe granular films.

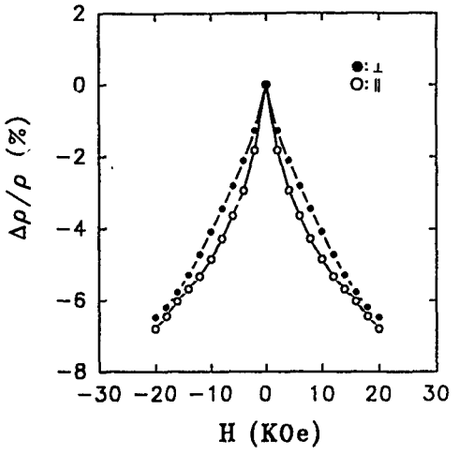

FIG. 3. GMR curves of easy and hard directions in $Fe_{29}Ag_{71}$ thin films annealed at 400 °C for 80 min in an N_2 atmosphere.

The diffraction patterns of $Fe_{29}Ag_{71}$ as sputtered and magnetoannealed at 400 °C for 30 min are shown in Fig. 2. For the as-sputtered film, a large peak attributable to (111) plane of Ag is detected, which indicates that a strong (111) preferred orientation was developed in the film. With magnetoannealing, the peak for (111) plane of Ag becomes sharp and a small broad peak around 44.3° is observed. The small peak may be attributed to (200) plane of Ag and (110) plane of Fe because d_{200} of Ag and d_{110} of Fe are similar. The intensity of the small peak was increased with increasing Fe content of thin films, which strongly suggested that the peak include the peak of (110) plane of Fe.

The anisotropic GMR characteristics are developed in annealed thin films with respect to the direction of magnetic field during annealing, i.e., parallel (easy) and perpendicular (hard). For the thin films annealed at 300 and 400 °C, the shape of the GMR curves was significantly different between the easy and hard direction of thin films. For $Fe_{15}Ag_{85}$ thin film annealed at 400 °C for 10 min, we observed that the GMR curve became almost linear in a hard direction. Figure 3 shows the GMR curves of $Fe_{29}Ag_{71}$ annealed at 400 °C for 80 min. As can be seen in Fig. 3, the GMR curve of the easy direction becomes sharper than that of the hard direction. The difference in GMR values between these two directions is not considerably large although GMR values in easy direction is always larger than those in the hard direction. However, there is the considerable difference in GMR values between easy and hard direction for the films annealed at 500 °C. Figure 4 shows the variation of GMR values of $Fe_{29}Ag_{71}$ with annealing time at different temperatures of 400 and 500 °C. It can be seen from Fig. 4 that the GMR values of these thin films increase with annealing time, reach the maximum at about 80 and 40 min, respectively, and decrease. The difference in GMR values between easy and hard direction is larger in the sample annealed at 500 °C than that at 400 °C. To understand the cause of this difference between easy and hard direction, the M-H loop of $Fe_{29}Ag_{71}$ annealed

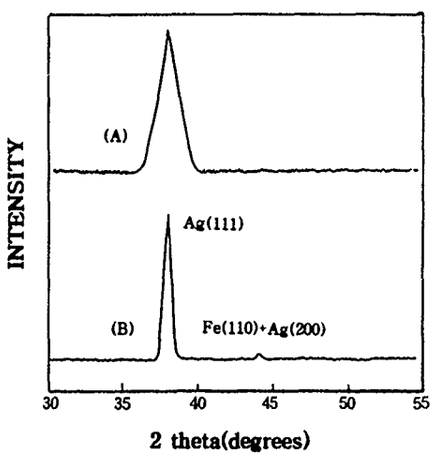

FIG. 2. X-ray diffraction patterns of $Fe_{29}Ag_{71}$ thin films as-sputtered(A) and magnetoannealed at 400 °C for 30 min in an N_2 atmosphere(B).

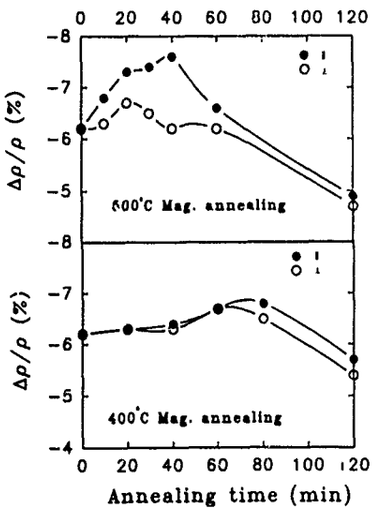

FIG. 4. The variation of GMR values of $Fe_{29}Ag_{71}$ with annealing time at different temperature of 400 (N_2 atmosphere) and 500 °C (vacuum atmosphere).

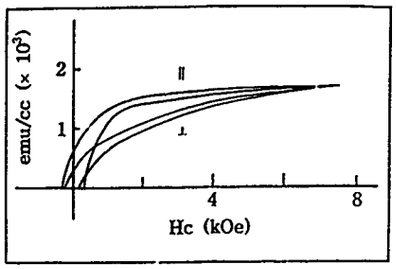

FIG. 5. The M-H loop of $Fe_{29}Ag_{71}$ thin film annealed at 500 °C for 40 min in a vacuum atmosphere.

at 500 °C for 40 min was measured and the result is shown in Fig. 5. The coercivities of easy and hard direction are 210 and 180 Oe, respectively, from Fig. 5. The difference in the M-H loop shape and coercivity indicates that the magnetic anisotropy is developed along the magnetic field direction during annealing. Therefore, the anisotropic GMR characteristics of Fe-Ag thin films annealed in the presence of magnetic field is closely related to the magnetic anisotropy because except for GMR measuring direction, the other conditions, e.g., sputtering condition, composition, annealing condition of thin films were the same. The small difference in GMR values between easy and hard direction in the sample annealed at 400 °C shown in Fig. 4 can be explained by small magnetic anisotropy due to low annealing temperature.

In this study, the origin of the magnetic anisotropy is not elucidated yet. Further study on this point is suggested.

IV. CONCLUSION

It is found that the anisotropic GMR characteristics were developed when Fe-Ag granular thin films were annealed in a presence of magnetic field. The shape of GMR curves was different between easy and hard direction when the thin films were annealed at 300 and 400 °C. But the difference of GMR values was small. For the thin films annealed at 500 °C, there was considerable difference in GMR values between easy and hard direction which was closely related with the magnetic anisotropy developed along the field direction during magnetoannealing.

Influence of microstructure on magnetoresistance of FeAg granular films

Chengtao Yu, Ye Yang, Yuqing Zhou, Shuxiang Li, Wuyan Lai, and Zhenxi Wang
Institute of Physics, Chinese Academy of Sciences, P.O. Box 603, Beijing 100080, China

The magnetoresistance of FeAg granular films with optimum composition has been systematically studied as a function of film thickness. It was found that the giant magnetoresistance increases rapidly with increasing film thickness in the initial stage, and beyond about 500 Å the improvements become limited. The saturation field was also found to rise with increasing film thickness. Transmission electron microscope studies showed that with the increase of film thickness the microstructure becomes more homogeneous, with smaller grains and fewer structural defects such as twins. A discussion of the influence of microstructure on magnetoresistance and saturation field is presented.

I. INTRODUCTION

The discovery of giant magnetoresistance (GMR) in multilayer systems[1] and subsequently in granular films[2,3] has stimulated worldwide research activities, due to both its fundamental significance and its potential application to magnetic sensors. It has generally been agreed that in both multilayer systems and granular films the GMR arises from spin-dependent scattering occurring either at the surface of or within the magnetic entity. For granular films, however, there exists evidence[4] that interface scattering plays a dominant role in magnetoresistance (MR). The GMR is believed to be closely related to features of magnetic granules such as size, shape, and distribution. So far, much attention has paid to this problem both experimentally[5] and theoretically,[6,7] but it is still far from completely understood. Concerning the effect of the feature of magnetic particle, most of the experimental work has focused on post-deposition annealing, which is believed to promote grain growth or phase segregation. In several candidates suitable for fabricating granular films, Fe and Ag are virtually immiscible at equilibrium, and thus even for as-deposited FeAg film, large GMR has been observed[8] due to presence of iron precipitated during the material fabricating process. Therefore, the deposition process certainly plays an important role in structure evolution and thus affects the GMR.

In this article, we adopted the optimum composition of FeAg, focused on the influence of film thickness and attempted to reveal the influence of microstructure on MR.

II. EXPERIMENTS

FeAg granular films were prepared by magnetron sputtering from a composite target onto water cooled glass substrates at an Ar pressure of 0.5 Pa after a base pressure of better than 4×10^{-5} Pa was achieved. The composite target consisted of an Ag disk with small fan-shaped iron chips. Composition was adjusted by the number of iron chips placed on the Ag disk. Once the target was mounted, it was cleaned by extensive presputtering. In each batch, eight samples were produced, and the whole sputtering process was controlled by computer. A profilometer was employed to measure film thickness, and the steps for measurements were yielded by removing a strip of scotch tape placed on the substrate previously. The MR was measured by using a conventional four-terminal configuration on a specimen of 2×6 mm^2 with magnetic field perpendicular to current but within the film plane. The microstructure of the granular film was investigated by transmission electron microscope (TEM) and its composition was analyzed by energy dispersive analysis.

III. RESULTS AND DISCUSSION

For FeAg granular film the optimum nominal composition showing the largest MR was found to be about 17.5 vol % Fe, and in both the Fe-poor and Fe-rich regime the magnetoresistance decreased abruptly, which is consistent with the literature.[8] Energy dispersive analysis indicated that the nominal optimum composition actually contains 26 at. % iron, corresponding to a volume fraction of 20% Fe.

Figure 1 shows the MR curves for three as-deposited $Fe_{26}Ag_{74}$ samples with different thicknesses at a temperature of 1.5 K. The MR reported here is referenced to the maximum resistivity at zero field and is defined as $\Delta\rho/\rho_{H=0}=(\rho_H-\rho_{H=0})/\rho_{H=0}$, where $\rho_{H=0}$ and ρ_H denote the resistivity at zero field and field H, respectively, and $\Delta\rho$ represents the net change in resistivity. As can be seen in Fig. 1, the value of MR changes considerably in samples with different thicknesses. For a sample with a thickness of 120 Å, the MR at 60 kOe is −7.14%, while for sample with thickness of 1800 Å, it reaches −18%. From Fig. 1, it also should be noticed that with increasing thickness, not only the MR but also the saturation field increases. Even in the highest magnetic field available the MR curves are still far from

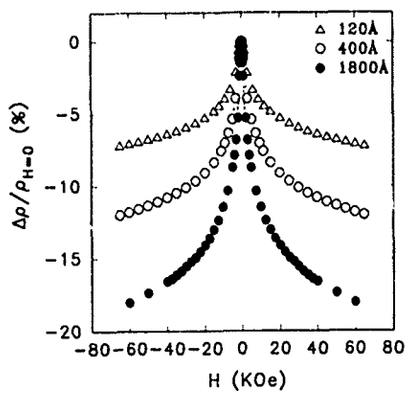

FIG. 1. Magnetic field dependence of MR for as-deposited $Fe_{26}Ag_{74}$ granular films with different thicknesses at temperature 1.5 K.

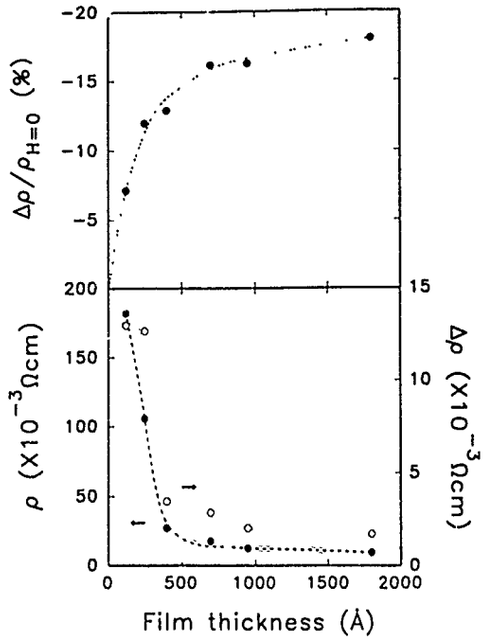

FIG. 2. MR $\Delta\rho/\rho_{H=0}$ (top), resistivity ρ, and the net change in resistivity $\Delta\rho$ (bottom) for $Fe_{26}Ag_{74}$ granular films as a function of film thickness at 1.5 K. Dashed lines are guides to the eye.

complete saturation, especially for thicker samples, and thus, to some extent, the MR values given here are underestimated.

Shown in Fig. 2 is the thickness dependence of the MR, from which it can be seen that with increase of film thickness the MR increases rapidly, and beyond about 500 Å, this change approaches saturation. What is also shown in Fig. 2 is the thickness dependence of both the zero-field resistivity ρ, and the net change in resistivity $\Delta\rho$ in a field of 60 kOe. It demonstrates that both ρ and $\Delta\rho$ drop abruptly with increasing thickness in the initial stage of deposition, but beyond about 500 Å both change moderately. However, it should be stressed that the drops in ρ are more significant than that in $\Delta\rho$, and this gives rise to the increasing trend of MR with film thickness. It is generally believed that for thinner films the role of surface scattering becomes significant relative to scattering occurring within the film, and consequently the resistivity rises. In addition, the existence of mismatch between film and substrate may result in high stress and structure defects such as twins, and these also enhance resistivity prominently. However, to some extent, the deposition process can be considered as an *in situ* annealing. Sputtering for a relatively long time may ease mismatch stress, alleviate disorder, and also promote precipitation, and as a result the resistivity decreases and MR rises. This structure evolution has been confirmed by TEM.

In Fig. 3 are shown bright-field (TEM) images for three $Fe_{26}Ag_{74}$ samples with different thicknesses, and in the upper-right-hand corners are the corresponding selected-area diffraction (SAD) patterns. Although energy dispersive analyses in nanomode indicated that the black areas contain considerably less concentration of iron than the white, the contrast does not necessarily imply an elemental difference.

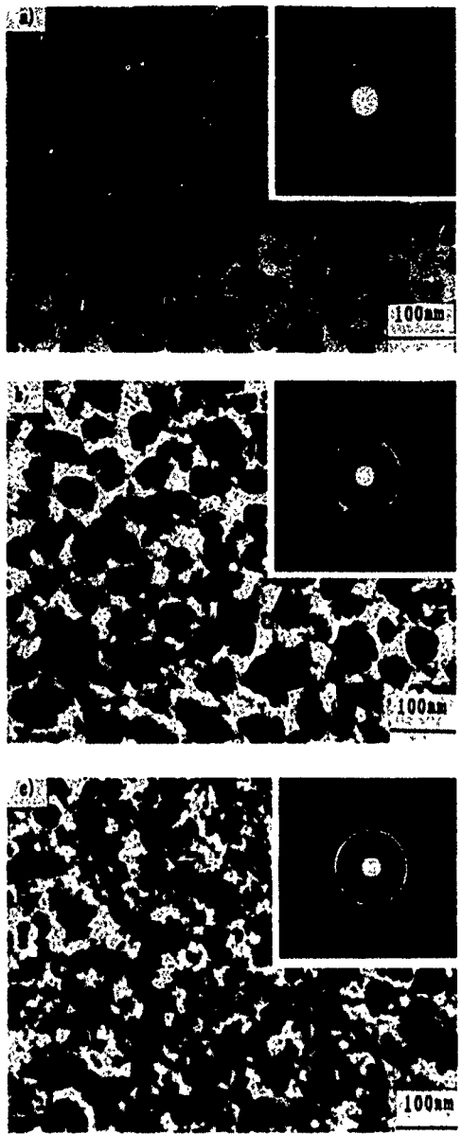

FIG. 3. Bright field (TEM) images and SAD patterns for $Fe_{26}Ag_{74}$ granular films with different thickness (a) 120 Å, (b) 400 Å, and (c) 1800 Å.

It also contains a contribution from crystal orientation. From Fig. 3, it can be seen that the thicker the film, the smaller the grains, and also the more homogeneous the microstructure. For the sample of 120 Å, the average grain size is on the order of 500 Å and the size distribution has a wide range, while for the sample of 1800 Å, the grain size decreases to the order of 200 Å or less and it also shows a tendency toward homogenization. This probably resulted from phase segregation rather than nucleation on structure defects. As a result, this process led to the existence of plenty of fine iron particles, which gave rise to difficulty in saturation as observed from the MR curves. Certainly, a great number of Fe precipitated particles would also contribute to improvements of the MR. Besides, it should be noted in the micrograph of the thinnest sample, which exhibited the maximum resistivity and the minimum MR, that a number of twins are visible. They would be expected to cause extra scattering and en-

hance resistivity. For thicker films, the possibility of increasing resistivity caused by small grain boundaries may be overwhelmed by eliminating giant twins and other defects as well as lowering the surface scattering fraction.

Although there exists evidence for the presence of fine Fe particles, it is difficult to determine the Fe and Ag phases separately by electron or x-ray diffraction because of the overlap between Fe and Ag spectral lines, and in particular the line broadening for especially fine grains or particles. All electron diffraction patterns shown in Fig. 3 can be indexed as those lines of fcc Ag, but they still show apparent differences. For the thinnest sample, the spectral rings are characterized by dispersive diffraction spots, which implies the existence of large grains or preferential crystal orientation. For thicker samples, those rings become complete and also broaden. It is an indication of the existence of fine grains with random orientation, promoted by phase segregation.

Further studies concerning the relation between microstructure and magnetic properties are presently being carried out.

IV. CONCLUSION

The MR of granular $Fe_{26}Ag_{74}$ films has been found to be sensitive to the film thickness, which, to some extent, determines the microstructure and reflects the film growth process. In the initial stage, the MR increases greatly with the increase of film thickness, and beyond about 500 Å the improvements approach saturation. The maximum value of MR observed in as-deposited $Fe_{26}Ag_{74}$ is -18%. Studies of the films with TEM and SAD demonstrated that the low values of MR for thinner samples are mainly attributable to the existence of a large number of defects, such as twins, as well as the increasing effects of surface scattering, while for thicker samples the increase of both MR and saturation field can be explained by relief of structural disorder and promotion of iron precipitation, caused by a relatively long time deposition, which may serve as an *in situ* annealing.

The ferromagnetic resonance (FMR) spectra and coercivities of FeSi-SiO_2 granular films have been measured over a wide range of FeSi volume fractions (f_v). The films were prepared using the ion-beam sputtering technique and transmission electron microscopy showed that the FeSi alloy granules are embedded in a matrix of SiO_2. An enhanced coercivity (H_c), as high as 329 Oe at room temperature, is observed. For some samples, there are several resonance peaks in the FMR spectra, which include one major peak and several minor peaks. The major and minor peaks correspond to the usual uniform mode and spin-wave respectively. In our experiments, the field separations between the major and the minor peaks show a complex fashion. Our results are discussed in comparison with some theoretical models.

I. INTRODUCTION

Granular solids consist of nanometer size metal granules embedded in an immiscible matrix which may be insulating or metallic. Because of the unique microstructure of ultrafine particles, many interesting and potentially useful properties have been found in granular systems.[1,2] The magnetic behaviors of metal granules are very different from that of the bulk. In particular, intrinsic magnetic properties, such as saturation magnetization (M_s) and anisotropy constant (K), are changed dramatically and greatly enhanced coercivities are usually observed. Such properties, especially giant coercivity, show potential for applications, among them, as novel magnetic recording media.[3]

With the development of the technology of film fabrication and the advancement of structure analytic methods, the magnetic properties of granular metal films have been investigated intensively.[4–6] Recently, some studies have also been carried out in the granular alloy films.[7] However, many properties on these films are still unknown and need to be clarified. To further understand the magnetic properties in the important area of ultrafine alloy, we have successfully fabricated FeSi-SiO_2 granular alloy films using the ion-beam sputtering technique. In this paper, we will describe the preparation and characterization of the films. Using these samples, we have made detailed measurements on their coercivities and ferromagnetic resonance (FMR) spectra. Our experimental study shows that an enhanced coercivity, as high as 329 Oe at room temperature, has been achieved in the films. Furthermore, we found that in some of our samples, there are several resonance peaks in FMR spectra. In the following, we should first discuss the experimental setup, then we will present our results and compare them with some existing theories.

II. EXPERIMENTS

The granular FeSi-SiO_2 films were prepared by the ion-beam sputtering technique. The films were deposited onto glass substrates which were fixed at the temperature 300 °C. During deposition, an ambient pressure of 2×10^{-2} Pa of argon was maintained. The sputtering targets were mosaic targets of FeSi(97% Fe-3% Si) alloy and SiO_2. The fractional area of SiO_2 on the targets can be changed so that various samples in the range of FeSi volume fractions (f_v) between 0.25 and 1.0 are obtained. The composition of the samples was determined using electron microprobe analysis.

The microstructure of the samples was examined by transmission electron microscopy (TEM), electron diffraction, and x-ray diffraction. The magnetic properties of the films were measured by a vibration sample magnetometer (VSM) with magnetic fields up to 20 kOe, the external field was applied parallel to the plane of the films during the measurements. The FMR spectra of the samples were recorded using an electron paramagnetic resonance (EPR) spectrometer operating at 9.97 GHz, the angle between the applied dc field and film plane changed from 90° to 0°.

III. RESULTS AND DISCUSSION

We have prepared samples with various FeSi volume fractions f_v. The microstructure of the films is composition dependent, the typical TEM micrographs are shown in Fig. 1(a) for $f_v\approx0.45$ and Fig. 1(b) for $f_v\approx0.7$. For smaller value of f_v, one can see that fine and roughly spherical FeSi particles are separated by the host material. The particles are of the order of a few nm in diameter and have a rather narrow size distribution. While for larger f_v, the fine particles aggregate into large connected granules; this can be clearly seen in Fig. 1(b).

The coercivities (H_c) of the films were measured at room temperature by VSM with the external field parallel to the plane of the films. The dependence of H_c on f_v is shown in Fig. 2. One found that H_c first increases as f_v increases, after reaches a maximum $H_c\approx329$ Oe at $f_v\approx0.7$, H_c sharply drops as f_v further increases. We found that the increase in the region of H_c at smaller f_v corresponds to the situation where the size of fine particles increases, while the rapid drop of H_c corresponds to the case when these fine particles form granular networks. This is similar to the observations of Xiao *et al.*[3] The maximum coercivity of our granular samples is about 85 times that of sputtered pure FeSi films.

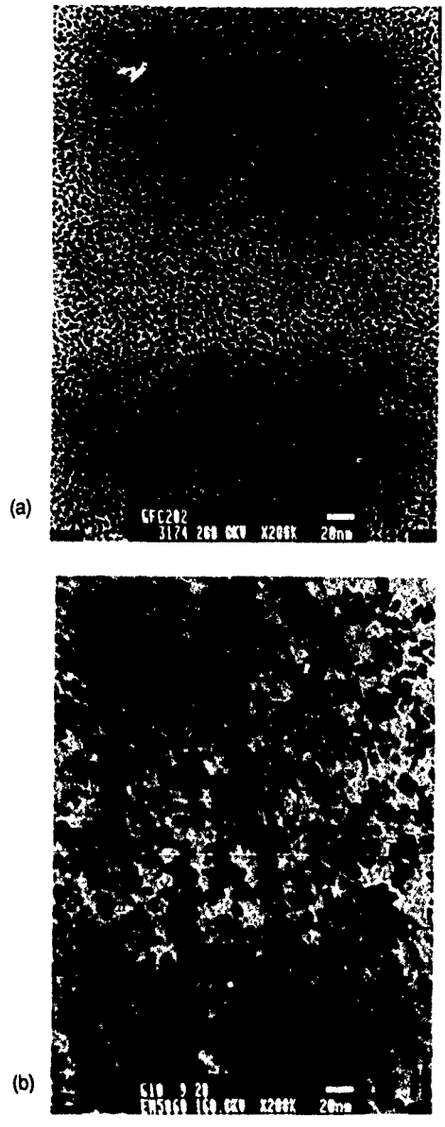

FIG. 1. TEM micrographs of FeSi-SiO_2 granular films (a) $f_v \approx 0.45$ and (b) $f_v \approx 0.7$.

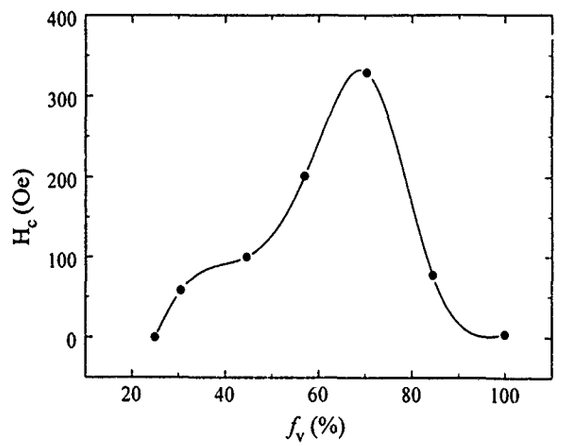

FIG. 2. Magnetic coercivities measured at 300 K of FeSi-SiO_2 granular films vs FeSi volume fraction f_v with the external field parallel to the film plane.

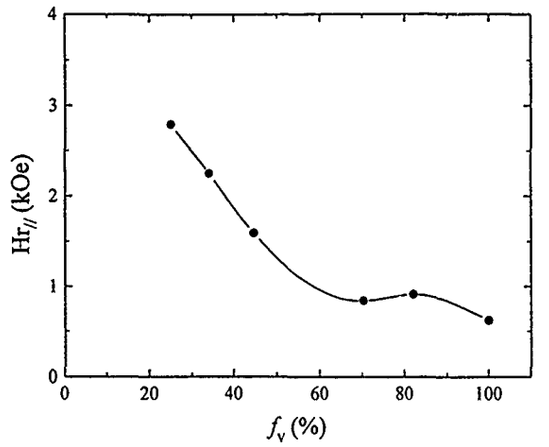

FIG. 3. The magnetic resonance field as function of FeSi volume fractions f_v for the applied dc field parallel to the film plane.

In comparison with Fe-SiO_2 granular solids, our maximum H_c is smaller. This is due to the fact that the FeSi alloy has a lower anisotropy constant than pure iron.

The FMR spectra of the samples were measured over a wide range of f_v at room temperature. Presented in Fig. 3 is the resonance field ($H_{r\|}$) obtained for applied dc field H in the film plane. $H_{r\|}$ decreases monotonically as f_v increases up to 0.6, then changes very little as f_v increases to 1. Our result indicates that the structure of the samples changes as f_v increases. The demagnetizing factor of our samples is reduced continuously as the fine particles gradually form uniform FeSi layer.

Figure 4 shows the dependence of the resonance fields H_r on θ for $f_v \approx 0.45$, with the θ denoting the angle between the applied dc field and film plane. When θ is close to 90°, there are several resonance peaks in the FMR spectra, which includes a major peak and four minor peaks. As θ changes from 90° to 0°, the positions of both the major and minor

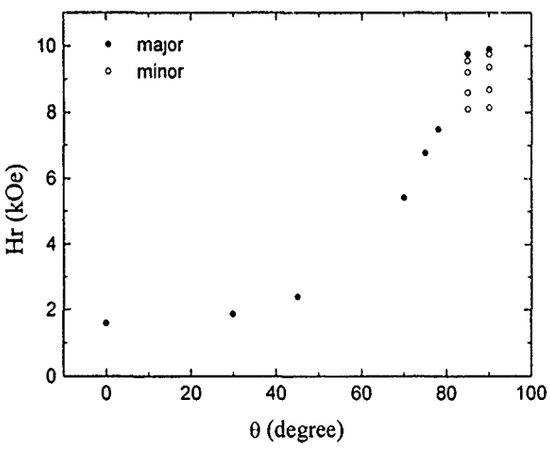

FIG. 4. The dependence of magnetic resonance field on the angle θ between the applied dc field and film plane for $f_v \approx 0.45$. The solid circles and the open circles correspond to the field positions of the major and minor peaks, respectively.

peaks shift towards low-field side. While the intensity of the major peak is almost unchanged, the intensities for the minor peaks become drastically reduced and disappear at the critical angle $\theta_c \approx 80°$. This behavior suggests that the major peak is the uniform mode and the minor peaks are spin-wave modes.[8] At $\theta=90°$, the separations between the first and the nth peak are about 150, 540, 1220, and 1760 Oe, respectively. The corresponding ratios are 1:3.6:8.1:11.7. The spin-wave resonance (SWR) theories[8–10] predict that this ratio should be proportional to n^2 or n depending on whether magnetic inhomogeneities are localized near the surface or distributed in the thickness of the films. Our result is within these two different cases and closer to the surface inhomogeneity model. This results from the fact that although a nanoscale volume inhomogeneity is characteristic of the granular films, there are abundant surfaces in our granular samples due to small size of particles, and magnetic inhomogeneities localized near metal-insulator interfaces may play an important role.

In conclusion, we have successfully prepared FeSi-SiO_2 granular films with different FeSi volume fractions using the ion-beam sputtering technique. Using these samples we have studied ferromagnetic resonance spectra and coercivities. We have observed a large H_c as high as 329 Oe. The FMR spectra for perpendicular configuration showed several peaks which can be attributed to the usual uniform mode and spin-wave modes. These materials open up a rich perspective for both fundamental investigations and technological applications.

A pair of parallel uniaxial particles with dipole-dipole coupling has, for bond angles $\beta=0$ and $\pi/2$, up to four locally stable configurations: $\uparrow\uparrow$, $\uparrow\downarrow$, $\downarrow\uparrow$, and $\downarrow\downarrow$. Assuming thermal relaxation via coherent rotation and a periodic driving field we solve a master equation for the occupation probabilities of these states and find the coercivity and switching field distribution of the ensemble of coupled particles. For either value of the bond angle we compare numerical solutions of the master equation with approximate expressions based on extremal analysis and find good agreement between the two.

There exists a vast body of literature dedicated to thermal relaxation effects in bistable systems while thermal relaxation in systems with more than two metastable minima has received, to date, but scant attention, a notable exception being the work of Pfeiffer.[1] We have recently[2] applied his master equation approach to an array of interacting, thermally relaxing bistable systems and we were able to demonstrate that the relaxation rates within such an array must be interpreted as rates of transitions between its metastable configurations. The simplest possible interacting array is formed by two identical, magnetostatically coupled uniaxial particles with individual energies $E^{(i)}=KV\sin^2\theta_i-M_sHV\cos\theta_i$ (K is anisotropy constant, V particle volume, M_s saturation magnetization, H is external field applied in the z direction, and θ_i is the angle spanned by the magnetization vector and applied field), and coupling $E_{\rm int}=r^{-3}\mathbf{M}_1\cdot\mathbf{M}_2-3r^{-5}(\mathbf{M}_1\cdot\mathbf{r})(\mathbf{M}_2\cdot\mathbf{r})$ where $\mathbf{r}=r(\sin\beta\mathbf{i}+\cos\beta\mathbf{k})$ is the radius vector joining the two particles and β the bond angle. The total energy is $E=E^{(1)}+E^{(2)}+E_{\rm int}$ and for brevity we write $\mathscr{E}=E/KV$ and $h=H/H_n$ ($H_n=2K/M_s$ is the nucleation field of an isolated particle). For bond angles $\beta=0$ and $\beta=\pi/2$ Chen *et al.*[3] found analytic expressions for the extremal energies and barrier heights of the system. We briefly summarize here their findings, write down our set of master equations,[2] and compute then the major hysteresis loop, coercivity, and switching field distribution as functions of the coupling strength $\rho=M_s^2V/(2Kr^3)$.

For either value of β there exist[3] up to four metastable states schematically represented as $\uparrow\uparrow$, $\downarrow\uparrow$, and $\uparrow\downarrow$ (these two are equivalent) and $\downarrow\downarrow$. Their energies are $\mathscr{E}_1=-\epsilon-4h$, $\mathscr{E}_2=\epsilon$, and $\mathscr{E}_3=-\epsilon+4h$, respectively; in these formulas $\epsilon=4\rho$ if $\beta=0$ and $\epsilon=-2\rho$ if $\beta=\pi/2$. For bond angle $\beta=0$ there exist three critical fields $h_{n_1}\geq h_p\geq h_{n_2}$,

$$h_{n_1}(\rho)=1+\rho, \tag{1}$$

$$h_p(\rho)=(1+\rho)(1-3\rho)^{1/2}(1-\rho)^{-1/2}, \tag{2}$$

$$h_{n_2}(\rho)=(1-3\rho)^{1/2}(1-\rho)^{1/2}. \tag{3}$$

The degree of metastability changes at the nucleation fields h_{n_i} while, as will be explained, at the critical field h_p only one of the relaxation channels changes and no change in the number of local minima takes place. There exist also three saddle points, labeled *a*, *b*, and *c*, with energies

$$\mathscr{E}^{(\alpha)}=1+3\rho^2+h^2\mp 2hh_{n_2}(\rho), \tag{4}$$

$$\mathscr{E}^{(c)}=2(1-\rho^2+h^2)/h_{n_1}(\rho), \tag{5}$$

where $\alpha=a,b$ and the upper sign refers to the saddle *a*. The minimum and saddle point energies define [see Eq. (11) below] the barrier heights to be overcome by thermal relaxation). If $\beta=\pi/2$ then the system has again three critical fields $h_{n_1}\geq h_{n_2}\geq h_p$,

$$h_{n_1}(\rho)=(1-\rho)^{1/2}(1+3\rho)^{1/2}, \tag{6}$$

$$h_{n_2}(\rho)=1-3\rho, \tag{7}$$

$$h_p(\rho)=(1-3\rho)(1-\rho)^{1/2}(1+3\rho)^{-1/2}, \tag{8}$$

and three saddle points with energies

$$\mathscr{E}^{(\alpha)}=1-3\rho^2+h^2\mp 2hh_p(\rho), \tag{9}$$

$$\mathscr{E}^{(c)}=2[h^2+h_{n_2}(\rho)(1-2\rho)]/h_{n_2}(\rho). \tag{10}$$

As previously mentioned, there exist up to three physically distinct metastable configurations of the two-particle cluster. They correspond to local energy minima and we shall define

$$\kappa_{ij}^{(\alpha)}(h,\rho)=\kappa_{i\to j}^{(\alpha)}(h,\rho)=f_0\exp(-KV\mathscr{E}_{ij}^{(\alpha)}/T) \tag{11}$$

as the rate of thermally activated flux from the metastable state i to j passing through the saddle α. Here T is temperature ($k_B=1$), f_0 is the prefactor (we set[4] $f_0=e^{25}$ Hz) and the reduced barrier heights $\mathscr{E}_{ij}^{(\alpha)}=\mathscr{E}^{(\alpha)}-\mathscr{E}_i$.

For bond angle $\beta=0$ and applied field $|h|<h_{n_2}(\rho)$ the relaxation channels open in the two particle system may schematically be represented as $1\overset{a}{\leftrightarrow}2\overset{b}{\leftrightarrow}3$ where $1=\uparrow\uparrow$, $2=\downarrow\uparrow+\uparrow\downarrow$, and $3=\downarrow\downarrow$. The probabilities n_i (occupation numbers) that the system finds itself in the ith metastable state the satisfy[2] the equations

 0021-8979/94/76(10)/6493/3/$6.00 © 1994 American Institute of Physics

$$\dot{n}_1 = -2\kappa_{12}^{(a)} n_1 + \kappa_{21}^{(a)} n_2, \tag{12}$$

$$\dot{n}_2 = 2\kappa_{12}^{(a)} n_1 - (\kappa_{21}^{(a)} + \kappa_{23}^{(b)}) n_2 + 2\kappa_{32}^{(b)} n_3, \tag{13}$$

$$\dot{n}_3 = \kappa_{23}^{(b)} n_2 - 2\kappa_{32}^{(b)} n_3, \tag{14}$$

where $\dot{n}_i = dn_i/dt$. The factors 2 above have their origin in the degeneracy of the metastable state 2. The stationary state of Eqs. (12)–(14) is thermal equilibrium and it is easily shown[2] that in the decoupled limit one recovers the single particle result. In applied fields $h_{n_2} \leqslant |h| < h_p$ the local minima 2 do not exist so that

$$\dot{n}_1 = -\dot{n}_3 = -2\kappa_{13}^{(\alpha)} n_1 + 2\kappa_{31}^{(\alpha)} n_3 \tag{15}$$

and $n_2 \equiv 0$; $\alpha = b$ if $h > 0$ and $\alpha = a$ if $h < 0$, while $\alpha = c$ at fields $h_p \leqslant |h| < h_{n_1}$. The relaxation rates $\kappa_{ij}^{(\alpha)}$ are continuous across all critical fields $h_i(\rho)$ but equation sets (12)–(14) and (15) are discontinuous at the nucleation fields $\pm h_{n_2}(\rho)$ where the levels 2 vanish. In hysteresis calculations it is therefore necessary to verify that the vanishing intermediate states 2 are empty before the transition from the tristable to the bistable regime is made. The coercivity h_c is obviously bounded by the nucleation field h_{n_1}, $h_c \leqslant h_{n_1}$.

The case of bond angle $\beta = \pi/2$ and applied field $|h| < h_p$ is described by Eqs. (12)–(14). However, a direct relaxation channel opens between the states 1 and 3 if $h_p \leqslant |h| < h_{n_2}$ and we write[2] here

$$\dot{n}_1 = -2(\kappa_{12}^{(a)} + \kappa_{13}^{(c)}) n_1 + \kappa_{21}^{(a)} n_2 + 2\kappa_{31}^{(c)} n_3, \tag{16}$$

$$\dot{n}_2 = 2\kappa_{12}^{(a)} n_1 - (\kappa_{21}^{(a)} + \kappa_{23}^{(b)}) n_2 + 2\kappa_{32}^{(b)} n_3, \tag{17}$$

$$\dot{n}_3 = 2\kappa_{13}^{(c)} n_3 + \kappa_{23}^{(b)} n_2 - 2(\kappa_{31}^{(c)} + \kappa_{32}^{(b)}) n_3. \tag{18}$$

At $h_{n_1} > h \geqslant h_{n_2}$ the system has the two metastable states 1 and 2 and at $-h_{n_1} < h \leqslant -h_{n_2}$ the states 3 and 2. The evolution equations are

$$\dot{n}_2 = -\dot{n}_i = -\kappa_{2i}^{(\alpha)} n_2 + 2\kappa_{i2}^{(\alpha)} n_i, \tag{19}$$

where $i = 1$ and $\alpha = b$ for $h > 0$ while $i = 3$ and $\alpha = a$ for $h < 0$. In this case $h_c \leqslant h_{n_2}$. For either value of β the system is monostable in fields $|h| \geqslant h_{n_1}$.

Now let the applied field h vary with time as $h(t) = h_{n_1}(\rho)\cos 2\pi f t$ where f is the field sweep rate. At time $t = 0$, accordingly, $n_1 = 1$ and $n_2 = n_3 = 0$ in Eqs. (15) and (19). These are the initial conditions for the differential systems (12)–(15) describing the time evolution of the two particle cluster at bond angle $\beta = 0$ and for the systems (12)–(14), (16)–(19) corresponding to $\beta = \pi/2$. Their sample numerical[5] solutions are presented in Figs. 1 and 2 where we also introduce the reduced magnetization $m = 2(n_1 - n_3)$ and switching field distribution (SFD) $\chi = \partial m/\partial h$. In all cases we have chosen $q = KV/T = 42$ so that the half lifetime of an *isolated* particle is about one year.

At zero bond angle (Fig. 1) the antiparallel configurations 2 are energetically unfavorable and at the chosen temperature $n_2 \approx 0$ at all times for $\rho > 0.01$ (not shown in Fig. 1). The coercivity[6] $h_c(\rho, f)$ is shown in Fig. 3. Since $n_2 \approx 0$ the system may be treated as having only the two levels 1 and 3 approximately described by the evolution equation

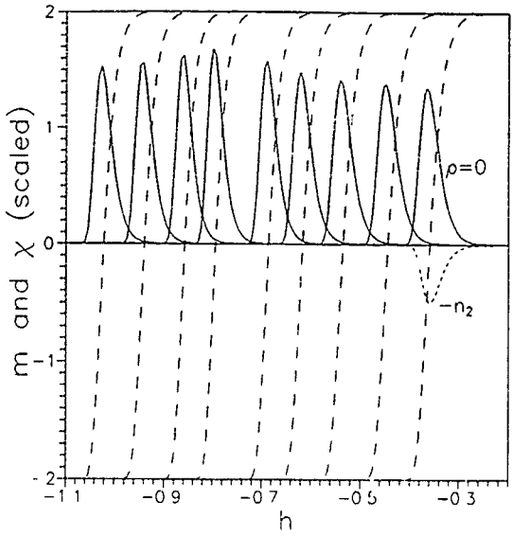

FIG. 1. Bond angle $\beta = 0$. Nonequilibrium magnetization $m[h(t)]$ (long dash) and switching field distribution $\chi[h(t)]$ (solid lines) vs applied field $h(t)$. Coupling strength $\rho = 0$ (rightmost curve, marked), 0.05, 0.10, 0.15, 0.20, 0.32 (the highest SFD peak shown here), 0.40, 0.50 and 0.60 (leftmost curve). For $\rho = 0$ we also show the probability $n_2[h(t)]$ (short dash), for all other values of ρ $n_2 \approx 0$ at all times. Sweep rate $f = 10^1$ Hz.

$\dot{n}_1 = -\Gamma n_1 = -\dot{n}_3$ where we retain only the dominant rate: $\Gamma = 2\kappa_{12}^{(a)}$ if $-h_p < h < 0$ and $\Gamma = 2\kappa_{13}^{(c)}$ if $-h_{n_1} < h < -h_p$; $\mathcal{A}_{12}^{(a)} = (h - h_{n_2})^2 + 4(2\rho + h)$ and $\mathcal{A}_{13}^{(c)} = 2(h + h_{n_1})^2/h_{n_1}$. At coercivity $n_1 = n_3 = 1/2$ and the SFD function has, approximately,[4] a maximum, $d\chi/dh|_{h=h_c} = 0$, so that

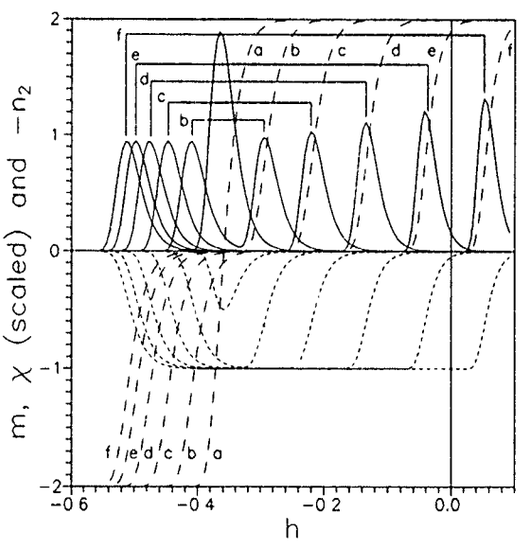

FIG. 2. Bond angle $\beta = \pi/2$. Nonequilibrium magnetization $m[h(t)]$ (long dash), switching field distribution $\chi[h(t)]$ (solid lines), and the probability $n_2[h(t)]$ (short dash, plotted as $-n_2$ for clarity) vs applied field $h(t)$. The magnetization curves labeled as a ($\rho = 0$), b ($\rho = 0.05$), c ($\rho = 0.10$), d ($\rho = 0.15$), e ($\rho = 0.20$), and f ($\rho = 0.25$). For $\rho > 0$ the SFD function has a minimum at coercivity and two flanking peaks which we connect by labeled braces. The curves $n_2(h)$ are unlabeled, the broadest curve corresponds to $\rho = 0.25$, the narrowest one (with max $n_2 = 1/2$) to $\rho = 0$. Note how stable the antiparallel states 2 become at large coupling strengths. Sweep rate $f = 10^1$ Hz.

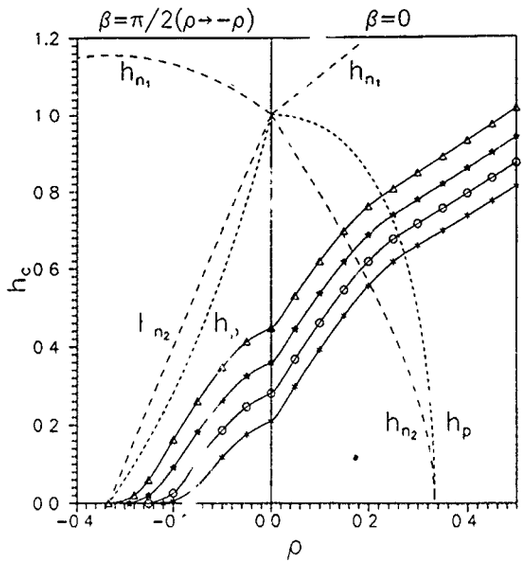

FIG. 3. The exact reduced coercivity (Ref. 6) $h_c(\rho,f)$ for bond angles $\beta=0$ and $\pi/2$. Sweep rates are $f=10^{-3}$ Hz (*), 10^{-1} Hz (○), 10^{1} Hz (☆), and 10^{3} Hz (△). Note in particular that at small interaction strengths $h_c \propto \rho$ for $\beta=0$ but $h_c \propto -\rho^2$ for $\beta=\pi/2$. Also shown are the nucleation fields h_{n_i} and the critical fields h_p.

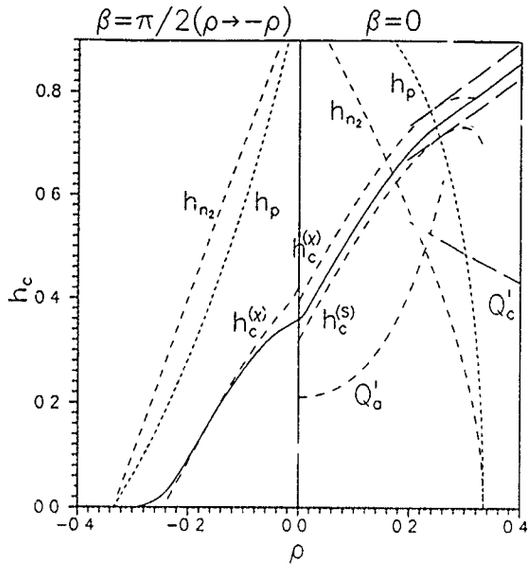

FIG. 4. The exact reduced coercivity (Ref. 6) $h_c(\rho,f)$ ($f=10^{1}$ Hz, solid line) compared with the approximate expressions $h_c^{(S)}$ [solution of Sharrock's formula (Ref. 7) $\beta=0$ only] and $h_c^{(\chi)}$ [solution of Eq. (21) for $\beta=0$ and Eq. (22) for $\beta=\pi/2$]. Approximate solutions based on $\mathcal{Q}_{12}^{(a)}$ (short dash) exist at $h_c<h_p$ and those based on $\mathcal{Q}_{13}^{(c)}$ (long dash) at $h_c>h_p$. To emphasize the matching at $h_c=h_p$ we extend both solutions a little into the unphysical region beyond h_p. Also shown are the (scaled) derivatives $Q_a'(h_c^{(\chi)})$ and $Q_c'(h_c^{(\chi)})$ (same markings as for coercivity).

$$2\pi f h_c \dot{m}(h_c) - \sigma(h_c)\ddot{m}(h_c) = 0, \tag{20}$$

$\sigma(h) = (h_{n_1}^2 - h^2)^{1/2}$. Substituting for $\dot{m}$ and $\ddot{m}$ we finally obtain

$$\ln(f_0/\pi f) - Q_\alpha(h_c) = \ln\{\sigma(h_c)[Q_\alpha'(h_c) - h_c/\sigma^2(h_c)]\}, \tag{21}$$

where $Q_\alpha(h_c) = q\mathcal{Q}_{ij}^{(\alpha)}(h_c)$ for brevity and $Q_\alpha' = dQ_\alpha/dh$. Without the right-hand side this is exactly Sharrock's formula[7] for coercivity and Fig. 4 shows that both the solution $h_c^{(\chi)}$ of Eq. (21) and the solution $h_c^{(S)}$ of Sharrock's formula provide a very good approximation to the exact solution $h_c(\rho)$. Regarding the SFD function $\chi(h)$ it was shown[4] that approximately $\chi_{\max}(h) \sim Q_\alpha'(h_c)$ so that according to Fig. 4 the SFD function $\chi(h)$ should attain the greatest height if $h_c(\rho)=h_p(\rho)$ and this trend is indeed observed in Fig. 1 and in its counterparts at other sweep rates.

At bond angle $\beta=\pi/2$ the evolution of the two particle cluster is dominated by the great stability[8] of the antiparallel configurations 2 (see Fig. 2), $n_2(h_c)\approx 1$ and the SFD function has a local *minimum* flanked by two local maxima. The two level approximation is obviously not applicable, yet an approximate expression for $h_c(\rho)$ follows from Eqs. (20) and (12)–(14) supplemented by the auxilliary extremal conditions $n_1(h_c)=n_3(h_c)$ and $\dot{n}_2(h_c)=0$:

$$2\kappa_{12}^{(a)}(h_c) - \kappa_{23}^{(b)}(h_c) = 2\pi f\sigma(h_c)[Q_a'(h_c) + Q_b'(h_c) - 2h_c/\sigma^2(h_c)], \tag{22}$$

where $Q_a/q = \mathcal{Q}_{12}^{(a)} = (h - h_{n_1})^2 + 4(h-\rho)$ and $Q_b/q = \mathcal{Q}_{23}^{(b)} = (h + h_{n_1})^2$. The solution $h_c^{(\chi)}$ of Eq. (22) is compared with the exact coercivity $h_c(\rho)$ in Fig. 4. An approximate expression for the SFD peak values $\chi_{\max}(h_c+\delta_1) > \chi_{\max}(h_c-\delta_2)$, $\delta_i>0$, is not known to us.

The evolution (master) equations of Sec. II are fairly complicated but we have shown here that at least the coercivity $h_c(\rho)$ may easily be found from the approximate Eqs. (21) and (22). It is remarkable that for $\beta=\pi/2$ and small ρ the exact coercivity is a nonlinear function of the coupling strength ($h_c \propto -\rho^2$) while this result cannot be obtained from the approximate Eq. (22) (compare Fig. 4) nor from a mean field theory.[9] Equations (21) and (22) fail if the hysteresis loop approaches the curve of equilibrium magnetization, i.e., at high temperatures or small sweep rates.

Interactions are represented by the state dependent mean field $\bar{h}(t)=h(t)+\alpha m(t)$ where $m(t)$ is the instanteneous magnetization and α a small empirical constant; $h_c \propto \alpha$ if $|\alpha| \ll 1$.

Some specific features of fine Fe and Fe-Ni particles

Yu. V. Baldokhin, P. Ya. Kolotyrkin, Yu. I. Petrov, and E. A. Shafranovsky

By comparing results of Mössbauer spectroscopy and x-ray diffraction investigations of ultrafine Fe and Fe-Ni particles, a formerly stated supposition on the existence of two spin states of the fcc phase in pure iron and Fe-Ni alloys has been verified. Some structural peculiarities of particles under study have been observed also. For the pure bcc-Fe particles with an average diameter of 30 and 50 nm the existence of two hyperfine fields (H_1=330 kOe, H_2=360 kOe) at room temperature has been found. It is supposed that H_2 in the bcc phase could be considered as a remnant of a high spin state of the fcc-Fe phase at high temperature. Particles of Fe-Ni(30.3 wt %), Fe-Ni(35 wt %), and Fe-Ni(52 wt %) alloys with an average diameter ranging from 5 to 15 nm were studied also. Particles of Fe-Ni (30.3 wt %) and Fe-Ni(35 wt %) alloys with diameter of 5–8 nm had the bcc structure. A mixture of the bcc and fcc phases appeared with an increase of the particle size. At the same time only the fcc structure remained for the largest particles. The observed size structural dependences and the existence of the stable bcc phase in small particles can be explained by the martensite fcc-bcc transition.

I. INTRODUCTION

This work aims to study Fe and some binary system peculiarities under transition from bulk to fine particles in order to reveal some of their size-dependent properties and to understand the nature of these properties of the bulk itself more profoundly. Subjects of inquiry are chosen magnetic Fe and Fe-Ni fine particles. The change in the crystalline and hyperfine magnetic structure of small particles of Fe and Fe-Ni alloys enriched with Fe as compared with the bulk have been investigated. It is well known from experimental data and the theoretical point of view that some Fe-based alloys with fcc structure show many anomalies of physical properties. This variety of anomalies is named Invar anomalies and the most specific one is a behavior of the thermal expansion. The thermal expansion constant is practically equal to zero within a wide temperature range. The nature of the anomalies in fcc Invars is supposed to be due to (i) the peculiarities of the electron and magnetic structure, (ii) size-dependent properties of small particles, (iii) an influence of various composition, interatomic distances, a number of nearest neighbors, α-γ and antiferro-ferromagnetic transformations, and high and low spin states.

II. SAMPLE PREPARATION

The fine particles are produced with the so-called "gas evaporation" technique. The principle of the method lies in substance vapor condensation in an inert gas atmosphere which transfers the condensation heat from the arising aerosol particles to the reaction vessel walls (the solidification rate is about 10^4–10^5 deg/s). By varying the species and the pressure of the inert gas as well as the vessel size, it is possible to alter the average diameter of aerosol particles within a range from one to hundreds of nanometers. The particles obtained are deposited on the vessel walls and have a rather narrow size distribution (maximum deviation from the average value is usually no more than a double value).

III. EXPERIMENTAL RESULTS AND DISCUSSION

Analyzing thermodynamic functions as well as results of electric and magnetic measurements for pure iron and its alloys, Weiss[1] came to the conclusion that a high temperature fcc-Fe phase could exist in two spin electron states, one of which was antiferromagnetic (Néel temperature T_N=80 K, magnetic moment per atom μ=0.5 μ_B, lattice constant a=3.55±0.01 Å), and the other was ferromagnetic (Curie temperature T_C=1800 K, magnetic moment μ=2.8 μ_B, lattice constant a=3.64±0.01 Å). However, so far no direct proof has existed that the fcc phase in pure iron was possible in two spin states. In an attempt to clear up this question, we used the capability of small particles obtained by the condensation of a vapor substance in argon (gas evaporation technique), to retain their high temperature state.[2] A comparison of Mössbauer spectra with x-ray diffraction data on thermal expansion of such Fe particles gave a direct verification of Weiss's hypothesis[3] for the first time.

The Mössbauer spectra obtained at 300 K for particles with a diameter of about 50 nm are shown in Fig. 1.[3] Computer analysis of the initial powder revealed two spectra with the following hyperfine parameters: (1) an effective magnetic field on Fe nuclei H_1=330 kOe, a fraction of whole spectrum area S_1=37.8%, electric quadrupole interaction Δ_1=0, an isomer chemical shift δ_1=0 (δ is referred to metallic iron at room temperature), half a width of the first line $(\Gamma/2)_1$=0.55 mm/s (this spectrum corresponds to a slightly disordered bcc-Fe phase); (2) H_2=360 kOe, S_2=62.2%, δ_2=0.02 mm/s, Δ_2=0.1 mm/s, $(\Gamma/2)_2$=0.56 mm/s. The superposition of these two spectra demonstrated a complex magnetic structure of the sample. At the same time x-ray patterns showed the presence of only a bcc-Fe phase with a lattice constant a=2.866±0.002 Å. The Mössbauer spectrum of the powder was varied essentially by fast quenching to room temperature after heating in argon at T=800 °C for half an hour [Fig. 1(b)]. The area of such the spectrum with the H_2 component was extended to S_2=82% while the content of the bcc-Fe phase with the H_1 component was reduced

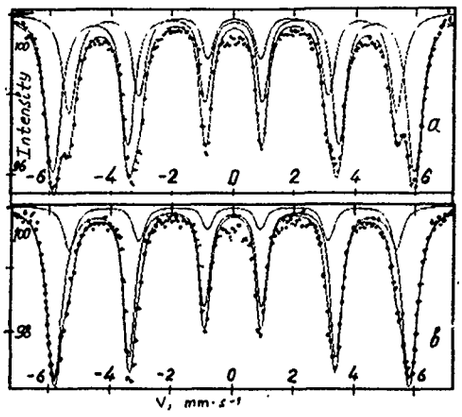

FIG. 1. Mössbauer spectra of Fe particles with a diameter of 50 nm: (a) the initial powder; (b) the same powder after heating at temperature $T=800$ °C for half an hour followed by quenching down to room temperature.

down to $S_1=18\%$. These results allowed us to suppose that the hyperfine magnetic field H_2 in the bcc phase could be considered as a remnant of a high spin state available in the fcc-Fe phase at high temperature.

It was interesting to ascertain to what degree the peculiarities of the Mössbauer spectra for Fe particles are retained in small particles of an Fe-Ni Invar alloy for which a stabilization of the high temperature fcc phase in iron is typical. Preliminary results of studies of Fe-Ni alloy particles have been published earlier.[4]

Particles of Fe-Ni(30.3 wt %), Fe-Ni(35 wt %), and Fe-Ni(52 wt %) alloys with an average diameter ranging from 5 to 15 nm were studied by x-ray diffraction and Mössbauer spectroscopy. Foil and wire alloys were used for preparing samples. They were evaporated within a vacuum chamber from W wire placed at the center of a beaker with a diameter of 10 cm. The vacuum chamber was filled with argon up to a given pressure ranging from 0.08 to 3.5 Torr and a swift sample evaporation was made. Metal vapor condensation in argon (the gas evaporation technique) resulted in ultrafine deposits on the beaker walls formed from spherical particles with a narrow size distribution. The following results were obtained from the x-ray diffraction measurements. (1) The lattice constants for even the smallest particles did not differ from those for a bulk solid. (2) The Fe-Ni(52 wt %) alloy retained the fcc structure whatever the particle size. (3) The Fe-Ni(30.3 wt %) and Fe-Ni(35 wt %) alloys in a bulk solid originally have a fcc structure with a small fraction of the bcc phase, while the particles with a diameter of 5–8 nm consist of only the bcc phase. As the particle size increases the content of the fcc phase rises while the fraction of the bcc phase is reduced. The bcc-fcc transition is completed entirely in Fe-Ni(35 wt %) particles with a diameter of about 12 nm though larger Fe-Ni(30.3 wt %) particles with a diameter of 15 nm have a conspicuous bcc phase fraction.

It should be noted that the observed structural size dependence and stable existence of the bcc phase in small particles of Fe-enhanced alloys run counter to the expected suppression of the martensite fcc-bcc transition in such particles.[5]

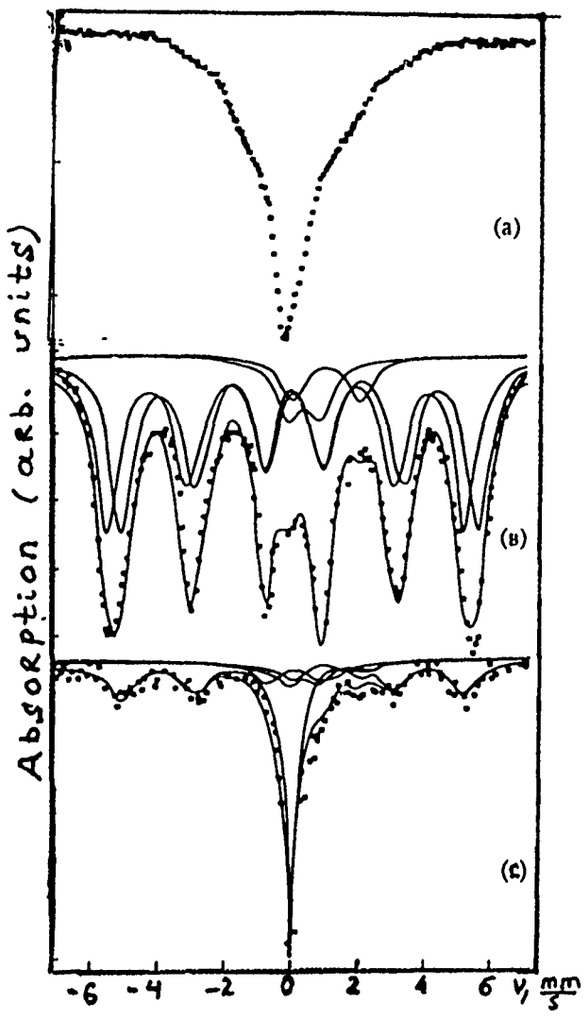

FIG. 2. Mössbauer spectra of Fe-Ni alloys: (a) Fe-Ni(30.3 wt %) foil; (b) Fe-Ni(35 wt %) powder with a mean particle size of 8 nm; (c) the same powder as a previous one heated at temperature $T=900$ °C for half an hour followed by quenching to room temperature.

Typical Mössbauer spectra for Fe-Ni alloys are shown in Fig. 2. The spectra of particles are quite different from spectra of foils. Parameters for the Mössbauer spectra of samples are listed in Table I. The spectrum for the Fe-Ni(30.3 wt %) foil displays a broad single line [Fig. 2(a)] while the spectra for Fe-Ni(35 wt %) foil and Fe-Ni(52 wt %) wire could be represented as two 6-line spectra: $H_1=278$ kOe ($S_1=44\%$), $H_2=238$ kOe ($S_2=56\%$), and $H_1=308$ kOe ($S_1=50\%$), $H_2=313$ kOe ($S_2=50\%$), respectively. In the case of the Fe-Ni(52 wt %) alloy its Mössbauer spectrum pattern and a crystalline structure keep under the transition from a bulk solid to particles with the diameter of 7 nm. The Fe-Ni(35 wt %) and Fe-Ni(30.3 wt %) alloys behave the other way around, that is the fcc structure of the bulk solid changes into bcc structure for the particles with a diameter of 5–8 nm. The form of the Mössbauer spectrum and the crystallographic features of the Fe-Ni(30.3% wt %) particles with about 15 nm diam, which contain both phases at the 1.3 fcc/bcc ratio, do not change after exposing samples at 77 K for 2 h.

[a]d—particle size, nm; H_{eff}—hyperfine magnetic field, kOe; γ—single line with the isomer shift $\delta=-0.07$ mm/s corresponds to the fcc phase; ϵ—unresolved structure ("sagging wire"); Cl—clusters of Fe^{2+}, Fe^{3+} [see Fig. 2(b)]; S—relative area of subspectra, %.
[b]Sample after heating at $T=900$ °C for 2 h.

The spectrum for Fe-Ni(35 wt %) particles with a mean diameter of 8 nm, as shown in Fig. 2(b), could be represented by two 6-line spectra: $H_1=345$ kOe ($S_1=44\%$) and $H_2=318$ kOe ($S_2=44\%$) with a small fraction of Fe^{3+} and Fe^{2+} oxides. Practically the same value of H_1 and H_2 were observed for the Fe-Ni(30.3 wt %) particles with diameters in the range of 5–8 nm. When the Fe-Ni(30,3 wt %) and Fe-Ni(35 wt %) the smallest particles of 5–8 nm size were quenched from 900 °C to room temperature, the 6-line spectrum with $H_1=345$ kOe transformed into a central line ($S_1=43\%$, $\delta_1=-0.07$ mm/s) [Fig. 2(c)] with simultaneously about twice the increase of the particle size. This spectrum transformation is undoubtedly due to a bcc-fcc phase transition. This is also borne out with the appearance of the narrow central line ($S_1=57\%$, $\delta_1=-0.05$ mm/s) corresponding to the fcc phase side by side with the 6-line spectrum ($H_2=330$ kOe, $S_2=43\%$, $\delta_2=0.02$ mm/s, $\Delta_2=0.02$ mm/s) corresponding to the bcc phase for the Fe-Ni(30.3% wt %) particles with a mean diameter of 15 nm (see Table I).

IV. CONCLUSIONS

As in the case of the small particles of both pure iron and Fe-Ni alloy the Mössbauer spectra have a complex structure indicating, probably, the essential role of a high temperature Fe fcc modification which can be displayed in two different states depending on the size, the particle making conditions, and the heat treatment.

Though it has been recently shown theoretically that the ferromagnetic fcc Fe was unstable relative to tetragonal deformation, and hence it could not exist itself,[6] nevertheless in the case of pure iron the experimental results[3] evidence an availability of two spin states in the fcc Fe. As for the Fe-Ni Invar alloy in this case also the above given experimental results indicate the existence, at least, of two spin states in the fcc phase. So, in accordance with the theory[1] for the Fe-Ni(30.3 wt %) and Fe-Ni(35 wt %) particles the central paramagnetic peak in Fig. 2(c) apparently belongs to an antiferromagnetic low spin state of the fcc phase but one of the two Mössbauer spectrum components [Fig. 2(c)] with the higher hyperfine field ($H_1=345$ kOe) on Fe nuclei, probably, corresponds to the hereditary high spin magnetic structure of the fcc phase in a crystalline bcc structure of small particles. This last magnetic structure is formed during a particle making procedure. At the same time after the powder heat treatment at a temperature of 900 °C followed by a quenching to room temperature it transforms to the low spin state of the fcc phase simultaneously with the structural bcc-fcc transition.

Magnetoresistance of the magnetically ordered icosahedral quasicrystals Al-Pd-Mn-B

M. H. Yewondwossen, S. P. Ritcey, Z. J. Yang, and R. A. Dunlap
Department of Physics, Dalhousie University, Halifax, Nova Scotia B3H 3J5, Canada

The transverse magnetoresistance has been measured for the newly discovered magnetically ordered icosahedral quasicrystals $Al_{70-x}Pd_{15}Mn_{15}B_x$ (x=0,2,4,6,8,10). Experiments were conducted at 4.2 K in magnetic fields up to 5.5 T. The results showed a systematic change as a function of boron concentration. The magnetoresistance for x=0,2,4,6 showed a negative field dependence which became weak with increasing x. The samples with x=8,10 showed a negative magnetoresistance at low fields, which became positive for higher applied fields. The minimum in the magnetoresistance shifted to lower field value with increasing boron content (to about 0.5 T for 10 at. %B). The analysis of the results has been based on the theory of three-dimensional weak localization, with a strong influence of spin-orbit scattering. The magnetoresistance is negative for low boron concentration due to weak spin-orbit scattering, and is positive for high boron concentration due to strong spin-orbit scattering.

I. INTRODUCTION

Since the first discovery of quasicrystals in Al-Mn alloys[1] the influence of the quasiperiodicity on the physical properties has been studied extensively. In particular, the effect of the local icosahedral symmetry on the magnetic and electronic properties has been of particular interest.[2,3] Quasicrystals show magnetic behavior that ranges from diamagnetic to ferromagnetic.[3] Most quasicrystalline materials have been reported to be either diamagnetic or paramagnetic, while a few have exhibited spin glasslike behavior.[3] Weak ferromagnetism has been found in Al-Ce-Fe,[4] Al-Mn-Ge,[5] and Al-Mn-Si.[6,7]

Recently a new class of Al-Pd-Mn-B quasicrystals with large magnetization ($\sim 5\times10^{-7}$ H m^2 kg^{-1}) and Curie temperatures around 500 K have been reported.[8] The room-temperature magnetization was found to increase with increasing B content in the series of alloys of the composition $Al_{70-x}Pd_{15}Mn_{15}B_x$. The magnetization is observed only in the metastable quasicrystalline phase and is not present in the equilibrium crystalline phase. In this work the magnetoresistance of $Al_{70-x}Pd_{15}Mn_{15}B_x$ has been investigated at 4.2 K. Weak localization theory is used to analyze the result and deduce the inelastic scattering time τ_i and spin-orbit scattering time τ_{so}.

II. EXPERIMENTAL METHODS

$Al_{70-x}Pd_{15}Mn_{15}B_x$ alloy ingots were prepared from high purity elements by arc melting followed by melt spinning onto a copper roller with a surface speed of 60 m s^{-1}. Resulting ribbons had cross sections of $\sim$25 μm thick by $\sim$1.5 mm wide. The single phase quasicrystalline nature of the ribbons was confirmed by room temperature x-ray diffraction using Cu-K_α radiation on a Siemens D500 scanning diffractometer. The magnetoresistance was measured at 4.2 K in a transverse field up to 5.5 T using a conventional four-point dc technique. The electrical leads were attached to the sample using silver loaded epoxy.

III. RESULTS AND DISCUSSION

Weak localization (WL) effects are manifested at low temperature as small quantum perturbations of the classical Boltzmann conductivity and can provide detailed information about the electron scattering processes. The theory of WL has had reasonable success in explaining the anomalous behavior of the transport properties of three-dimensional disordered systems.[9,10] The magnetoresistance is negative in the case of weak spin-orbit scattering systems, i.e., $\tau_i<\tau_{so}$. In the case of strong spin-orbit scattering systems the magnetoresistance is positive and $\tau_i>\tau_{so}$.

The magnetoresistance, $\Delta\rho/\rho^2$, due to WL effects is given as a function of the applied magnetic field, B, by the model of Altshuler *et al.*[11] as

$$\frac{\Delta\rho}{\rho^2}=\frac{\alpha e^2}{\pi h}\sqrt{\frac{2\pi eB}{h}}\left[\frac{1}{2}f_3\left(\frac{B}{B_i}\right)-\frac{3}{2}f_3\left(\frac{B}{B_{so}}\right)\right], \tag{1}$$

where

$$B_i=\frac{h}{8\pi eD\tau_i}, \tag{2}$$

$$B_{so}=B_i+\frac{h}{4\pi eD\tau_{so}} \tag{3}$$

and D is the diffusion coefficient and α accounts for uncertainties in sample geometry. The function $f_3(x)$ is the Kawabata function given by[12]

$$f_3(x)=\sum_{n=0}^{\infty}\left[2\left(n+1+\frac{1}{x}\right)^{1/2}-2\left(n+\frac{1}{x}\right)^{1/2}-\left(n+\frac{1}{2}+\frac{1}{x}\right)^{-1/2}\right]. \tag{4}$$

The transverse magnetoresistance measured at 4.2 K for the $Al_{70-x}Pd_{15}Mn_{15}B_x$ (x=0,2,4,6,8,10) alloys is shown in Fig. 1. The magnetoresistance is negative for $x\leqslant6$ and positive for x=8 and 10. Data have been fit to Eq. (1) using standard

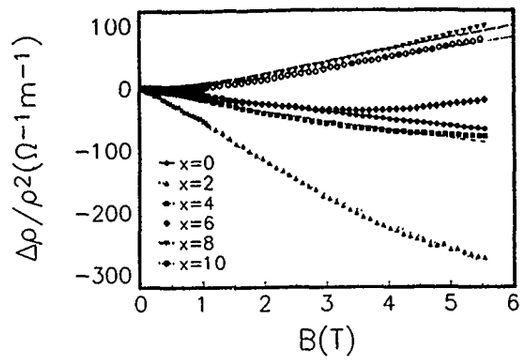

FIG. 1. The transverse magnetoresistance measured at 4.2 K for the $Al_{70-x}Pd_{15}Mn_{15}B_x$ (x=0,2,4,6,8,10) alloys. Least-squares fits to Eq. (1) are illustrated by the solid and broken lines.

nonlinear least-squares methods. The slowly converging function $f_3(x)$ used by Kawabata[12] was replaced by the more compact form proposed by Baxter *et al.*[13]

$$f_3(x)=2\left[\sqrt{2+\frac{1}{x}}-\sqrt{\frac{1}{x}}\right]-\left[\left(\frac{1}{2}+\frac{1}{x}\right)^{-1/2}+\left(\frac{3}{2}+\frac{1}{x}\right)^{-1/2}\right]+\frac{1}{48}\left(2.03+\frac{1}{x}\right)^{-3/2}. \quad (5)$$

The diffusion coefficient is taken to be 0.075 $cm^2\,s^{-1}$,[14] from literature values for similar Al-Mn-Pd based quasicrystals. The characteristic scattering times τ_i and τ_{so} are obtained as free parameters in the fits. The parameters obtained from these fits are summarized in Table I and fitted curves are illustrated in Fig. 1.

Equation (1) gives a good fit to the data for the two alloys with the strongest spin-orbit scattering and positive $\Delta\rho/\rho^2$, i.e., alloys with 8 and 10 at. % boron. The presence of strong spin-orbit scattering in these alloys is evidenced by the relative values obtained from the fits to the scattering times; $\tau_i > \tau_{so}$. The fit for alloys with weak spin-orbit scattering, i.e., alloys with 0, 2 and 4 at. % boron, indicates that the relative scattering times are $\tau_i < \tau_{so}$. The alloy with x=6 at. % boron exhibits complex behavior of $\Delta\rho/\rho^2$ as a function of applied field. Subsequently the function given in Eq. (1) does not provide a suitable fit to the experimental data for the alloy of this composition.

TABLE I. Scattering times and coefficient values obtained by fitting measured magnetoresistance data to Eq. (1).

x (at. %)	τ_i (10^{-10} s)	τ_{so} (10^{-10} s)
0	2.51	9.8
2	1.96	960
4	2.59	0.57
8	0.30	0.0015
10	0.22	0.0015

IV. CONCLUSIONS

The values of the parameters given in Table I as well as the qualitative behavior of the experimental data as illustrated in Fig. 1 demonstrate a crossover from weak spin-orbit scattering to strong spin-orbit scattering as a function of increasing boron content in the alloys. This crossover corresponds to a transition from $\tau_i < \tau_{so}$ to $\tau_i > \tau_{so}$ and a corresponding loss of phase coherence in the scattering. The present experimental results have demonstrated that the theory of WL gives at least a semiquantitative description of the magnetoresistance of magnetically ordered $Al_{70-x}Pd_{15}Mn_{15}B_x$ quasicrystals; in particular those which exhibit strong spin-orbit scattering. WL theory gives a poorer quantitative description of weak and intermediate spin-orbit scattering. The breakdown of the theory for similar cases in three-dimensional systems have been reported by other authors.[15] The increase in the spin-orbit component of the scattering which results from the increase in boron content of the alloys may be seen as an increase in the d-band density of states at the Fermi energy. This is consistent with the observed increase in the strength of the magnetic coupling in these alloys as indicated by an increase in the measured magnetization.[8]

The magnetic and electrical transport properties of amorphous Fe-Zr based alloys with compositions near 10 at. % Zr with various elements substituted for Fe are of particular interest. In the case of Mn substitutions the Curie temperature and the average magnetic moment decrease monotonically with increasing Mn content and the temperature dependence of the magnetization is significantly modified. The electrical transport properties of amorphous $Fe_{90-x}Mn_xZr_{10}$ (for $x=0$, 4, 8, and 12) over the temperature range of 4.2–300 K and the magnetoresistance for fields up to 4.0 T at 4.2 K are reported in the present work. A broad minimum in the resistivity is observed at around 255, 235, 200, and 180 K for the four compositions, respectively. In the case of the $x=8$ sample a second minimum occurs at around 50 K. The magnetoresistance of all samples shows a sharp increase for small fields and a linear field relationship for fields above about 0.1 T.

I. INTRODUCTION

The amorphous FeZr (a-FeZr) alloys with compositions near 10 at. % Zr form an interesting disordered magnetic phase. A variety of unusual properties, e.g., small Fe moment, low Curie temperature (T_C), a large high field susceptibility, etc., have been observed in these materials. The replacement of Fe with other $3d$-transition metals (TM) can introduce significant changes in the magnetic properties. In particular Mn substitutions[1] have the following effects on a-FeZr: (1) a monotonic decrease in T_c with increasing Mn content, (2) a large high field susceptibility for alloys with up to at least 10 at. % Mn, and (3) re-entrant behavior of the initial susceptibility for samples with Mn content up to at least 10 at. %.

As the Mn substituted alloys show re-entrant magnetic behavior over a wide range of compositions, i.e., 0–10 at. % Mn, these samples are a suitable means for investigating the details of the magnetic transitions in amorphous ferromagnets.[2,3] Few magnetic and electronic transport studies have been reported for Mn substituted a-FeZr alloys and these do not allow for well-defined conclusions concerning the inter-relationship of magnetism and electronic properties. In the present work we report the results of a detailed investigation of resistivity and magnetoresistance of a-$Fe_{90-x}Mn_xZr_{10}$ alloys over the temperature range of 4.2–300 K. Particular emphasis is placed on the regions near magnetic phase transitions with the idea of improving our understanding of the effects of magnetic interactions on electron scattering mechanisms.

II. EXPERIMENTAL METHODS

Amorphous alloys of the composition $Fe_{90-x}Mn_xZr_{10}$ with $x=0$, 4, 8, and 12 were prepared by arc melting high purity elemental components followed by quenching from the melt on to a single Cu roller in an argon atmosphere. X-ray diffraction patterns obtained using Cu $K\alpha$ radiation confirmed the amorphous nature of all as-prepared ribbons. The magnetic properties of the alloys were characterized by standard ac susceptibility measurements and will be presented in detail elsewhere.[4] Four-point resistivity and magnetoresistance measurements were carried out over the temperature range of 4.2–300 K in applied magnetic field from 0 to 4.5 T using standard dc techniques.

III. RESULTS AND DISCUSSION

The temperature dependence of the reduced electrical resistivity, $\rho(T)/\rho(300\text{ K})$ for the a-$Fe_{90-x}Mn_xZr_{10}$ samples is illustrated in Fig. 1. The magnetic data (observed T_C) and the resistivity data (T_{min}) of this series of alloys is shown in Fig. 2. It is clear from the figures that

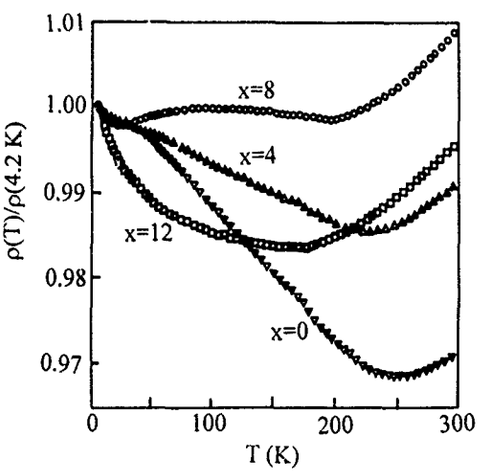

FIG. 1. $\rho(T)/[\rho(4.2\text{ K})]$ as a function of temperature for a-$Fe_{90-x}Mn_xZr_{10}$ with $x=0$, 4, 8, and 12.

 0021-8979/94/76(10)/6501/3/$6.00 © 1994 American Institute of Physics

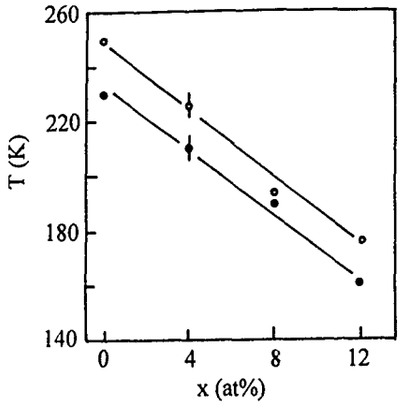

FIG. 2. T_{min} (○) and T_C (●) as a function of Mn concentration (x) for a-$Fe_{90-x}Mn_xZr_{10}$.

(1) all samples show a resistivity minimum at a temperature (T_{min}) near T_C,
(2) both T_C and T_{min} decrease by about 30% as x increases to 12 at. %,
(3) in the case of $x=0$ and $x=4$ a small anomaly in the resistivity at low temperatures (~20 K) is observed,
(4) a second minimum is observed at low temperatures for 8 at. % of Mn and a broad minimum is observed in the case of 12 at. % of Mn alloy.

These observations suggest that the resistivity minimum around T_C is closely correlated to the magnetic behavior. This is in agreement with the results of studies of pressure effects on T_C and T_{min} in similar alloys.[5]

Magnetoresistance data provide information about the microscopic magnetization and can aid in the understanding of the relationship between magnetic interactions and electron scattering mechanisms. Spin disorder scattering and the Kondo effect (in the case of dilute magnetic alloys) can account for the differences between the zero field and the in-field resistivity. This scattering is expected to be sensitive to magnetic ordering on a distance scale comparable to the electron mean free path in the alloys. On the other hand, the coherent-exchange scattering (CES) model, which is well suited to magnetic systems, takes into account the contribution to resistivity from coherent exchange scattering by neighboring ions and predicts that the change in resistivity due to magnetic ordering is either positive or negative depending on whether the interference between the scattered waves is constructive or destructive.

In order to determine the effects of an applied magnetic field on the resistivity minimum, we have carried out temperature dependent resistivity measurements in external fields of 0.7 and 4.0 T. Figure 3 illustrates that there is a shift in T_{min} as the applied field is increased. It is also evident that the external field suppresses the minimum. Transverse and longitudinal magnetoresistance measurements were carried out in a field of 4.5 T at 4.2 K and the results for samples with $x=0$, 4, 8, and 12 are shown in Fig. 4. The magnetoresistance increases monotonically with applied field and the slope is observed to be positive for both geometries. It is also

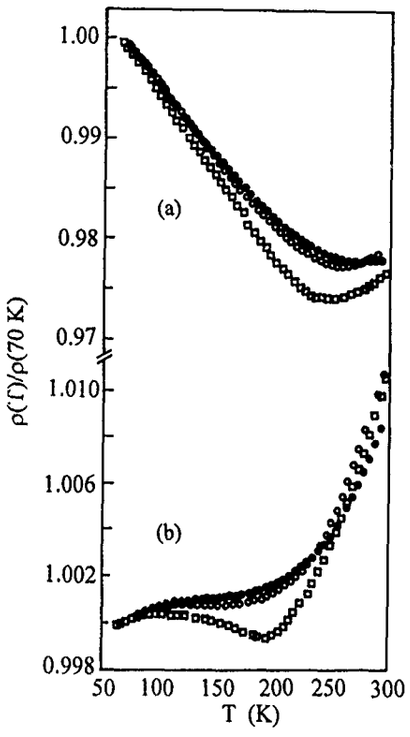

FIG. 3. Normalized resistivity, $\rho(T)/[\rho(70\ K)]$, as a function of temperature for a-$Fe_{90-x}Mn_xZr_{10}$ with (a) $x=0$ and (b) $x=8$ for different values of the applied magnetic field: 0 T (■); 0.7 T (○); and 4.0 T (●).

seen that the magnitude of the spontaneous resistive anisotropy decreases with increasing Mn concentration. The technical saturation is achieved at lower applied field values in the longitudinal mode than in the transverse case and this is an indication that the domain rotation process occurs at lower fields for the longitudinal geometry.

The present materials are concentrated magnetic alloys and variations in the exchange interaction between localized

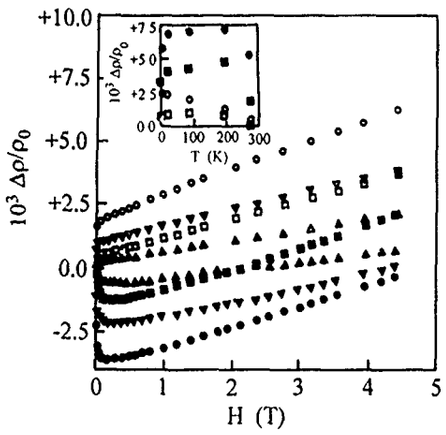

FIG. 4. $\Delta\rho/\rho_0=[\rho(H,T)-\rho(0,T)]/[\rho(0,T)]$ as a function of applied magnetic field for $x=0$ (●,○); $x=4$ (▼,▽); $x=8$ (■,□); and $x=12$ (▲,△). Closed symbols represent the transverse mode and open symbols represent the longitudinal mode. Inset: magnetoresistance as a function of temperature for $x=0$ (closed symbols) and $x=8$ (open symbols) in an applied field of 0.7 T (□,■) and 4.0 T (○,●).

moments at the first nearest-neighbor distance will result in the formation of regions of short range ferromagnetic and antiferromagnetic order. The large values of high field susceptibility which have been observed for the present series[1] have been interpreted in terms of weakly coupled antiferromagnetic spins and are a prerequisite for the existence of a Kondo anomaly. However, the longitudinal magnetoresistance as measured in the present work is positive at all temperatures (see insert in Fig. 4 for $x=0$ and 8) and this is inconsistent with the assumption that T_{min} is due to Kondo behavior. It is also seen that the magnetoresistance shows a maximum at a temperature near T_C. Similar behavior has also been observed in rare earth-transition metal alloys[6] and has been attributed to the effects of coherent exchange scattering. The present results are, therefore, consistent with the CES model and it is suggested that the magnetic and electronic transport behavior observed for the series of a-$Fe_{90-x}Mn_xZr_{10}$ alloys can be explained on the basis of this model.

Field dependence of nuclear magnetic resonance in molecular beam epitaxy grown Co(111)/Cu multilayers

T. Thomson, H. Kubo,[a] J. S. Lord, and P. C. Riedi
Department of Physics, University of St. Andrews, St. Andrews, Fife KY16 9SS, United Kingdom

M. J. Walker
Department of Physics, University of Leeds, Leeds LS2 9JT, United Kingdom

An initial study of the field dependence of ^{59}Co nuclear magnetic resonance (NMR) has been undertaken for two Co/Cu(111) multilayer films grown by molecular beam epitaxy. The multilayer structure of the films was nominally identical, $[Co(15\ Å)/Cu(7\ Å)]_{\times 20}$, however by growing the multilayers with similar structures on different buffer layers, Cu(200 Å) and Au(10 Å), saturation magnetoresistances $\Delta R/R$ of 4% and 22%, respectively, were obtained. The NMR signal in ferromagnetic materials arises due to the enhancement effect from the electronic magnetization. This enhancement effect is therefore a function of the domain structure and any external magnetic field. By applying a simple model of how the NMR enhancement factor varies with applied field, in the absence of a domain structure, the anisotropy fields at the interfaces and in the bulk were determined separately at $T=4.2$ K. These were then compared with the coercive field obtained from magnetization measurements. Our results show that at low temperature the anisotropy field at the interfaces is approximately equal to the coercivity obtained from magnetization measurements (260 Oe), while in the bulk the anisotropy field was found to be ~550 Oe for the low magnetoresistance sample with $\Delta R/R=4\%$, and ~1230 Oe for the high magnetoresistance sample with $\Delta R/R=22\%$.

I. INTRODUCTION

The technique of spin echo nuclear magnetic resonance (NMR) using the ^{59}Co nucleus has already provided significant structural information on Co/Cu(111) superlattices.[1–3] In particular it has been established that sharp interfaces in molecular beam epitaxy (MBE) grown Co/Cu(111) multilayers are not incompatible with giant magnetoresistance (GMR).[4] This article extends the NMR work on these materials by considering the field dependence of the NMR at a temperature of 4.2 K. Investigating the field dependence of the NMR in ferromagnetic materials allows the change in the enhancement factor of the signal intensity to be examined, which can then be related to the domain structure and anisotropy fields.

In MBE grown Co/Cu(111) multilayers the NMR frequency of the nuclei with parent atoms at a plane interface (nine nearest-neighbor Co atoms and three nearest-neighbor Cu atoms) is ~46 MHz below that of those nuclei in the bulk (12 nearest-neighbor Co atoms). This separation allows independent investigation of the magnetic environment associated with the interfaces and the bulk. If a magnetic field large enough to remove the domain structure is applied, the anisotropy field can be determined from the field dependence of the NMR signal. Hence the anisotropy field can be determined separately for the interfaces and the bulk.

II. THEORY

The utility of ^{59}Co NMR arises from the fact that the effective field (B_{eff}) experienced by a nucleus depends on the atomic environment of the parent atom. When applied to MBE grown Co/Cu(111) superlattices, B_{eff} is essentially determined by the parent atom and the surrounding nearest-neighbor atoms. Thus B_{eff} can be written as

$$B_{\text{eff}}=a\mu_{\text{self}}+b\Sigma\mu_i, \tag{1}$$

where the first term is due to the parent atom and the second term is due to the nearest neighbors. Work on Co/Cu alloys and multilayer materials[3,5,6] has shown that the second term contributes a discrete shift of about −16 MHz per atom when a nearest-neighbor Co atom is replaced by a Cu atom.

NMR is observable in ferromagnetic materials due to the enhancement effect.[7,8] The amplitude of the rf field experienced by a nucleus has two components: a regular component due to the applied rf field, and an enhanced component due to the oscillation of the electronic magnetization induced by the applied rf field. In a domain wall or in a domain within a low anisotropy material the enhancement factor is of the order of $\eta\approx 10^3$. Thus the response of the nuclei to an applied resonance rf field is largely determined by the electronic enhancement factor (η). In a spin echo experiment the magnitude of the received echo is also proportional to η.

The enhancement factor varies according to the situation of the electron spin moments responsible for the electronic magnetization. In the absence of domain walls the strength of the NMR signal for a particular environment can be related to the domain enhancement factor η_d where $\eta_d \gg 1$[8] by

$$\text{signal}\propto \eta_d \propto \frac{B_{\text{eff}}}{B_{\text{app}}+B_{\text{ani}}}, \tag{2}$$

where B_{eff} is the effective field at the nucleus, B_{app} is the applied field, B_{ani} is the anisotropy field experienced by the atoms under consideration.

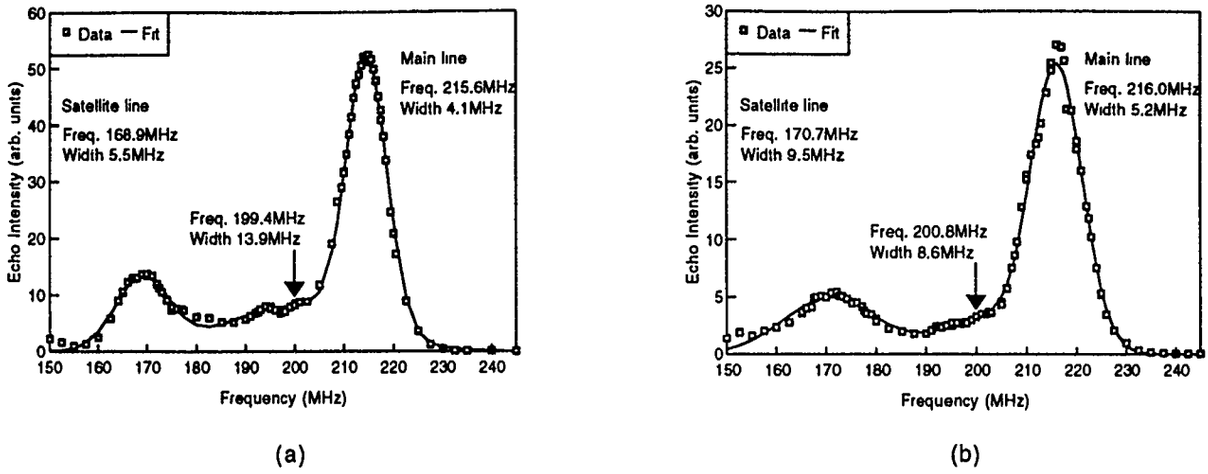

FIG. 1. ^{59}Co NMR spectrum for good quality Co/Cu(111) multilayer films (a) sample No. 66 $\Delta R/R=4\%$, (b) sample No. 56 $\Delta R/R=22\%$.

Thus by measuring the NMR intensity as a function of field, once a sufficiently large field has been applied to ensure that all the domain walls have been swept out, the anisotropy field can be determined.

III. EXPERIMENT

Two samples, Nos. 66 and 56, were produced under similar ultrahigh vacuum conditions by MBE[9] at the SERC facility located at the University of Leeds. The films were grown on GaAs(110) substrates with a Ge(500 Å)/Co(15 Å) buffer layer, a Cu(200 Å) seed layer was used for sample No. 66 and an Au(10 Å) seed layer for sample No. 56. The multilayer structure consisted of $[\text{Co}(15\text{ Å})\text{Cu}(7\text{ Å})]_{\times 20}$ with a thin Au cap to inhibit oxidation. The progress of the growth was monitored by *in situ* reflection high energy electron diffraction measurements and these confirmed that they were no

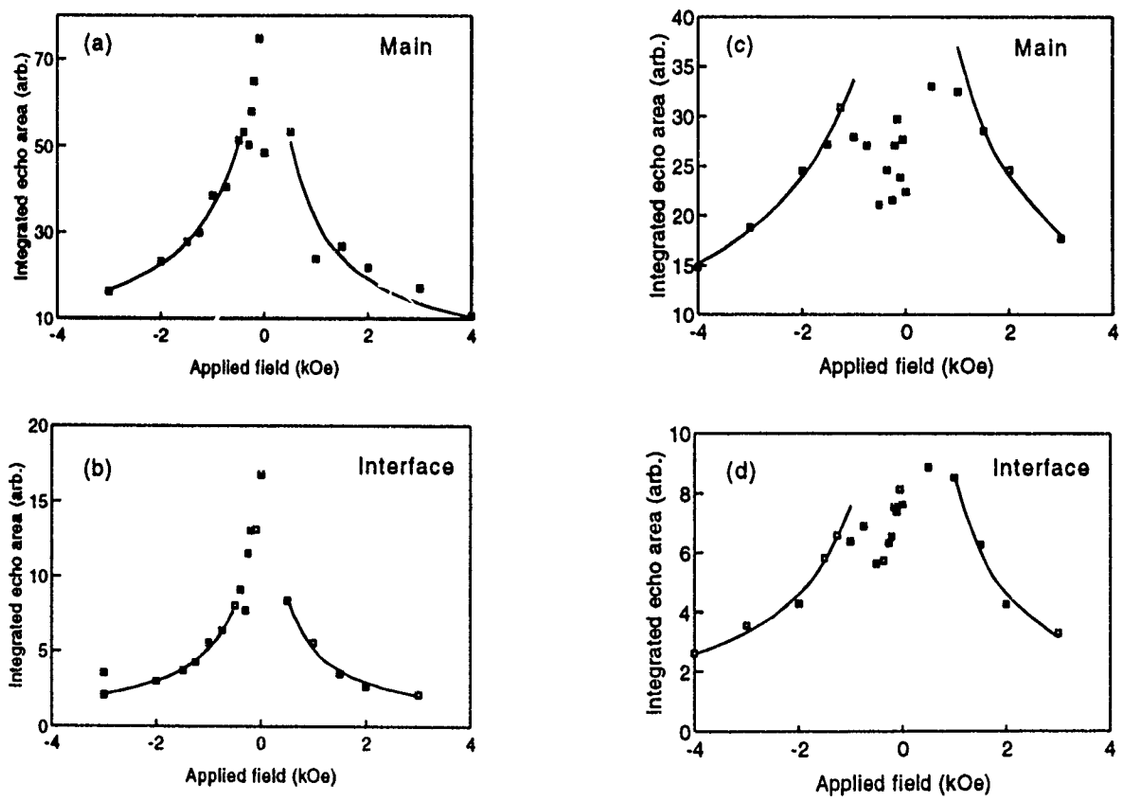

FIG. 2. Field dependence of ^{59}Co NMR integrated area for (a) sample No. 66 main peak (b) sample No. 66 interface peak (c) sample No 56 main peak, (d) sample No. 56 interface peak. A saturating field of 9 kOe was applied prior to each measurement.

TABLE I. Anisotropy fields determined from field dependence of NMR, coercivity measured on a VSM. NMR measured at 4.2 K and H_c at 8 K. Uncertainty in NMR measurements ~100 Oe.

Sample No.	$\Delta R/R$	Anisotropy field (Oe)		Coercive field (Oe)
		Bulk	Interface	
66	4%	550	340	260
56	22%	1230	360	260

gross structural differences between the films. However recent work[10] has confirmed that in these MBE grown materials an increase in the GMR is correlated with less interfacial roughness. The saturation magnetoresistance in a field of ~6 T and a temperature of $T=4.2$ K was $\Delta R/R=4\%$ for sample No. 66 while for No. 56, $\Delta R/R=22\%$.

The ^{59}Co NMR was measured using a swept frequency, coherently detected spin echo spectrometer.[11] The pulse power was adjusted to ensure the maximum response at each field and frequency. The data collected were corrected for ω^2 in the usual way. A further correction to allow for the variation in spin-spin relaxation time, T_2, as a function of frequency was also carried out. The final data therefore gave an accurate representation of the product of the enhancement effect and the number of nuclei in a particular atomic environment at all frequencies and fields.

The coercivity was measured at $T=8$ K in a PAR 4500 vibrating sample magnetometer (VSM) fitted with a CF1200 cryostat and a bipolar power supply.

IV. RESULTS AND DISCUSSION

The zero applied field spectrum, shown in Fig. 1 for both sample Nos. 66 and 56, demonstrates the typical features of a good quality Co/Cu(111) multilayer, with a peak at ~170 MHz associated with the 3×Cu, 9×Co nearest-neighbor configuration of a perfect interface, and a main peak at ~215 MHz due to Co atoms in a bulk fcc environment. The shift in the main peak frequency from the value of 217.4 MHz found in free fcc Co powder is due to strain caused by the lattice mismatch (2%) between Cu and Co which increases the atomic spacing of the Co in the plane of the film. The small echo intensity between these peaks is probably due to Co atoms surrounded by one or two Cu atoms.

Figure 2 shows the field dependence of the integrated echo intensity for both the main peak and interface peak of sample Nos. 66 and 56. The parameters obtained from fitting Eq. (2) are summarized in Table I. In order to ensure that the multilayer was in a single domain state the data was fitted over the range of applied field for which the gyromagnetic ratio (γ) had the value associated with free Co. The gyromagnetic ratio was determined from the shift in NMR peak frequency as a function of field. This shift was similar for both the interface and bulk peaks in a particular sample, and in the absence of domain structure was close to the free Co value of $\gamma=10.054$ MHz/T.

Table I shows that the interfacial anisotropy field determined from NMR measurements is, within error, the same for both samples and is similar to the coercivity. If these data are correlated, then it implies that magnetization reversal is nucleated at the interfaces. The anisotropy field measured for atoms in a bulk environment is larger than that measured at the interfaces, and shows significant differences between the two samples.

V. CONCLUSIONS

By examining the high field region of the field dependence of the NMR of Co/Cu multilayers, the NMR response can be fitted to a simple model that allows independent determination of the anisotropy field in the bulk and at the interfaces. Our results show that an anisotropy field, approximately equal to the coercivity, exists at the interfaces. The ratio of bulk to interface anisotropy was found to be approximately double for the sample exhibiting a stronger GMR effect.

Dependence of giant magnetoresistance in Co/Cu multilayers on the thickness of the Co layers

A. M. Shukh,[a] D. H. Shin, and H. Hoffmann
Institut für Angewandte Physik III, Universitat Regensburg, 93053 Regensburg, Germany

The dependence of the giant magnetoresistance (GMR) on the thickness of the Co layers in Co/Cu multilayers was investigated experimentally. The thickness of the Cu layer was held constant at t_{Cu}=19 Å, which corresponds to the second maximum of the GMR ratio oscillating dependence on t_{Cu}. The Co layer thickness was varied from 4.8 to 79.0 Å. High resolution transmission electron microscopy showed the existence of the two-dimensional artificial superstructure with defined periodicity as well as sharp and flat interfaces. From wide angle x-ray diffraction it was concluded that at Co layer thickness below 40 Å the multilayers are polycrystalline with mainly fcc lattice structure and (111) texture. In the case of thicker Co layers indications of hcp Co could be found. The GMR ratio reaches a maximum at Co layer thickness about 11 Å. It was shown that the GMR in sputtered Co/Cu multilayers is due to spin scattering at the interfaces and resistance is strongly influenced by interface scattering.

I. INTRODUCTION

Considerable attention is paid in the literature to the giant magnetoresistance (GMR) effect observed in multilayers composed of alternating metal and ferromagnetic layers of special thicknesses. Since the discovery of GMR in Fe/Cr multilayers,[1] the effect has been observed in a variety of multilayer systems. At present the Co/Cu multilayers seem to be of the greatest interest because of the large GMR and of its weak temperature dependence.[2–4] Because of these properties this system could be a candidate for an application.

The dependence of the GMR in Co/Cu multilayers on the thickness of the Cu interlayers is well known from the previous publications.[2,3,5] However the influence of the Co layer thickness on the amount of the GMR has not been clarified yet. In this article we report about such experiments and their results.

II. EXPERIMENT

The multilayers Fe(100 Å)/[Co(t_{Co})/Cu(t_{Cu})]$_{20}$/Fe(50 Å) were deposited onto glass substrates (diameter 10 mm) at room temperature. The base pressure before the deposition was below 8×10^{-8} Torr and the Ar pressure during sputtering was kept 6.0 mTorr. The glass substrates were chemically cleaned and plasma etched just before the deposition.

An Fe buffer layer with the thickness t_{Fe}=100 Å and Fe protective layer at t_{Fe}=50 Å were dc magnetron sputtered, while the Co/Cu multilayers were deposited by rf sputtering. By experience, Co/Cu multilayers with the Fe buffer layer usually exhibit a much larger GMR ratio[4,6,7] than systems without an Fe buffer, especially in the case of Cu layer thickness below 10 Å. The deposition rates were between 1.8 and 3.0 Å/s, calibrated by x-ray fluorescence measurements. The thicknesses t_{Cu}, t_{Co}, and t_{Fe} were determined from the calibrated deposition rates and sputtering time as well as multilayer cross-sectional investigations by transmission electron microscopy (TEM). The multilayers showed the existence of a two-dimensional artificial superstructure with defined periodicity, as well as sharp and flat interfaces.

The magnetoresistance of the multilayers was investigated at room temperature by a four-point method. The electrical current was oriented in plane of the multilayers. The external magnetic field was applied in plane perpendicular to the current. The magnetoresistance ratio $\Delta R/R_s$ is defined by $\Delta R/R_s=(R_m-R_s)/R_s$, where R_m is a maximum value of the resistance, and R_s is resistance of multilayer at magnetic saturation in the applied magnetic field. The magnetization loops of the samples were taken by a vibrating sample magnetometer at room temperature. The structure of the multilayers was investigated using x-ray diffraction.

III. RESULTS AND DISCUSSION

For constant thickness of the Co layers (t_{Co}=10.8 Å) the oscillation of the GMR ratio $\Delta R/R_s$ with variation of the Cu interlayer thickness t_{Cu} coincides with the oscillation of the saturation field H_s. In the thickness interval 6.6 Å$\leq t_{Cu}\leq$30.4 Å we found three maxima for the GMR ratio $\Delta R/R_s$ and the saturation field H_s at t_{Cu} equal to 9, 19, and 30 Å, respectively. Our results are in good agreement with the results of other authors.[2,3,5] The maximum of the GMR ratio (ranging up to $\Delta R/R_s$=36% at room temperature) was always observed for the multilayers with the interlayer thickness $t_{Cu}\approx$9 Å. Regarding the thickness of the Cu layer the oscillation period is about 10 Å.

In this article the dependence of the GMR on the thickness of the Co layers t_{Co} at constant thickness of the Cu interlayers t_{Cu} should be investigated. A thickness t_{Cu}=19 Å (second maximum of the GMR ratio dependence on t_{Cu}) has been selected. By experience, at this thickness the experiments showed good reproducibility. Typical magnetoresistance loops for three samples with various thicknesses of the Co layers t_{Co} are given in Fig. 1 for t_{Co}=4.8, 18, and 79 Å, respectively.

Figure 2 shows the wide angle x-ray diffraction patterns of Co/Cu multilayers with various Co layer thicknesses. At $t_{Co}<$40 Å multilayers are fcc with predominantly (111) texture. The same was found in Co/Cu multilayers grown by molecular beam epitaxy.[8] With increasing t_{Co} all peaks shift

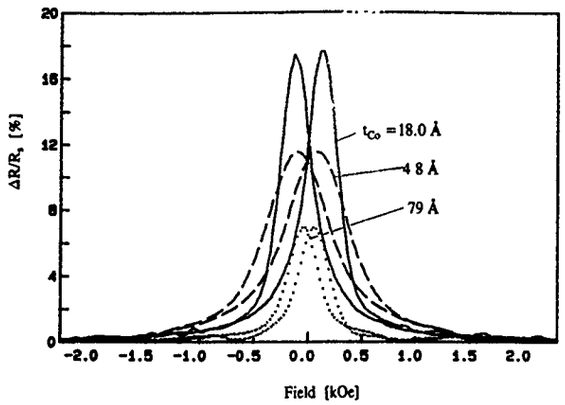

FIG. 1. Transverse magnetoresistance vs in-plane field for three multilayers of the form Fe(100 Å)/[Co(t_{Co})/Cu(19 Å)]$_{20}$/Fe(50 Å) for Co layer thicknesses 4.8, 18, and 79 Å at room temperature.

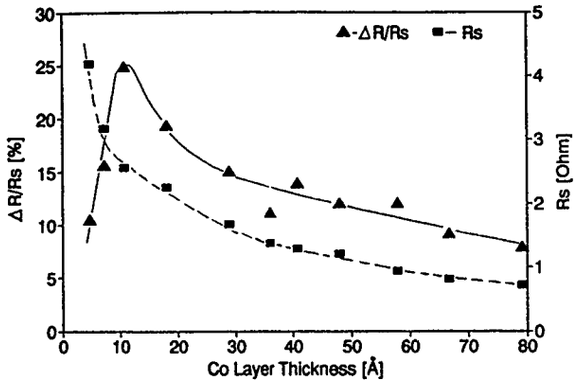

FIG. 3. GMR ratio $\Delta R/R_s$ and resistance R_s at magnetic saturation vs Co layer thickness for Fe(100 Å)/[Co(t_{Co})/Cu(19 Å)]$_{20}$/Fe(50 Å) multilayers.

toward the higher 2θ values (smaller value of the lattice, peculiar to the Co layers). The intensities of (111), (200), and other fcc peaks decrease but the intensity of a left-side satellite peak of (111) increases with t_{Co} increase. This peak approximately corresponds to (100) peak of hcp Co. The presence of the hcp phase in sputtered Co/Cu multilayers at t_{Co}=30 Å was observed by nuclear magnetic resonance spin-echo investigation.[9]

The dependences of the GMR ratio $\Delta R/R_s$ and the total resistance of the multilayers at magnetic saturation R_s on the thickness of the Co layers are given in Fig. 3. As can be seen from Fig. 3 the GMR ratio reaches a maximum ($\Delta R/R_s$=25%) at $t_{Co}\approx$11 Å and decreases with increasing thickness of the Co layers. The GMR ratio $\Delta R/R_s$ depends on ΔR as well as on R_s. Due to the film structure both values depend on different ways on the thickness t_{Co} of the Co layers. This needs to separate ΔR and R_s for the discussion.

The change of the resistance ΔR of the multilayers is given by the difference of the resistance of the multilayer system at antiparallel and parallel alignments of the magnetization of the adjacent ferromagnetic Co layers. This difference $\Delta R = R_m - R_s$ should be solely caused by the difference of the spin scattering due to the orientation of the magnetization. Figure 4 shows the dependence of ΔR on the reciprocal thickness $1/t_{Co}$ of the Co layers. From the straight line for all thicknesses above t_{Co}>10 Å it has to concluded that the observed GMR is due to interface spin scattering. This finding agrees with former results.[10] The decrease of ΔR at layer thickness t_{Co}<10 Å ($1/t_{Co}$>0.11/Å) will be discussed below.

The dependence of the resistance R_s of the multilayer at magnetic saturation on the thickness t_{Co} of the single Co layers is given in Fig. 3. Magnetic saturation means that the magnetic moment of all single layer Co films are parallel aligned, due to the applied external magnetic field. In this case we do not need to separate the spin-dependent part of scattering. The application of a model of parallel resistors allows us to obtain for the total conductance $1/R_s$

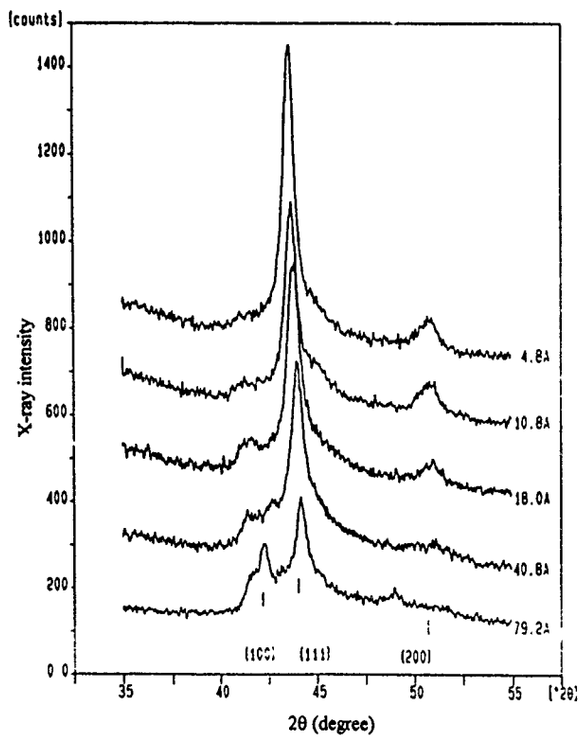

FIG. 2. Wide angle x-ray diffraction patterns of Co/Cu multilayers with various thickness of Co layers (Cu K_α radiation).

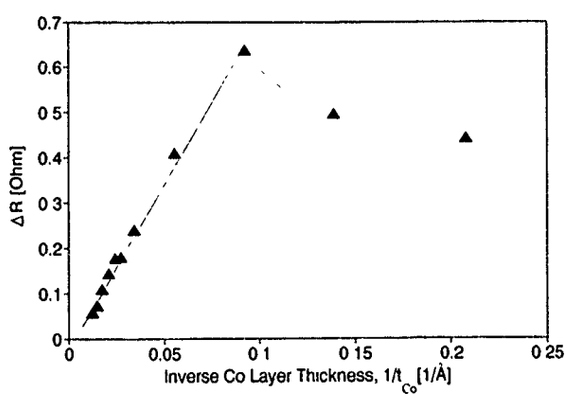

FIG. 4. Magnetoresistance change ΔR as a function of inverse Co layer thickness for the multilayers Fe(100 Å)/[Co(t_{Co})/Cu(19 Å)]$_{20}$/Fe(50 Å).

$$\frac{1}{R_s}=\frac{1}{R_{\text{Fe buffer}}}+\frac{1}{R_{\text{Fe prot}}}+N\left(\frac{1}{R_{\text{Cu}}}+\frac{1}{R_{\text{Co}}}\right), \tag{1}$$

where $R_{\text{Fe buffer}}$ and $R_{\text{Fe prot}}$ are resistances of the Fe buffer and Fe protection layers, respectively, N is the number of the Co/Cu periods of the multilayers, and R_{Cu} and R_{Co} are resistances of the single Cu and Co layers, respectively.

Since in the present experiments the thicknesses of the Fe buffer layer, of the Fe protection layer, of the Cu layers, and the number of periods were constant it is assumed in a first approximation

$$1/R_s=A+N/R_{\text{Co}} \tag{2}$$

with a constant value

$$A=(1/R_{\text{Fe buffer}})+(1/R_{\text{Fe prot}})+(N/R_{\text{Cu}}). \tag{3}$$

This constant value needs a special investigation, which has been shown in other publications.[10,11]

The dependence of the total resistance on the thickness t_{Co} of the Co layers has to be discussed on the thickness dependence of the resistivity of the films, including surface scattering and the fluctuation of the film thickness. These discussions have been given in the past.[11] For a very first approach it is assumed that the Co layers are continuous and of constant thickness. (The lower thicknesses will be discussed below.) In this case the resistance R_{Co} of a single Co layer depends on its thickness t_{Co} and is given by

$$R_{\text{Co}}=\rho_{\text{Co}}L_{\text{Co}}/W_{\text{Co}}t_{\text{Co}}, \tag{4}$$

where L_{Co} and W_{Co} are the length and width of the Co layers, respectively. Due to Sondheimer[12] approximation of Fuchs'[13] theory

$$\rho_{\text{Co}}=\rho^{\infty}_{\text{Co}}\left(1+\frac{3}{8}\frac{l^{\infty}_{\text{Co}}}{t_{\text{Co}}}\right), \tag{5}$$

where l^{∞}_{Co} and $\rho^{\infty}_{\text{Co}}$ are the mean free path of the electrons and the resistivity of infinite thick Co films, respectively. In the case $l^{\infty}_{\text{Co}}\gg t_{\text{Co}}$ which can be assumed in a very first approximation one obtains

$$\rho_{\text{Co}}=3l^{\infty}_{\text{Co}}\rho^{\infty}_{\text{Co}}/8t_{\text{Co}}, \tag{6}$$

and

$$R_{\text{Co}}=b/t^2_{\text{Co}}, \tag{7}$$

where

$$b=\frac{3}{8}\frac{L_{\text{Co}}}{W_{\text{Co}}}l^{\infty}_{\text{Co}}\rho^{\infty}_{\text{Co}}=\text{const.} \tag{8}$$

This leads to

$$1/R_s=A+(N/b)t^2_{\text{Co}}. \tag{9}$$

In Fig. 5 the inverse $1/R_s$ of the resistance R_s is plotted against the square t^2_{Co} of the thickness of the Co layers,

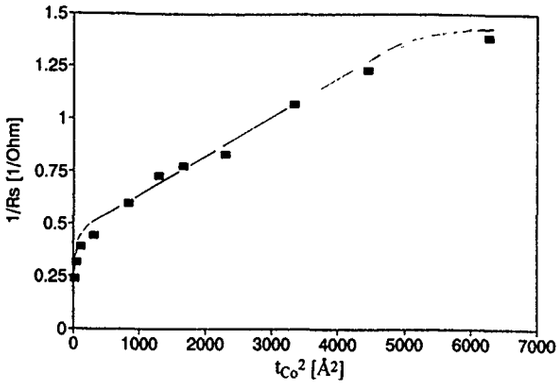

FIG. 5. Inverse resistance $1/R_s$ at magnetic saturation vs square thickness of Co layer for Fe(100 Å)/[Co(t_{Co})/Cu(19 Å)]$_{20}$/Fe(50 Å) multilayers.

which leads to a straight line. Deviation at large thickness are explained since there the approximation $l^{\infty}_{\text{Co}}\gg t_{\text{Co}}$ is not longer valid.

At small thickness $t_{\text{Co}}<25$ Å of the Co layer one has to take care of the layer roughness, which on mesoscopie scale leads to fluctuation of the layer thickness and increases the resistance. This effect is not included in the foregoing considerations. The system then is described by Co islands in a Cu matrix, which can be seen from Fig. 2.

Vertical inhomogeneity of the magnetization reversal in antiferromagnetically coupled Co/Cu multilayers at the first maximum

R. Mattheis, W. Andrä, L. Fritzsch, J. Langer, and S. Schmidt
Institut für Physikalische Hochtechnologie Jena, PF 100 239, D-07702 Jena, Germany

Magnetization behavior in antiferromagnetically (AFM) coupled multilayer systems was calculated by using an atomic layer model. Comparisons with the experimental results obtained on sputtered Co/Cu multilayers reveal remarkable differences in the magnetization reversal and in the field dependence of the magnetoresistance. Kerr loops measured from both sides of the stack display strong vertical differences. At the lower side near the Fe seed layer the magnetization reversal is in good agreement with that of our calculations whereas near the surface in large portions of the stack the AFM coupling is destroyed or varied. These effects are presumably caused by magnetic short circuits at defects in the multilayer structure. Cross-section transmission electron microscopy reveals growth defects which seem to be responsible for the deviations from the calculated ideal behavior.

I. INTRODUCTION

Due to their large magnetoresistance (MR) value up to 80% at room temperature,[1] Co/Cu multilayers are favored candidates for advanced magnetoresistive applications. A large scatter in the amplitude of the MR and also the saturation field, H_s has been found.[2–5] Defects in the multilayer stack causing magnetic short circuits (MSC) seem to be responsible. A linear correlation between the amplitude of the giant magnetoresistance (GMR) and the antiferromagnetically (AFM) coupled part of the stack was found.[4]

We prepared Co/Cu stacks on thermally oxidized Si wafers and glass plates. Details of the preparation are reported elsewhere.[5] Each Co/Cu stack consists of 24 pairs of 1.7 nm Co and x nm Cu with a 3.4 nm Co covering layer. In some samples a 5 nm Fe buffer layer was used. Magneto-optical investigations were performed using the longitudinal Kerr effect. For transmission electron microscopy a Philips CM 20 was used.

II. RESULTS AND DISCUSSION

A. Magnetization reversal and GMR calculated for ideal multilayers

Calculations of the magnetization reversal were performed using the atomic layer model (ALM).[6] Both systems, Co/Cu multilayers with and without Fe seed layer, were calculated assuming constant AFM coupling C_i between all Co layers and vanishing in-plane anisotropy. The field dependence of the MR was estimated by using the angle differences between nearest Co layers and their parallel connection to determine the total resistance.

A linear dependence of the magnetization and a parabolic dependence of the MR were obtained only for a stack with two Co layers ($n=2$) with no Fe buffer. In Fig. 1 the angle of magnetization of each individual Co layer for systems with even numbers of Co (4 and 24) layers is shown. The outermost Co layers, with only one neighboring Co layer, react most sensitively and strongly deviate from the cosine law throughout the whole magnetization process. The inner layers show strong differences only at low fields ($<0.25\ H/H_s$). Systems with an odd number of Co layers possess a nonvanishing residual magnetization at zero field, stable up to a threshold field H_{th} (Fig. 2). The value for H_{th} decreases with increasing number of Co layers. The resulting $M(H)$ curves are very similar to those with even number of bilayers for fields higher than H_{th}. Our MR curves are normalized with respect to the ordinate (at $H=0$) as well as to the abscissa (at $H=H_s$). The deviation from the parabolic curve is small for even n (Fig. 2). For odd n it decreases with increasing number n.

In the case of an Fe buffer the state at the remanence is determined by the Fe layer independent of the number n. Therefore, the angle dependence resembles that of one of the systems without an Fe buffer and odd n (Fig. 3). With increasing n the curves become more and more similar to those without an Fe buffer. In general, a nearly linear behavior of the AFM-coupled Co magnetization with increasing field is obtained with small deviations at low and high fields. A similar tendency was found for the magnetoresistivity.

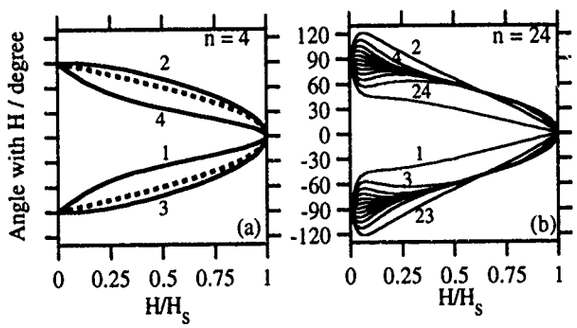

FIG. 1. Angle of the magnetization of each individual Co layer vs normalized field in a four bilayer (a) and a 24 bilayer (b) stack without an Fe buffer. The numbers indicated on the curves refer to the individual Co layer beginning from the substrate surface. In (a) the cosine law is shown as a dotted line. This is the exact solution obtained for $n=2$.

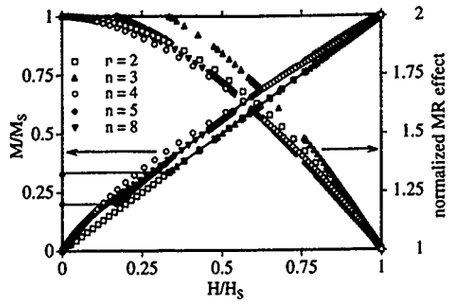

FIG. 2. Relative magnetization and normalized MR vs normalized field for different numbers of Co/Cu bilayers. The MR values were normalized to a value of 2 and 1 for zero field and saturation field H_s, respectively.

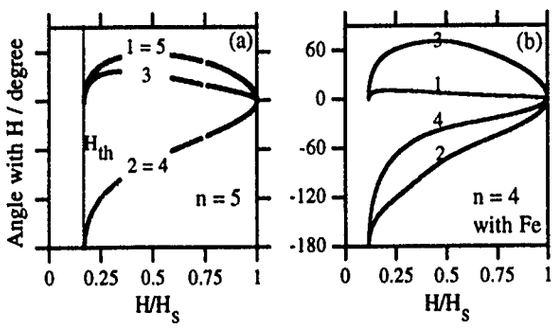

FIG. 3. Angle of the magnetization of each individual Co layer vs normalized field in a five bilayer stack without Fe buffer (a) and four bilayer stack with Fe buffer (b). In the stack without Fe buffer (a) the magnetization in the first and fifth layer as well as in the second and fourth layer is identical. Additionally in (a) the position of the threshold field is indicated.

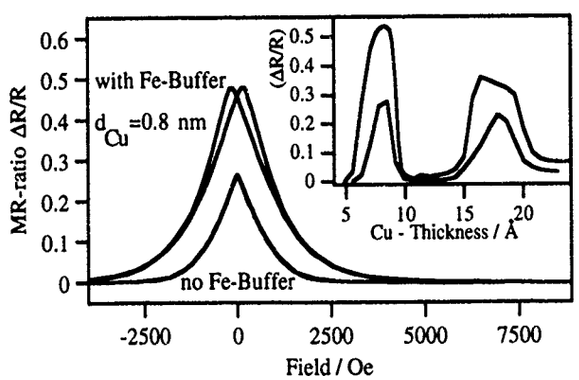

FIG. 4. Resistance vs applied field for our Co/Cu system with and without Fe buffer at the first maximum. The inset shows the amplitude of the GMR vs the thickness of the Cu spacer layer.

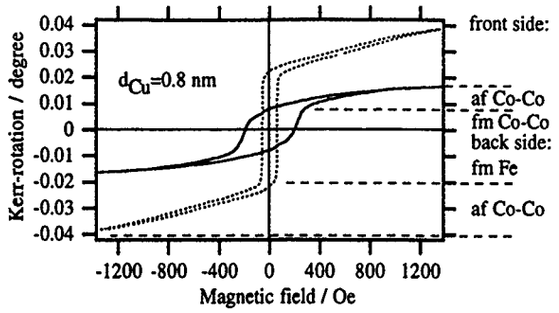

FIG. 5. Kerr loops from frontside (solid line) and backside (dotted line) of our Co/Cu system with Fe buffer. Backside means substrate side. The small Faraday rotation caused by the glass substrate was taken away. It is obvious that the AFM fraction measured from the backside is larger than that measured from the frontside. The ferromagnetic fraction detected from the backside is due to the Fe buffer.

B. Experimental results

An Fe buffer causes a strong increase in the amplitude of GMR and also of the saturation field H_s (Fig. 4). The measured dependence of $R(H)$ in both systems is different from the one calculated in A but nearly the same on glass and thermally oxidized silicon.

The magnetization reversal was studied by Kerr loops taken from both sides of the multilayers on glass substrates (information depth ≈25 nm).[7] For a multilayer with an Fe buffer (Fig. 5) the Kerr angle rotation resembles the calculated magnetization curve only at the lower part of the stack near the Fe buffer. Due to differences in H_c for Fe and Co (Fig. 5) we estimated that 100% of the lower and 60% of the upper part are AFM coupled: Bearing in mind the results of our structural investigations, layer defects concentrated in the upper part may be responsible for the observed behavior. The Kerr loops on Co/Cu multilayers without Fe buffers (Fig. 6) show a remarkable proportion of ferromagnetically coupled Co even near the substrate.

Cross-section transmission electron microscopy (XTEM) on stacks with Fe buffers (Fig. 7) reveals that the interfaces between Co and Cu get rougher with increasing distance from the substrate surface. At the arrow the metallic layers are interrupted and slightly shifted due to a grain boundary.

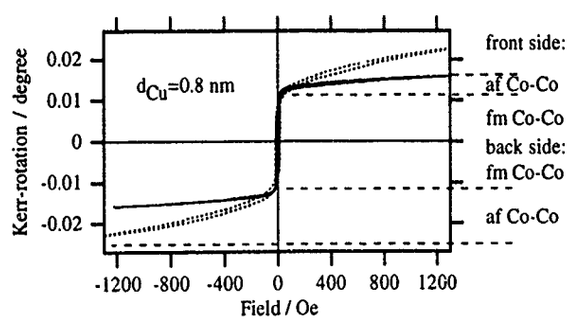

FIG. 6. Kerr loops from frontside (solid line) and backside (dotted line) of our Co/Cu system without Fe buffer. The small Faraday rotation caused by the glass substrate was taken away.

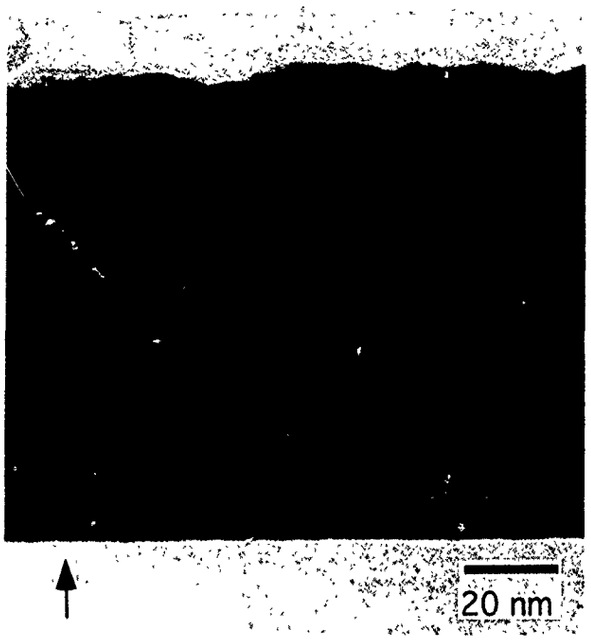

FIG. 7. Low magnification cross-sectional image of the system $Si/SiO_2/Fe(50\ Å)/[Co(17\ Å)/Cu(22\ Å)]_{24}/Co(34\ Å)$, underfocus. The arrow indicates a defect induced by a grain boundary. Co layers appear darker, Cu layers lighter.

In all other areas the metallic layers exhibit continuous straight lines without defects. The cross sections of multilayers without Fe buffers show smaller grains both in lateral and vertical dimension. Because of the greater number of grain boundaries it is reasonable that these systems contain more defects in their layer structure. Moreover, the interfaces between the layers are rougher compared to systems with Fe buffers.

C. Influence of structural defects

To check the influence of a lateral defect causing a MSC between neighboring Co layers a model similar to the ALM was used. The MSC was assumed to have the shape of a nearly straight line with a width of a few lattice constants. This may be caused by grain grooving at the grain boundary as is depicted in the marked region in Fig. 7. The two Co layers are magnetized in antiparallel directions for $H=0$ a great distance from the MSC. Due to the ferromagnetic exchange coupling at the MSC the magnetization directions are locally rotated towards the defect line. Taking into account the coupling between the two short circuited layers and including their nearest Co neighbors, the local magnetization distribution can be calculated. First estimations yielded a width of the magnetization distortion in the range of 10–100 nm depending on the coefficient of a AFM coupling.

III. CONCLUSIONS

Deviations from the simple cosine law for the calculated field dependence of the direction of magnetization were found in all systems with Fe buffer layer and in systems without Fe for $n>2$. These deviations are primarily limited to the outer layers on both sides. Comparisons between the calculated and measured magnetization and MR curves display remarkable differences. Depth selective Kerr loops show strong indications for vertical inhomogeneities. These are probably caused by defect regions responsible for the ferromagnetic part of the magnetic reversal of the upper layers. XTEM investigations reveal MSCs at grain boundaries which could be a possible source for the observed effects. The use of the Fe buffer layer seems to improve the perfection of the multilayer structure, at least for the first layers of the stack.

The structure and magnetic properties of sputtered Co/Cu multilayer films with various layer thicknesses have been studied. X-ray diffractometry and high resolution electron microscopy show the films to be polycrystalline with a fcc structure and strong [111] texture in the growth direction. The magnetoresistance (MR) of the films depends critically on Cu layer thickness (t_{Cu}), with maximum values for films with t_{Cu} around 1 nm. Large differences in saturating field are seen for films with t_{Cu} and t_{Co} differing by a nominal 0.1 nm. The magnetic domain structure, studied using Lorentz microscopy, shows strong dependence on t_{Cu}. High MR-value films showed evidence of antiphase magnetic domain boundaries. The high MR samples show antiferromagnetic coupling, with higher saturating fields than seen in the ferromagnetically coupled films.

I. INTRODUCTION

Multilayer films (MLFs) exhibiting giant magnetoresistance (GMR) are of interest both because of their fundamental properties and because of their potential development as magnetoresistive read heads and sensors. GMR was first discovered in Fe/Cr MLFs grown by molecular beam epitaxy,[1] and is attributed to the spin dependent scattering of conduction electrons, arising from the antiferromagnetic (AFM) alignment of the magnetization in adjacent Fe layers across the Cr layers. The interlayer exchange coupling associated with the AFM alignment is oscillatory with increasing nonmagnetic layer thickness.[2] Parkin *et al.* reported resistance changes up to 65% at room temperature, in an applied magnetic field of 10 kOe, for Co/Cu MLFs,[3] and in addition, the interlayer coupling constant of the Co/Cu MLFs has been reported to be about 8 times smaller than that of Fe(001)/Cr(001).[4] These properties make Co/Cu a promising system for magnetic sensors or magnetoresistive read heads to replace conventional inductive read heads.

In this article, we report the results of a study of the correlation of the microstructure and magnetic domain structure of sputtered polycrystalline Co/Cu MLFs with the MR and interlayer magnetic coupling.

II. EXPERIMENTAL TECHNIQUES

Co/Cu MLFs were deposited onto native oxide-coated Si (100) wafers in an UHV dc-magnetron sputtering system at the University of Cambridge. A series of 40 period MLFs, with Co layer thickness, t_{Co}, of 1.9 and 2.0 nm and t_{Cu} between 0.5 and 1.3 nm, were grown under 0.68 Pa of argon.

The crystallographic structure and periodicity of the MLFs were studied using a Philips x-ray diffractometer. The atomic-scale structure of the films, and the layer thicknesses, were determined from cross-sectional transmission electron microscopy (TEM) specimens using a JEOL 4000 EX HREM. Plan-view specimens were prepared for TEM and Lorentz microscopy by chemical or argon ion etching, or by floating the films off the substrates. Optical diffractogram (ODM) analysis of the high-resolution electron microscopy (HREM) negatives was used to determine the crystal structure of individual crystallites.

The magnetic domain structure was investigated by Lorentz microscopy, using the Foucault mode which reveals the magnetic domains as areas of different intensity. Use of a specially designed objective aperture mechanism[5] enabled high quality Foucault images to be obtained. Hysteresis curves were obtained at room temperature using an alternating gradient force magnetometer (AGFM) at Bangor University. An applied magnetic field of up to 3 kOe was used both parallel to and perpendicular to the film plane.

The MR of the Co/Cu MLFs was measured by the four-point probe method with magnetic fields parallel to both the film plane and the measuring current at room temperature. The MR ratio was calculated according to

$$r(H)=(R_H-R_{sat})/R_{sat},$$

where R_H is the resistance in an applied magnetic field H, and R_{sat} is the resistance under a saturating magnetic field.

III. RESULTS AND DISCUSSION

Figure 1 shows (a) small-angle and (b) high-angle x-ray diffraction (XRD) patterns from two Co/Cu MLFs with t_{Co}=2.0 nm, and t_{Cu}=0.5 and 1.0 nm. The strong low-angle peaks confirm the clear compositional modulation of the films, and the bilayer thicknesses calculated from the peaks using Bragg's law agree well with the nominal values. The high-angle patterns show a single strong peak between the bulk Cu and Co fcc 111 peak positions (calibrated against the Si 200 peak). With increasing Cu layer thickness the peak shifts toward lower angles. This shift, combined with the small peak width, suggests that large areas of the Co/Cu interfaces are coherent. The Co/Cu MLFs have a strong crystallographic texture, with a predominantly fcc structure and {111} parallel to the film plane. The difference in peak heights between curves A and B is due to differences in specimen area and is therefore not significant.

The [111] texture was confirmed by selected area electron diffraction of both plan-view and cross-sectional speci-

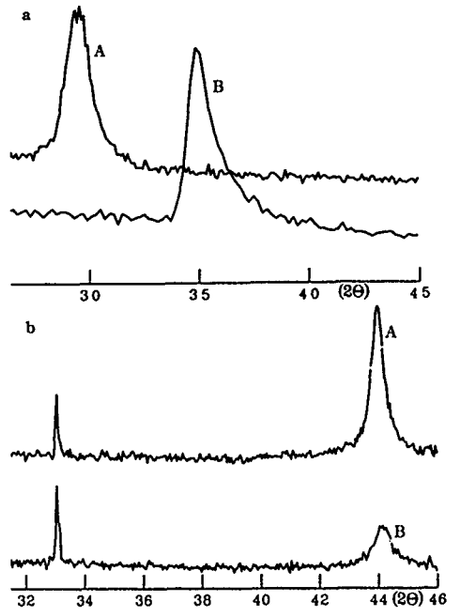

FIG. 1. (a) Low-angle and (b) high-angle XRD patterns from $(Co_{2\,0\ nm}/Cu_{1\,0\ nm})_{40}$ (curve A) and $(Co_{2.0\ nm}/Cu_{0\,5\ nm})_{40}$ (curve B) MLFs. Vertical scale is the intensity in arbitrary units. A and B have been displaced vertically for clarity.

mens. ODM analysis of the HREM images show a dominant fcc structure with a lattice spacing in agreement with the high-angle XRD data. A typical HREM image of a cross-sectional specimen of a $(Co_{2.0\ nm}/Cu_{1.0\ nm})_{40}$ MLF is shown in Fig. 2(a). Textured columnar grains growing normal to the film plane are visible with a constant crystal structure across several layers and coherent Co/Cu interfaces. The columnar grain size, determined from both the XRD peak widths and the HREM images, has a value of about 11 nm for the film shown in Fig. 2. The film quality in all cases is very similar, as expected since the growth conditions were similar. Figure

FIG. 2. (a) HREM image of cross-sectional specimen of $(Co_{2.0\ nm}/Cu_{1\,0\ nm})_{40}$ MLF. Columnar grain boundary is marked. (b) Part of same area shown in (a) taken out of focus to show position of layers. Light contrast Cu layers are arrowed.

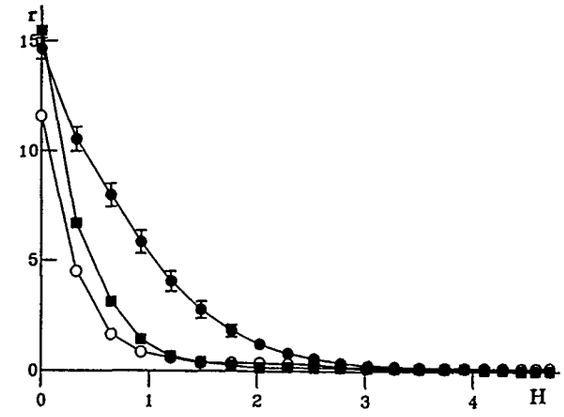

FIG. 3. Plots of r vs **H** (in kOe) for (a) $(Co_{2.0\ nm}/Cu_{1\,0\ nm})_{40}$ (closed circles), (b) $(Co_{1\,9\ nm}/Cu_{1.1\ nm})_{40}$ (closed squares), and (c) $(Co_{1\,9\ nm}/Cu_{1\,0\ nm})_{40}$ (open circles) MLFs. Note the decrease in saturating field for (b) and (c).

2(b) shows part of the same area of film, taken out of focus, to show the layers.

The MR ratio varies greatly for the films, depending on the thickness of the Cu layers, as has been observed by other authors.[6] The $(Co_{2\,0\ nm}/Cu_{0\,5\ nm})_{40}$ film shows zero MR, while films with t_{Cu} around 1 nm show saturation MR values around 15%, as can be seen in Fig. 3. Each curve is the average of three measurements on each of a number of samples with the same nominal layer thicknesses (circles—two samples, squares—three samples). The error bars are only shown for points for which they are larger than the symbols used. The most striking observation is the large decrease in saturating field for a change in nominal layer thickness of 0.1 nm, resulting in an increase in slope of the r vs **H**

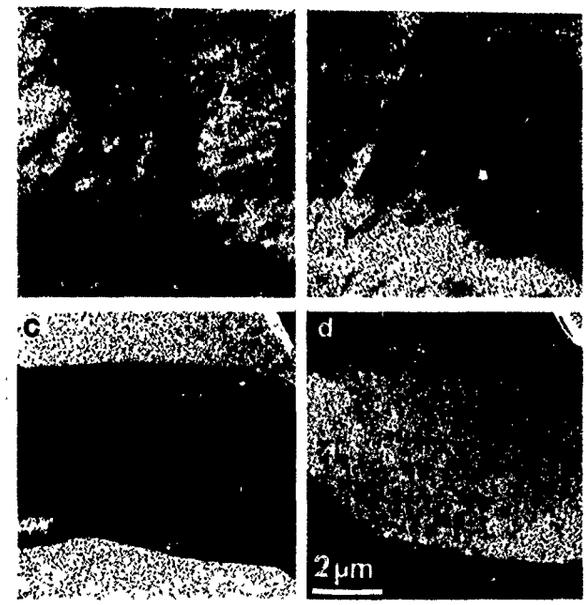

FIG. 4. Foucault images of magnetic domain structure in $(Co_{1\,9\ nm}/Cu_{1\,1\ nm})_{40}$ MLF showing AFM coupling, (a) and (b), and $(Co_{2\,0\ nm}/Cu_{0\,5\ nm})_{40}$ MLF showing FM coupling (c) and (d). Easy axis of magnetization in film plane for both films.

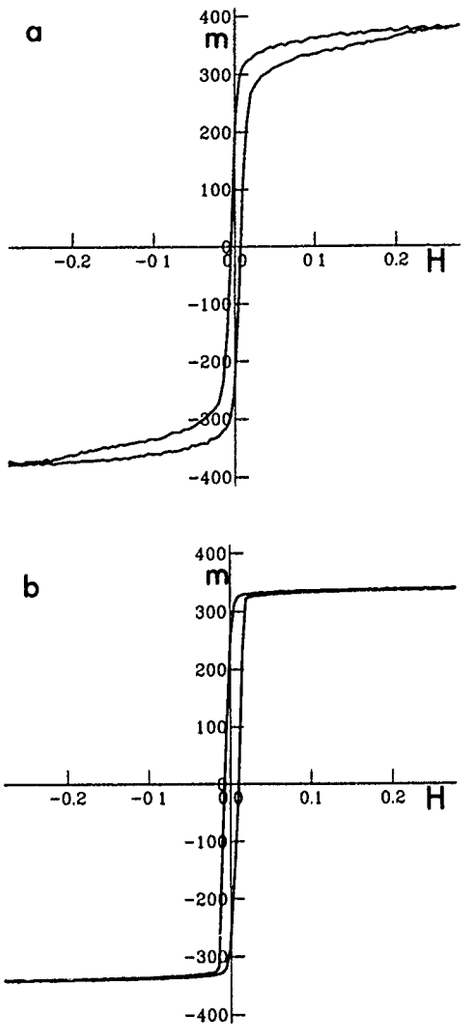

FIG. 5. Hysteresis loops (magnetic moment m in μemu against field H in kOe) obtained using an AGFM for (a) $(Co_{1.9\ nm}/Cu_{1.1\ nm})_{40}$ MLF showing AFM coupling, and (b) $(Co_{2.0\ nm}/Cu_{0.5\ nm})_{40}$ MLF showing FM coupling.

curve (a steep slope to this curve is required for films to be used as MR sensors and heads). The differences in r vs **H** may be related to differences in layer quality. TEM images of the $(Co_{2.0\ nm}/Cu_{1.0\ nm})_{40}$ films show the layers to be less flat than those in the t_{Co}=1.9 nm MLFs with more "faults" in the layers.

The value of MR ratio shown by the Co/Cu MLFs can be determined qualitatively from the type of magnetic domain structure observed. Figures 4(a) and 4(b) show the magnetic domain structure of a $(Co_{1.9\ nm}/Cu_{1.1\ nm})_{40}$ MLF (r=15%) imaged using the Foucault technique. The transition between areas showing bright and dark contrast occurs gradually rather than abruptly, with wavy rather than smooth boundaries. In addition, the overall change in contrast is relatively low. We attribute these features to the fact that the domain walls are in different positions in different layers, and to a relatively low degree of ferromagnetic (FM) coupling between the Co layers. The geometry of the domain pattern suggest that domains do not extend through the whole thickness of the MLF. This effect has also been observed in Fe/Cr MLFs.[7] The fact that domain contrast is visible is in agreement with the suggestion that antiphase domain boundaries parallel to the substrate are present,[8] and explains the fact that $r(0)$ is smaller than the ideal value for Co/Cu MLFs. In comparison, Figs. 4(c) and 4(d) show a pair of Foucault images illustrating the typical magnetic domain structure of a $(Co_{2.0\ nm}/Cu_{0.5\ nm})_{40}$ MLF, which shows a low MR. The strong magnetic domain contrast and regular domain shape show that the layer coupling is predominantly FM. Further evidence for the magnetic layer coupling is given by the shape of the hysteresis loops, as seen in Fig. 5 for films showing high $(Co_{1.9\ nm}/Cu_{1.1\ nm})$ and low MR $(Co_{2.0\ nm}/Cu_{0.5\ nm})$.

IV. CONCLUSIONS

The Co/Cu MLFs show a clear composition modulation and are polycrystalline, with columnar grains extending across several layers. The films have a strong (111) crystallographic texture with all layers showing a predominantly fcc structure. Coherent interfaces are observed between the Co and Cu layers over large areas. The magnetic domain contrast depends strongly on t_{Cu}, which determines the state of magnetic coupling. The samples with $t_{Co}\approx$2.0 nm and $t_{Cu}\approx$1.0 nm show the highest MR, and weak and irregular magnetic domain contrast. The magnetization measurements confirm that samples showing negligible MR exhibit FM coupling.

Epitaxial Co/Cr multilayers, and single-crystal Co thin films etc. have been grown on MgO and Al_2O_3 substrates with Cr and Mo as buffer layers by molecular beam epitaxy technique. From the structure and magnetoresistance studies, we have found that the ferromagnetic anisotropy of resistance (AMR) is strongly influenced by the buffer layer, but with negligible effect due to the variation of the structure of Co films. The AMR of Co film on Cr buffer layer is quite small (0.1%); however, the MR of Co/Cr multilayers is almost one order larger than the AMR of Co film on Cr buffer layer. An enhancement factor of 4 for the MR in Co/Cr multilayers by the interface roughness has been observed. This suggests that the effect due to the spin dependent scattering at the interfacial regions of the superlattice is larger than that due to the spin dependent scattering in the ferromagnetic layers for the MR in the Co/Cr multilayer system.

During the past several years, the magnetoresistance (MR) behaviors in many metallic multilayers have become the subject of considerable interest. Large (or giant) MR was first realized in Fe/Cr multilayer system,[1] and has been referred to as GMR. Relatively small MR occurs in the Co/Cr multilayers.[2] The MR in multilayers results from the spin dependent scattering of the conduction electrons which occurs both in the ferromagnetic layers and at the interfacial regions between the ferromagnetic and nonferromagnetic layers. It is quite different from the ferromagnetic anisotropy of resistance (AMR) in ferromagnetic systems, which depends on the direction of the magnetization.[3]

Epitaxial Co/Cr multilayers as well as single-crystal hcp-Co, fcc-Co, and polycrystal Co thin films have been grown on both MgO and Al_2O_3 substracts with Cr and Mo as buffer layers using an Eiko EL-10A molecular beam epitaxy (MBE) system with base pressure of $\sim 2\times10^{-10}$ Torr. Pure elements (≥99.99%) of Co, Cr, and Mo were evaporated from three independent e-beam evaporators. During deposition of the elements, the growth pressure was controlled at below 5×10^{-9} Torr, and the deposition rate at ~0.1 Å/s. To enable the growth of high-quality samples, polished and epitaxial grade MgO and Al_2O_3 substrates were chemically precleaned and rinsed in an ultrasonic cleaner. They were then outgassed at 900 to 1000 °C for at least 1/2 h under ultra high vacuum in the MBE system. For samples with a Mo (or Co) buffer layer, Mo (or Co) was deposited on the substrates at 900 (or 500) °C. The substrate temperature for all films during evaporating was kept between 300 and 350 °C. The crystallographic structure of the films were examined, throughout all the growth, by reflection high energy electron diffraction (RHEED). The interface roughness and the thickness of the superlattice structures were determined by the x-ray reflectivity analyses.

The magnetic properties of all the samples were studied by using a SQUID magnetometer. The AMR and MR measurements were carried out by the conventional four probe technique.

Before discussing the experimental data of AMR and MR in the CoCr system, we have to clarify their definition. The AMR in ferromagnetic films is defined by $(R_\parallel - R_\perp)/R_0$, where R_0 is the electrical resistance in zero internal magnetic field, and $R_\parallel$ and $R_\perp$ are the resistances when the saturated magnetization is parallel and perpendicular to the current, respectively.

The MR (or GMR) in multilayers is defined as $[R_{AF} - R_S]/R_S$, where R_S is the electrical resistance at saturated high magnetic field, and the spins in Co layers align in the field direction. R_{AF} is the electrical resistance when the field is removed, the Co layers adjacent to the Cr layer in-between exhibit antiferromagnetic coupling.

Crystal structures of thin films or multilayers may be considerably affected by the choice of buffer layers, substrates, and their orientations. In this study, we chose MgO(100), Al_2O_3 ($1\bar{1}02$), and Al_2O_3(0001) as substrates, and Cr and Mo as buffer layers to study the variation of AMR for Co films. In general, for Co grown on MgO(100) substrate without a buffer layer, an epitaxial fcc-Co film with (100) growth plane can be formed for Co thicknesses larger than about 60 Å, but for Co grown on an Al_2O_3(0001) substrate

without a buffer layer, a polycrystal Co film was observed. In addition when we grow a thin buffer layer of Cr(100) about 20 Å on either MgO(100) or Al_2O_3(1$\bar{1}$02), then both RHEED and x-ray diffraction (XRD) studies show an hcp-Co structure with (11$\bar{2}$0) plane parallel to the (100) surface of Cr. For example, Fig. 1 shows the typical RHEED patterns of (a) hcp-Co(11$\bar{2}$0) plane viewed along [0001], and (b) fcc-Co(100) plane viewed along [011]. The surfaces with solid circles cutting with unit cell of hcp(11$\bar{2}$0) and fcc(100) are

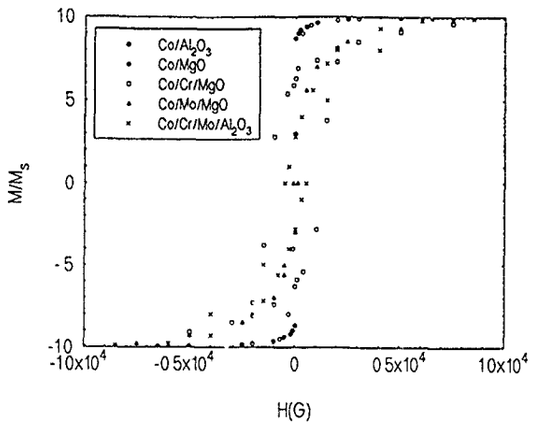

FIG. 2. The normalized magnetization as a function of magnetic field at room temperature for (a) Co/Al_2O_3, (b) Co/MgO, (c) Co/Cr/Mgo, (d) Co/Mo/MgO, and (e) $Co/Cr/Mo/Al_2O_3$.

schematically illustrated below each of the RHEED pictures.

Figure 2 shows the normalized magnetization as a function of the magnetic field at room temperature for 5 thin film samples (Co/Al_2O_3, Co/MgO, Co/Cr/MgO, Co/Mo/MgO, and $Co/Cr/Mo/Al_2O_3$). Generally speaking, the magnetization is saturated after roughly 6 kG for all the samples. Figure 3 presents the normalized difference of resistance as function of the magnetic field at room temperature for 5 thin film samples: (a) polycrystal Co on Al_2O_3 (0001), (b) fcc-Co(100) on MgO(100), (c) hcp-Co(11$\bar{2}$0) on Cr(100) which is on MgO(100), (d) hcp-Co(11$\bar{2}$0) on Mo(100) which is on MgO(100), and (e) hcp-Co(11$\bar{2}$0) on Cr(100) and Mo(100) which is on Al_2O_3(1$\bar{1}$02). One can see that the values of AMR for both polycrystal- and fcc-Co films without a buffer layer are roughly equal to 1.3%. However, the AMRs of all the Co films with either Cr or Mo as a buffer layer are roughly one order of magnitude smaller than that of Co films without a buffer layer. Therefore, we conclude that the effect to the AMR for Co films with different structure is negli-

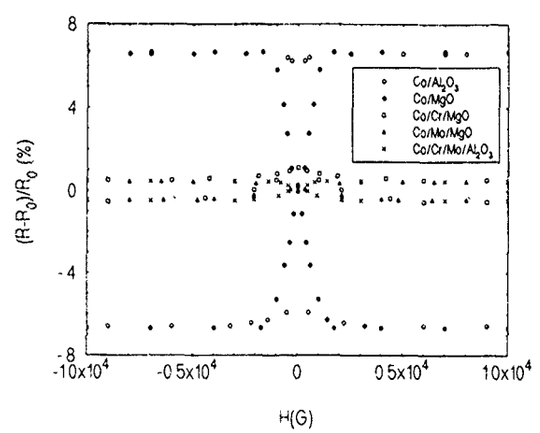

FIG. 3. The normalized difference of electrical resistance between magnetic field and zero field as a function of magnetic field at room temperature for (a) polycrystal Co/Al_2O_3, (b) fcc-Co/MgO, (c) hcp-Co/Cr/MgO, (d) hcp-Co/Mo/MgO, and (e) hcp-Co/Cr/Mo/Al_2O_3.

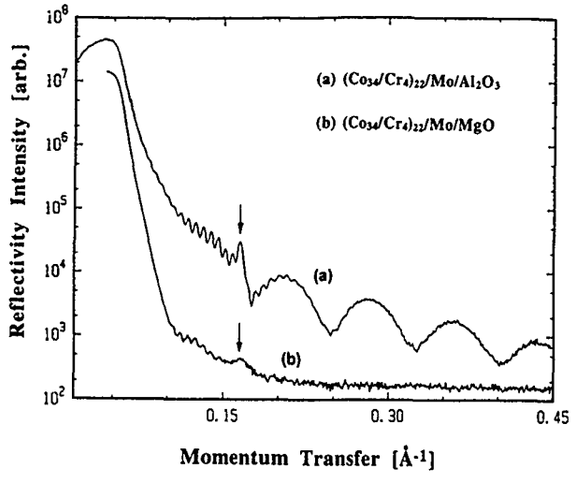

FIG. 4. X-ray reflectivity measurement of the samples (a) $(Co/Cr)_{22}/Mo/Al_2O_3$, and (b) $(Co/Cr)_{22}/Mo/MgO$. The arrow indicates the peak due to the period of the superlattice. The oscillation fringes pattern is due to the interference of the x-ray reflection between the two interfaces of Mo buffer layer and the interfaces of the total growth thickness.

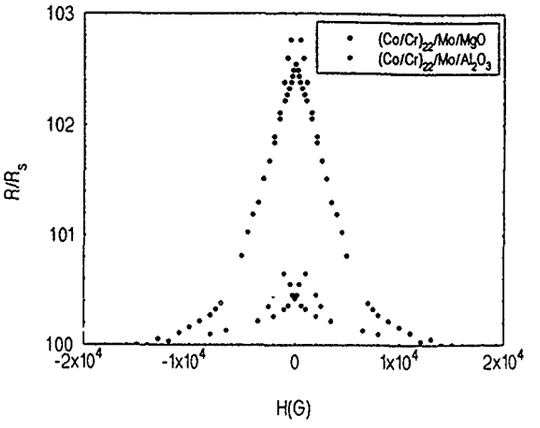

FIG. 5. The Normalized resistivity as a function of applied magnetic field at 10 K for (a) $(Co/Cr)_{22}/Mo/Al_2O_3$, and (b) $(Co/Cr)_{22}/Mo/MgO$ superlattices.

gible, if it is compared with the variation due to the addition of buffer layers of Cr and Mo. However, the exact mechanism of this reduction in AMR is not clear at present. It is noted that the buffer layers are not thick enough to shunt enough current to explain this reduction.

For Co/Cr multilayer samples, we have selected MgO(100), and $Al_2O_3(1\bar{1}02)$ as substrates. The thickness of each layer is varied from 4 to 30 Å for Cr, and from 20 to 40 Å for Co. We chose Cr as the first layer to form the multilayer structures. For samples without a Mo buffer layer, we found that the multilayers we made always had polycrystal structure if the thickness of the first Cr layer was less than 20 Å. This result tells us that it is difficult to grow epitaxial Co/Cr multilayers on either MgO or Al_2O_3 with Cr thickness less than 20 Å and Co thickness less than 60 Å. Therefore, we selected Mo as a buffer layer (about 100 Å) on both MgO and Al_2O_3 substrates to study the epitaxial behavior of the Co/Cr multilayer system. From the RHEED and XRD studies, both hcp-Co and bcc-Cr layers were identified for all the multilayer samples on either MgO or Al_2O_3 substrates. For the sake of comparison, Co/Cr multilayer samples with either MgO or Al_2O_3 as substrate were epitaxially grown side by side under the same batch of crystal growth process. Any difference between these two samples should be due to the different substrate only; e.g., the interface roughness of the multilayers is one of the important factors. For explanation, Fig. 4 shows result of the x-ray reflectivity measurement on two samples: (a) $(Co_{34\ Å}/Cr_{4\ Å})_{22}/Mo_{88\ Å}/Al_2O_3$, and (b) $(Co_{34\ Å}/Cr_{4\ Å})_{22}/Mo_{88\ Å}/MgO$. We can readily see that the reflectivity intensity drops more rapidly for the sample grown on MgO substrate. The reflectivity formula originally derived by Parratt[4] was used for the calculation of intensity reflected from a multiple-layer film on a substrate. Interfacial inhomogeneity due to roughness was included by adding effective Debye–Waller factors to each of the layers.[5,6] From this analysis the interface roughness of the sample grown on MgO is roughly 8 times larger than that on Al_2O_3.

The normalized electrical resistance as a function of applied field at 10 K for the above two superlattice samples are shown in Fig. 5. The MR, i.e., $(R-R_s)/R_s$, is roughly about 2.72%, and 0.65% for $(Co/Cr)_{22}/Mo/MgO$ and $(Co/Cr)_{22}/Mo/Al_2O_3$, respectively. This tells us that, roughly speaking, the MR is enhanced by a factor of 4 in the Co/Cr multilayers by the interface roughness. It is suggested that the effect by the spin dependent scattering at the interfacial regions of the superlattice is larger than that due to the spin dependent scattering in the ferromagnetic layers for the magnetoresistance in the Co/Cr multilayer system.

Giant magnetoresistance (GMR) of CoNiCu/Cu multilayers grown by electrodeposition was measured as a function of the copper layer thickness and effects of the order of 14% were obtained. The copper layer thickness ranged from 0.7 to 3.5 nm. Two peaks in the magnetoresistance were observed. One was centered at a copper thickness of ~1.0 nm and the second was centered at ~2.3 nm. Comparison of the field dependence of the magnetoresistance with the field dependence of the magnetization, as determined by vibrating-sample magnetometer, suggests that the saturation field for GMR and the magnetization are similar for the larger copper thicknesses, but are strikingly different near 1.0 nm copper thickness. This observation suggests that the GMR is affected by different factors depending on the thickness of the copper layer.

I. INTRODUCTION

Since the discovery of giant magnetoresistance (GMR), a considerable amount of research has been focused on the origin of the GMR effect and on understanding oscillatory exchange coupling mechanisms.[1–3] In Fe/Cr multilayers, it is generally accepted that spin-dependent scattering causes the GMR effect and is related to interface roughness.[1,4] However, recent studies indicated that spin-independent scattering at interfaces reduces the GMR.[5] In the Co/Cu or CoNi/Cu systems, the GMR depends on substrate type, surface roughness and the nature of the underlayers and overlayers. There have been many reports[6,7] of observations of GMR in sputtered Co/Cu multilayers suggesting strong antiferromagnetic (AFM) coupling. Typically three oscillations of GMR were observed as the spacer thickness varied from 0.6 to 4.0 nm. In molecular beam epitaxy (MBE) grown Co/Cu multilayers,[8] the magnetization shows significant hysteresis. It also appears that incomplete AFM coupling exists although the GMR effect is still large. No oscillations are reported in some (111) oriented epitaxial Co/Cu multilayers,[9] while other textures of Co/Cu, apparently with nearly comparable structures and perfection, exhibit different AFM coupling strength with GMR values that are attributed to the nature of the buffer layers as well as to the texture.[10] These results suggest that the magnetic properties of Co/Cu are sensitive to: (1) interface roughness, (2) nature of buffer layer and (3) texture. In none of these early studies was strain explicitly considered.

We present GMR and vibrating-sample magnetometer (VSM) results of studies on CoNiCu/Cu multilayers grown electrochemically. The AFM and ferromagnetic (FM) coupling states were also studied by analysis of: (1) the field dependence of GMR and (2) the magnetization curves as a function of spacer layer thickness. Finally, our data suggest that the GMR behavior is affected by interfacial alloying at low copper thickness and by strain at large copper layer thickness.

II. EXPERIMENT

Multilayers were electrochemically deposited on a (100) textured electropolished thin copper foil (0.127 mm thick) at room temperature. Electrodeposition was performed from a sulfamate electrolyte containing Co^{2+}, Ni^{2+}, and Cu^{2+} ions in a single cell. The procedure has been described previously.[11–13] We used a cathode potential of -1.8 V vs saturated calomel electrode (SCE) for NiCo alloy deposition and a potential of -0.26 V vs SCE for copper deposition. Copper is codeposited with CoNi so that the real composition of magnetic layers is about $Co_{64}Ni_{31}Cu_5$. Finally, the copper substrate was dissolved by chemical etching, and the free standing multilayer was glued on glass to facilitate handling. In this study the CoNiCu layer thickness was held constant and the copper layer thickness was varied.

The composition of the films was measured using x-ray fluorescence which confirmed that the cobalt to nickel ratio in all the magnetic multilayers was about 2:1. Structure and

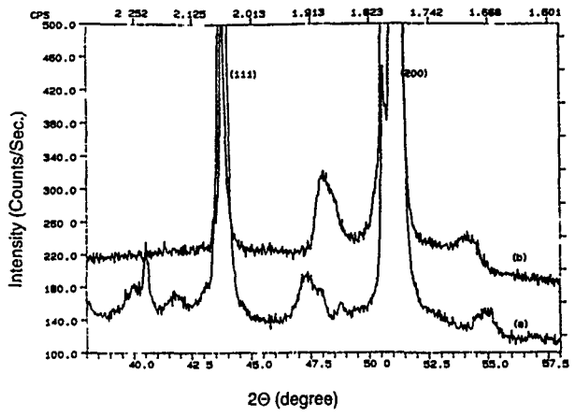

FIG. 1. A high angle x-ray diffraction pattern of [CoNiCu(2.2 nm/Cu(t_{Cu})]×400 multilayers with a t_{Cu} of 1.0 nm and (b) t_{Cu} of 2.3 nm. The vertical displacement is for clarity.

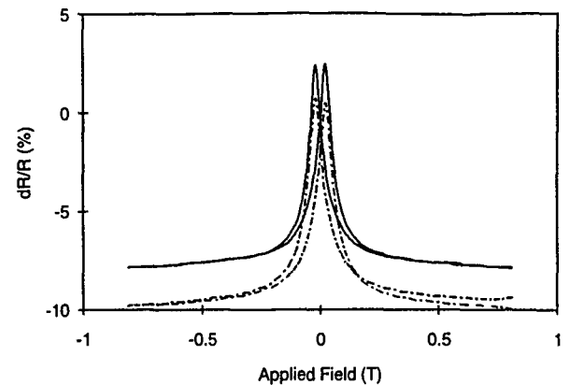

FIG. 2. Magnetoresistance of electrodeposited [CoNiCu(1.5 nm)/Cu(4.5 nm)]×250 multilayers measured at room temperature. The solid and dashed line show the data for longitudinal and transverse mode, respectively. Note that some drift was apparent at high fields for the transverse measurements.

periodicity of the multilayers were characterized by high angle x-ray diffraction and the MR measurement was performed by a four point probe technique at room temperature. Magnetic fields up to 0.8 T were applied in the film plane, both parallel and perpendicular to the current direction. Magnetization loops were obtained using a vibrating-sample magnetometer at room temperature.

III. RESULTS

High angle x-ray diffraction patterns from two of the CoNiCu/Cu multilayers are shown in Fig. 1. The high intensity (200) Bragg peak suggests a predominant (100) texture epitaxial to the substrate with some (111) contribution. The first order satellites indicate the presence of layers of well defined periodicity. In most samples the second order satellite was too weak to be observed. The superlattice period Λ is calculated from the satellite positions.[13] The observed increase in the Bragg peak width is believed due to an increase in coherence strain.[14]

A typical MR curve of a [CoNiCu(1.5 nm)/Cu(4.5 nm)] ×250 multilayer measured at room temperature is shown in Fig. 2. A 10% change resistivity was observed by changing the applied field from 0 to 0.1 T with a maximum sensitivity ~0.6%/mT in the linear slope region. Both longitudinal and transverse orientations were measured (Fig. 2). A symmetric change of almost the same amplitude was observed for both cases. The large isotropic magnetoresistance in both modes implies GMR behavior rather than isotropic normal magnetoresistance.

The variation of the maximum change in MR of [CoNiCu(2.2 nm)/Cu(t_{Cu})] multilayers as a function of copper thickness t_{Cu} is shown in Fig. 3. When the GMR saturation field exceeded the maximum 0.8 T available, the saturation value was determined by extrapolation. We observed a first GMR peak at a copper thickness of ~1.0 nm. Instead of a second oscillation of lower value, a large increase of GMR is observed at a copper layer thickness greater than 2.0 nm, giving rise to a broad peak centered at 2.3 nm. This result differs both from the results obtained from sputtered CoNi/Cu multilayers[15] and previous work for MBE grown Co/Cu (111) multilayers in which no oscillations were observed and in which the GMR decayed continuously with increasing copper thickness.

Further investigations of scattering mechanisms were carried out by a comparison of the GMR with the magnetization loops obtained by VSM. The magnetic field dependence of the GMR and of the corresponding magnetization are shown for the samples with copper layer thickness of 1.0 nm in Fig. 4(a) and 2.3 nm in Fig. 4(b). The shapes of the GMR curves observed with thin (~1.0 nm) and thick (~2.0 nm) copper layers [Figs. 4(a1) and 4(b1)] differ considerably. For the thinner copper layers, the GMR peak is broad with a small hysteresis suggesting stronger AFM coupling. As can be seen in Figs. 4(a2) and 4(b2), the coercivity increases with increasing copper thickness. Magnetization loops of these samples were measured at room temperature at fields up to 0.8 T [Figs. 4(a2) and 4(b2)]. As expected, incomplete AFM coupling is suggested in Figs. 4(a2) and 4(b2) by the gradu-

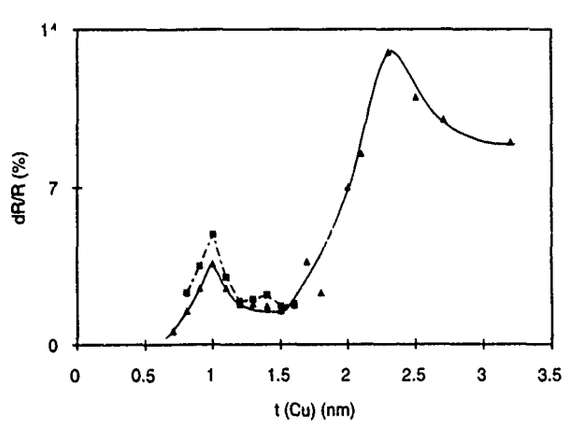

FIG. 3. Oscillation of GMR with variation of copper layer thickness. The thickness of the CoNiCu layer is 2.2 nm with 400 pairs of layers for all the samples. The squares indicate the measured maximum GMR data for applied field up to 0.8 T, and the triangle gives the extrapolated saturation GMR.

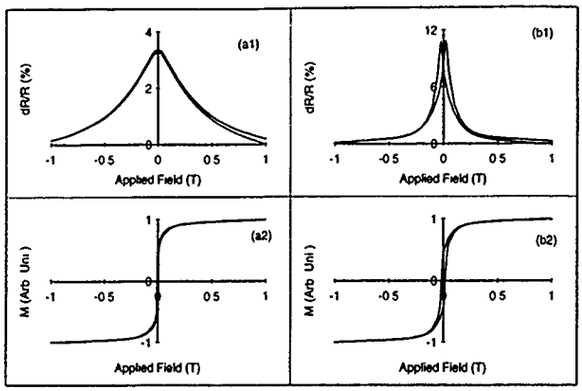

FIG. 4. The magnetic field dependence of GMR and magnetization of [CoNiCu(2.2 nm)/Cu(t_{Cu})]×400 multilayers for (a) t_{Cu}=1.0 nm, (b) t_{Cu}=2.3 nm. All the measurements have been carried out at room temperature and with the field parallel to the plane of the multilayer except when indicated.

ally increasing magnetization with increasing applied field as well as by the large remanent magnetization at low fields in all the samples. Remanent magnetization of around 70%–80% of saturation is consistent with the existence of some FM coupling between the magnetic layers. However, from previous work,[8,10] a small fraction of AFM coupling (~30% saturation magnetization) can still produce a reasonable GMR (~40%), which suggests that the AFM coupling may still be contributing to the GMR in our samples.

IV. DISCUSSION

We have observed a small increase in the GMR ratio (dR/R) at 1.0 nm copper thickness. We believe that this first peak is possibly due to AFM coupling and is analogous to that commonly observed in many Co/Cu and CoNi/Cu sputtered specimens.[6,7,15] The electrochemical process used in this study results in copper codepositing in the cobalt alloy layer. The copper content of the solution adjacent to the cathode is reduced during the deposition of copper and a gradient in this copper concentration will exist whose magnitude will be proportional to the thickness of the copper layer being deposited.[16] The subsequent cobalt layer will have a copper content inversely proportional to this gradient so that for thin copper layers the next cobalt alloy will be enriched in copper. The low GMR value of these thin (Cu) samples may be attributed to significant copper alloying while the thicker (Cu) specimens will have less copper contamination in the ferromagnetic layers and therefore larger GMR values.

The second GMR peak was found at ~2.3 nm, at a position consistent with predictions of Stiles[2] for a (200) textured copper spacer layer. The low frequency oscillation predicted by Stiles was not observed due, we believe, to surface roughness. However, unlike data presented for sputtered multilayers, our second peak is both higher and is significantly broader than reported in the published data for binary Co/Cu multilayers produced by sputtering.[6,7] The high angle x-ray diffraction patterns of the electrochemically produced specimens suggest that all the samples are epitaxial with low intensity symmetrical satellites around the [200] Bragg peak a small copper layer spacings, and well defined and high intensity but asymmetric satellites at larger copper layer spacings. The width of the Bragg peak increases with copper spacer thickness and may be due to increasing coherency strains as the copper layer thickness increases.[14] Both nickel and cobalt are magnetostrictive and so are sensitive to strains therefore, the broadening of the second peak is consistent with both a magnetorestrictive effect and to decreasing AFM/FM coupling strength as the copper thickness and resultant coherency strain increases.

The comparison of magnetization data with MR data for thin copper spacer layers (see Fig. 4) shows that a much higher field is required to saturate the MR suggesting strong AFM coupling. The small coercive field required to reverse the magnetization is consistent with this explanation. At higher copper layer thickness, good agreement between the saturation field of MR and the magnetization is obtained, possibly due to weaker AFM coupling. The large coercive field is consistent with decreased coupling for the thick copper spacer layers.

High sensitivity GMR in NiFeCo/Cu multilayers

S. Gangopadhyay, S. Hossain, J. Yang, J. A. Barnard, M. T. Kief, H. Fujiwara, and M. R. Parker
Materials for Information Technology, Box 870209, University of Alabama, Tuscaloosa, Alabama 35487-0209

Magnetoresistance and magnetic hysteresis in NiFeCo/Cu soft magnetic multilayers with a fixed number of bilayers (six) and magnetic and spacer layer thickness but varying composition has been studied. The highest value of the transverse GMR obtained is 6.8% in a saturation field of ≈40 Oe at room temperature. Very high sensitivity, around 1%-2%/Oe and unconventional easy-axis hysteresis and GMR loop shapes have been observed. The analysis of the GMR effects and the associated hysteretic behavior by using a model that includes biquadratic exchange coupling suggests that the samples are composed of at least two distinctively different parts.

Much interest has focused, in recent months, on the development of giant magnetoresistive (GMR) thin film materials with high magnetic field sensitivity. High sensitivity here means a relatively large percentage change in electrical resistance per unit applied magnetic field. One recently described approach to high sensitivity[1,2] has been the fabrication of quasigranular NiFe/Ag multilayers with sensitivities approaching 1%/Oe. A major difficulty with this system is that these high sensitivities are only achieved after a high-temperature (~300 °C) anneal. High sensitivities have also been demonstrated in spin-valve structures,[3] but here again, some technical difficulties are apparent in the realization of effective antiferromagnetic exchange layers.

The thin film alloy system discussed in the present paper has been described elsewhere[4,5] in terms of its transverse (or hard-axis) GMR characteristics.[6] The system in question is NiFeCo/Cu in a six-bilayer configuration prepared by high rate dc magnetron sputtering. Its longitudinal (or easy-axis) GMR effect is characterized by an extremely sharp spin flop[7,8] transition of high field sensitivity in the range (typically, for these particular alloys) of 1% to 2%/Oe. A phenomenological model[9] of biquadratic coupling in GMR multilayers has been used to describe the data.

dc magnetron sputtering was used to prepare NiFeCo/Cu multilayers, using high purity argon (99.99%) gas at a base pressure $\leq 3\times10^{-7}$ Torr. Samples were sputtered at a power of 100 W and the argon pressure during sputtering was fixed at 2 mTorr. Corning 7059 glass at ambient temperature was used as the substrate and a permanent magnet (field ~60 Oe) was held behind the glass to induce uniaxial anisotropy. A split target consisting of a 4 in. $Ni_{80}Fe_{20}$ disk, partially covered with a Co foil, was used to sputter the magnetic layer, and an 8 in. Cu target was used for the spacer layer. The thickness of the magnetic and Cu layers was 16 and 23 Å, respectively. Sputtering rates were calculated from thickness measurements of reference films. Multilayer and crystal structure were studied using low and high angle x-ray diffraction (XRD). MR measurements were made using a linear four-point probe method with the current flowing in the film plane and along the induced easy-axis direction. The most widely used definition of GMR is as follows: $\Delta R/R \simeq [R(H)-R(H)_{sat})]/R(H_{sat})$. A vibrating sample magnetometer (VSM) was used for other magnetic characterization.

Eight samples with composition of the magnetic layer varying between $Ni_{67}Fe_{17}Co_{21}$ (sample No. 1) and $Ni_{44}Fe_{11}Co_{45}$ (sample No. 8) were obtained using the split target geometry, which was comprised of a $Ni_{80}Fe_{20}$ 4 in. disk covered partially with a Co foil.[10] Figure 1 shows a typical low and high angle (insert) XRD spectra for these multilayer structures. LXRD shows the first and second order Bragg reflections due the chemical modulation of the sample structure in addition to the intermediate reflections, which indicates good multilayer structure. The high angle XRD shows that the films have (111) texture. A single broad diffraction peak which is slightly shifted from the fcc-Cu (111) d spacing is observed (the film is 60% Cu by volume fraction). Small shifts in d spacing away from bulk values are common in as-deposited multilayers which are likely to be strained.

Figure 2 shows the easy (EA) and hard-axis (HA) hysteresis loops for four different compositions of the magnetic layer. As the Co concentration increases, a canted and/or antiparallel spin alignment starts to develop. This is shown by the arrows in Fig. 2(b). Also, notice the evolution of the "double" hysteresis loop and consequent vanishing of remanence as the composition approaches that of sample No. 6 and its reappearance with any further increase in the Co concentration (sample No. 8). Although the coercivity along the HA increases monotonically from sample No. 1 to No. 8, the EA coercivity and remanence have a minimum for sample No. 6. The length of the exchange coupled region "cd," marked in Fig. 2(c) also increases with Co concentration.

The change in the magnitude of HA and EA GMR and the length of region "cd" are plotted as a function of the sample position (or composition) in Fig. 3. A representative error bar resulting due to the gradient sample composition along the x axis and causing an associated error in the GMR value is marked on sample No. 1 (open circle). The length of the region "cd," which is related to the canted and/or antiparallel spin alignment in the sample is found to scale with the composition of the magnetic layer. Also, as the Co content increases (or from sample No. 1 to No. 8), GMR increases until sample No. 6, whereupon any further increase in Co causes a slight decrease in GMR. The sharp spin transitions [Fig. 2(b)] observed along the EA direction result in an extremely high sensitivity. This is shown in Fig. 4, where the EA GMR for sample No. 5 ($Ni_{58}Fe_{14}Co_{28}$/Cu) along with

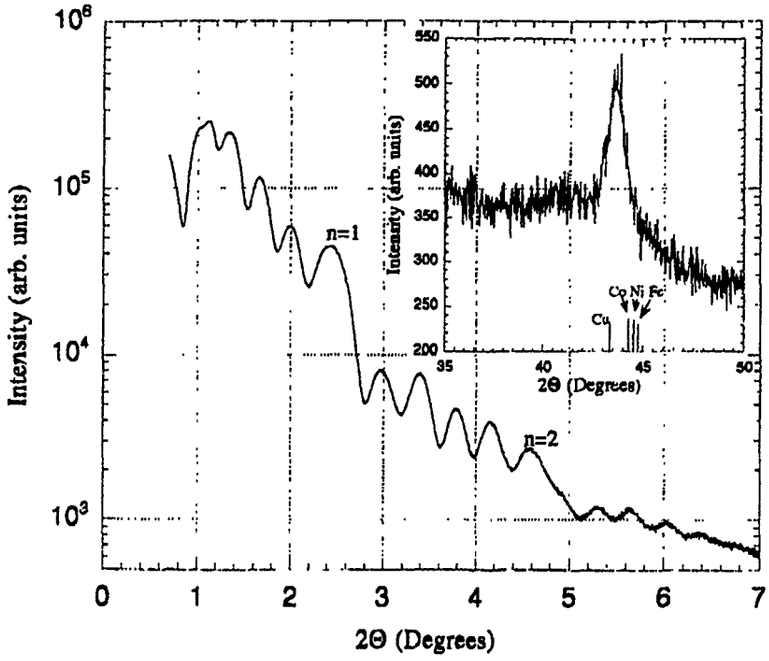

FIG. 1. A typical low- and high-angle XRD pattern of NiFeCo/Cu multilayer sample (No. 3). The relative position of the fcc-Ni (111), bcc-Fe(110), fcc-Co(111), and fcc-Cu(111) diffraction peaks are also marked.

its first derivative or $\Delta R/R$ per unit change in the field is plotted. To our knowledge, 2%/Oe is the highest sensitivity observed in magnetic multilayer or spin valve structures. But it should be pointed out that such a high sensitivity is only observed along the easy axis of the sample and it also features some hysteresis. Figure 5 compares the EA and HA GMR profiles. The HA GMR profile in this figure is typical of all the compositions studied, with a saturation field of 40–50 Oe and sensitivity of about 0.2%/Oe. The smooth variation in the MR along the HA indicates uniform magnetization rotation.

Figure 6 correlates the EA GMR and hysteresis curve profiles. The fields at which a change in the angle between the adjacent magnetic layers (marked with two arrows) takes place is marked by lower case letters *o* through *f* on the hysteresis loop. The corresponding transitions in the GMR loop are marked by the respective capital letters. The observed shape of the longitudinal GMR and hysteresis curve can be explained by considering a two phase magnetic sys-

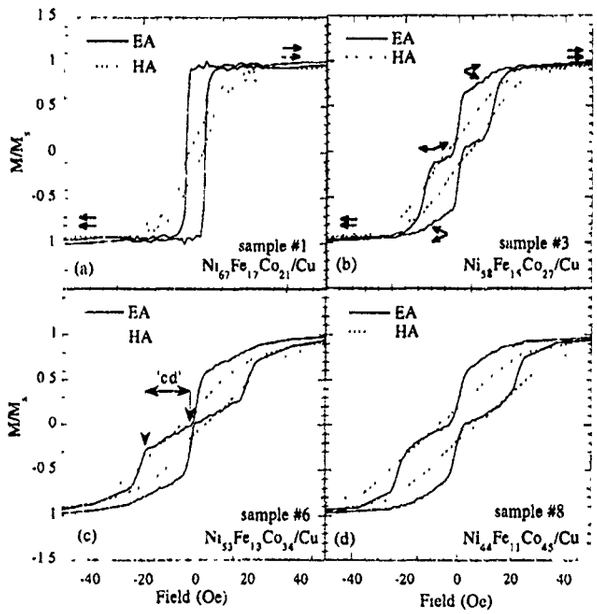

FIG. 2 Hysteresis loop profiles along the easy- and hard-axis directions for different compositions (marked on each figure) of the magnetic layer.

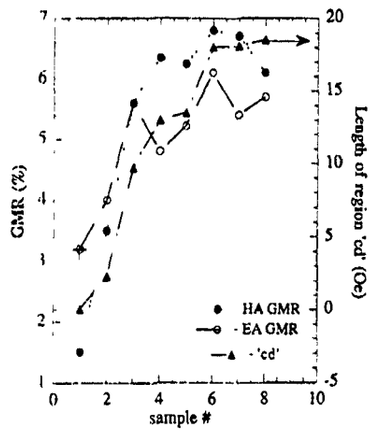

FIG. 3. Change in the magnitude of GMR along the easy and hard axis, and the length of region "*cd*" (defined in Fig. 2), as a function of the sample No. (or composition). The solid and dashed lines are drawn to guide the eye.

tem. The total energy per unit volume of any one of the phases is approximately given[9] by

$$E(\theta_1,\theta_2)=\frac{H_kM}{4}(\sin^2\theta_1+\sin^2\theta_2)+\frac{M}{4}[H_1\cos(\theta_1-\theta_2)+H_2\cos^2(\theta_1-\theta_2)]-\frac{MH}{2}[\cos(\psi-\theta_1)+\cos(\psi-\theta_2)], \quad (1)$$

where θ_1 and θ_2 are the angles between the magnetizations and the easy-axes, depending on whether they are in the odd or even numbered layer, respectively. The angle between the magnetic field and the easy axis is ψ, and H_k, H_1, and H_2 are the effective uniaxial anisotropy, and first- and second-order (biquadratic) exchange fields, respectively. Minimization of the total energy [Eq. (1)] with respect to θ_1 and θ_2 results in a qualitative fit to the observed hysteresis and GMR loop shapes. For samples 2 to 8 this is achieved when the ratios H_k/H_1 and H_2/H_1 are ≥ 0.5. The scaling phenomenon of the length "cd" [in Fig. 2(c)] with the sample composition is ascribed to the increase of the ratio H_k/H_1. The sharp spin flops from b to c, which consequently causes a double hysteresis loop, are also predicted by this model.[9] However, only one magnetic phase described by Eq. (1) cannot explain certain features of the hysteresis and GMR loop shown in Fig. 6, such as the opening of the region o to a and e to f and the corresponding regions of the GMR loop labeled by the capital letters. One way of explaining this is to consider an independent magnetic phase described also by Eq. (1) with an independent set of variables H_k, H_1, and H_2. An overlap of two such phases can simulate the hysteresis and GMR loops observed in this study.

We have shown clearly in as-deposited sputtered NiFeCo/Cu multilayers a sharp, highly distinctive spin-flop transition of extremely high GMR sensitivity (>1%/Oe) along the easy axis. This study has also shown that this switching mechanism can be controlled by varying the Co concentration. A direct observation of the domains or magnetization direction at various fields may prove the presence of the biquadratic coupling and a two phase system as discussed in the text and predicted by theory.

The element specific magnetic hysteresis curves of Fe/Cu/Co trilayer structures can be used in conjunction with the measured magnetoresistance curves to extract the coefficient of the giant magnetoresistance (GMR) independent of magnetic domain effects and incomplete alignment effects, allowing for a measure of the maximum attainable GMR for that trilayer. Information concerning the details of the trilayer switching can be extracted showing that sputtered polycrystalline films of Fe/Cu/Co deposited on Si switch their magnetization directions like multidomain Ising magnets.

I. INTRODUCTION

To understand and optimize trilayer and multilayer systems which exhibit giant magnetoresistance (GMR), an appreciable change of the resistance of the multilayer in response to an applied magnetic field, it is important to separate the intrinsic GMR, the maximum achievable change in the resistance, from extrinsic variations to the measured GMR. A clear example of an extrinsic modification to the magnetoresistance is the dependence of the resistance on micromagnetic details of the ferromagnetic film reversal.

The giant magnetoresistance as a function of the applied magnetic field, H, is typically defined as[1]

$$\mathrm{MR}(H)=\frac{R(H)-R(H_s)}{R(H_s)}, \tag{1}$$

where $R(H_s)$ is the film resistance at the saturation field H_s (the field where all ferromagnetic layers are fully aligned with each other). In the absence of anisotropic magnetoresistance, the maximum attainable magnetoresistance for a simple sandwich structure is understood to be the difference between the low resistance state of the sandwich, when the two films are fully aligned (at high field $>H_s$), and the high resistance state when the two films are fully anti-aligned (at low or zero field). For trilayer (sandwich) structures, an ideal switching behavior would result in square magnetic hysteresis loops and GMR curves with abrupt transitions separated by well defined plateau regions.[2] Unfortunately, the majority of reported systems display rounded hysteresis loops and peaks in the GMR curves.[1–3] Since the low resistance aligned film configuration can be achieved by application of a sufficiently large positive or negative magnetic field, the absence of plateaus in the GMR indicate that the fully anti-aligned magnetic film orientation is never achieved. Instead, during the moment reversal process, before the first ferromagnetic film has completely switched its magnetic orientation (establishing the anti-aligned state), the second magnetic film has already begun to reverse its moment direction.

There have been a large number of comparative studies which have attempted to determine variations of the intrinsic GMR on material and interface parameters (including magnetic layer and interlayer composition, layer thicknesses, and film and interface quality). Unfortunately, modifying these parameters may also dramatically affect the details of the film reversal process including the degree to which the two films are not completely anti-aligned. Any comparative studies of the GMR must first correct for, or eliminate these incomplete anti-alignment effects. To this end, we have developed a method to extract the coefficient of GMR, the maximum achievable GMR, from the nonideal magnetoresistance data, provided that the details of the magnetization reversal process of the two ferromagnetic films is known. For simplicity, we will consider only two models for the magnetization reversal process—the single domain xy model and the multidomain Ising model.

II. SINGLE DOMAIN *xy* MODEL

The single domain xy model treats each ferromagnetic film as a single magnetic domain with a constant total moment which can point in any direction in the film plane, but must remain in the film plane. The magnetization reversal is therefore accomplished by an in-plane rotation of the moment direction. Since magnetometry measures the projection of the magnetic moment along an analysis direction, typically coincident with the applied field direction, the mea-

 0021-8979/94/76(10)/6525/3/$6.00 © 1994 American Institute of Physics

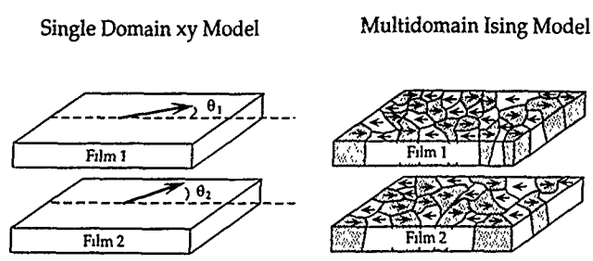

FIG. 1. Models for the magnetization reversal.

sured hysteresis loop can be used to determine the angle, θ, that the moment makes with the applied field direction

$$M_{xy}(H)=M_0\cos[\theta(H)], \tag{2}$$

where M_0 is the constant magnitude of the film magnetization vector.

If independent hysteresis loops of each of the magnetic films can be obtained, then a determination of the relative angles of both films as a function of applied field, and therefore the angle between the two magnetic films, can be made (a schematic of the two films is shown in the left-hand panel of Fig. 1). From the relative angles of each film, we can determine the magnetoresistance, given by[4,5]

$$\mathrm{MR}_{xy}(H)=G\sin^2\frac{\Delta\theta(H)}{2}=G\sin^2\left(\frac{\theta_1(H)-\theta_2(H)}{2}\right), \tag{3}$$

where G is the coefficient of the GMR and $\Delta\theta$ is the angle between the magnetic moments of the two single domain films. From the measured hysteresis curves of the two magnetic layers, we can then calculate the form of the magnetoresistance curve. By comparing this curve with the measured hysteresis curve, we can extract a value for G, the coefficient of magnetoresistance, which corresponds to the maximum achievable magnetoresistance.

III. MULTIDOMAIN ISING MODEL

The multidomain Ising model treats each magnetic film as if it were composed of many magnetic domains, each allowed to be oriented along with or opposed to the applied field direction. Now the magnetization reversal is accomplished through the abrupt magnetization reversal of the separate domains. The hysteresis loops, which reflect the net moment, are a measure of the fraction of the film pointing along the applied field

$$M_{\mathrm{Ising}}(H)=M_0[f^{\uparrow}(H)-f^{\downarrow}(H)], \tag{4}$$

where M_0 is the maximum moment and $f^{\uparrow}(f^{\downarrow})$ is the fraction of the film pointing along (opposed to) the field. For two magnetic layers, if the moment direction of domains in the two films are uncorrelated (i.e., the direction of the moment of a domain in one film is independent of the direction of the moment in a domain of the other film), then the measurements of the two independent hysteresis loops can be used to determine what fraction of the films are aligned and anti-aligned with each other. (A schematic of this model is shown in the right-hand panel of Fig. 1.)

In the simplest view, there are only two domain configurations which contribute to the overall resistivity, when the current flows between two domains of opposite orientation or between two domains of aligned orientation. Because these two configurations represent two well defined resistance states in parallel with each other, then if the domains are large compared to the mean spin scattering length[6] and if we ignore the additional resistivity associated with current flow between domains within the same magnetic layer (which would also depend on the distribution of domain sizes and domain configurations), then the total film resistance is just given by

$$R_T(H)=\frac{R_A}{f_A(H)}\|\frac{R_P}{f_P(H)}=\frac{R_AR_P}{R_Af_P-R_Pf_A}, \tag{5}$$

where $R_P(R_A)$ is the resistance of the film in the completely aligned (anti-aligned) configuration and $f_P(f_A)$ is the fraction of the film in the aligned (anti-aligned) state. The magnetoresistance can be expressed as (noting $f_P+f_A=1$)

$$\mathrm{MR}_{\mathrm{Ising}}(H)=\frac{R(H)-R_P}{R_P}=G\frac{f_A}{f_A+(R_A/R_P)f_P}, \tag{6}$$

where $G=(R_A-R_P)/R_P$. If $R_A\sim R_P$ (i.e., G is small) then

$$\mathrm{MR}_{\mathrm{Ising}}(H)\sim Gf_A=G[f_1^{\uparrow}(H)f_2^{\downarrow}(H)+f_1^{\downarrow}(H)f_2^{\uparrow}(H)], \tag{7}$$

where the term in the brackets is the fraction of the two films which are anti-aligned (in the absence of domain correlation).

IV. INDEPENDENT HYSTERESIS LOOPS

The major difficulty is of course in determining independently the hysteresis loops of the two magnetic films. Most magnetometry techniques determine the total hysteretic behavior of the system. Recently, we have developed a method to determine element-specific hysteresis loops of heteromagnetic materials.[7] By recording the absorption intensity of circularly polarized soft x-rays at each transition metal L_3 absorption edge as a function of applied field, the hysteretic behavior of each magnetic element in a compound or multilayer structure can be determined using magnetic circular dichroism (MCD).[8–12] In this way, the complicated conventional hysteresis curves can be resolved as a linear combination of simple elemental hysteresis curves. In the case of a multilayer system with different magnetic elements in each ferromagnetic layer, the separate element-specific magnetic hysteresis (ESMH) curves are now equivalent to the hysteretic behavior of the individual ferromagnetic layers.

To demonstrate this, an Fe/Cu/Co trilayer structure, known to exhibit a reasonable GMR effect,[13] was sputter deposited onto a Si(100) surface which was chemically degreased prior to the deposition. The multilayer film consists of 50 Å Fe film and a 50 Å Co film separated by 50 Å of Cu and capped with an additional 30 Å of Cu to prevent oxidation. The films were deposited in an argon gas of $\sim 3\times10^{-3}$ Torr at a rate of a few angstroms per second. X-ray absorption spectroscopy measurements showed that no oxidation of the buried Fe or Co layers has occurred. Details of the MCD setup have been described previously.[14,15]

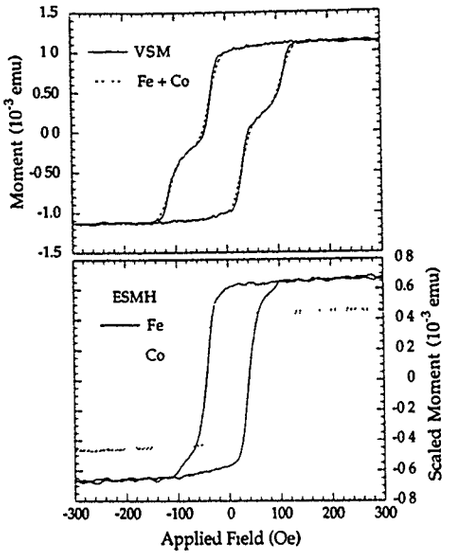

FIG. 2. Top panel: conventional total moment VSM hysteresis loop (solid line) and the summed element specific magnetic hysteresis loops for Fe and Co (dotted line). Bottom panel: ESMH loops for Fe and Co. The scaling values were determined by a best-fit of the summed data to the VSM data.

The conventional, total magnetic hysteresis behavior of this trilayer is shown in the top panel of Fig. 2. This hysteresis loop shows rounded transitions and is characteristic of non-ideal switching behavior. In the bottom panel are the scaled ESMH loops for Fe and Co. The weighting factors were determined by a least-squares-best fit of the summed data to the VSM data. These weighting factors, included in the ESMH loops of the lower panel of Fig. 2, give good agreement between the VSM spectra and the summed spectra, displayed as the dotted line in the top panel of Fig. 2. The differences in the spectra are attributed to film inhomogeneity and the different analyzed areas of the two magnetometry techniques.

From these elemental hysteresis loops, we can calculate the GMR curves for the single domain xy model and the multidomain Ising model. By comparing to the measured GMR curves (shown scaled to be aligned at the peaks in Fig. 3), not only are we able to extract a value for the coefficient of magnetoresistance, but we can differentiate which model is applicable to our multilayer. The two vertical axes are displayed in normalized MR values (MR/G) and vividly demonstrate the effects of the incomplete alignment. It is clear from these spectra that these films are best described by a multidomain Ising model (which is consistent with the polycrystalline nature of these films). From the value of the maximum measured GMR of 2.1% (corresponding to the peaks in the measured data in Fig. 3), we can extract a coefficient of GMR of 0.031 (3.1%), an increase of almost 50%. It is interesting to note that had the single domain xy model been the applicable description of the magnetization reversal, the extracted coefficient of GMR would be 0.068

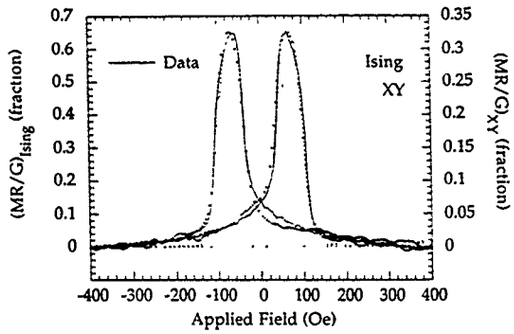

FIG. 3. Comparison of the measured magnetoresistance data (solid line) to the multidomain Ising model (dotted line) and the single domain xy model (dashed line). The coordinates are normalized values for the calculated spectra and the measured data is arbitrarily scaled to fit.

(6.8%) an increase of 200%! (The anisotropic magnetoresistance for this film is measured to be 0.4%.)

In summary, we have shown that in nonideal systems with peaked magnetoresistance curves and rounded hysteresis loops, the maximum measured GMR is reduced from the maximum attainable value by multidomain and incomplete alignment effects. We have also used ESMH measurements, in conjunction with the measured magnetoresistance curves, to extract the coefficient of GMR. In any comparative study of the GMR, it is this larger extracted coefficient which should be used.

Interface alloying and magnetic properties of Fe/Rh multilayers

K. Hanisch, W. Keune, R. A. Brand, C. Binek, and W. Kleemann
Laboratorium für Angewandte Physik, Universität Duisburg, D-47048 Duisburg, Germany

Rh(20 Å)/^{57}Fe(t_{Fe}) multilayers with Fe thicknesses t_{Fe} of 2, 5, 10, and 15 Å prepared by alternate evaporation in UHV have been investigated by x-ray diffraction (XRD), Mössbauer spectroscopy, and SQUID magnetometry. First- and second-order superstructure Bragg peaks (but no higher-order peaks) in small-angle XRD patterns suggest some compositional modulation. Mössbauer spectra taken at 4.2 K are characterized by a distribution $P(B_{hf})$ of hyperfine fields B_{hf}. Peaks observed in the $P(B_{hf})$ curves near 17 and 35 T are assigned to an fcc-RhFe interface alloy (~7–24 at. % Fe) with spin-glasslike properties and to a disordered ferromagnetic bcc-FeRh alloy (~96 at. % Fe), respectively. The magnetic transition temperature of the fcc alloy was found to be 23 and 45 K for t_{Fe}=2 and 5 Å, respectively, and B_{hf} follows a $T^{3/2}$ law. For t_{Fe}=2 Å, spin-glasslike behavior was observed by magnetometry.

Metallic multilayered films offer an exciting field for the exploration of magnetic properties in novel systems and at interfaces.[1] In a search for new multilayers with interesting magnetic behavior we have studied the Fe-Rh system. According to the thermodynamic Fe-Rh phase diagram[2] a wide solubility range exists at rather low temperatures on both the Fe-rich and Rh-rich side. Therefore, a tendency for interface-alloy formation may be expected in these multilayers. The properties of Fe/Rh interfaces are unknown so far.

We have prepared a series of Rh/Fe multilayers with constant Rh thickness (20 Å) by alternating evaporation of Rh and ^{57}Fe isotope (95% enriched) in an UHV system. The pressure during evaporation was $<5\times10^{-9}$ mbar. The substrates were polyimid foils for Mössbauer and magnetometric studies and Si wafers for small- and large-angle x-ray diffraction (XRD). To reduce intermixing, the substrate temperature was held at ~100 K during multilayer growth. Rh and ^{57}Fe were evaporated from a 2-kW electron-beam gun and a small resistively heated evaporation cell with alumina crucible, respectively. Four different types of multilayers have been prepared, namely [Rh(20 Å)/^{57}Fe(2 Å)]$_{100}$+Rh(20 Å), [Rh(20 Å)/^{57}Fe(5 Å)]$_{52}$+Rh(20 Å), [Rh(20 Å)/^{57}Fe(10 Å)]$_{30}$+Rh(20 Å), and [Rh(20 Å)/Fe(15 Å)]$_{20}$+Rh(20 Å). (All samples were coated by 20 Å Rh for protection.)

The small-angle XRD patterns (Fig. 1) exhibit a clear first-order superstructure Bragg peak for all samples, and an additional second-order peak for t_{Fe}=10 and 15 Å. This and the fact that no higher-order superstructure peaks have been detected (not shown in Fig. 1) demonstrates qualitatively that our samples are compositionally modulated structures with some degree of intermixing at the interfaces. The multilayer periodicity determined from Fig. 1 is 23.7, 24.9, 29.7, and 37.7 Å for t_{Fe}=2, 5, 10, and 15 Å, respectively, being in agreement with the nominal periodicity within 7% or better. The large-angle XRD patterns from our samples (not shown) exhibit a dominant fcc Rh(111)-Bragg peak and weaker peaks from higher-indexed Rh planes. However, the Rh peaks were found to be shifted slightly to higher Bragg angles upon increase of t_{Fe}, implying a fcc-lattice parameter (a_0) reduction with increasing Fe-film thickness from a_0=3.808 Å (pure Rh film) to 3.793, 3.780, 3.738, and 3.713 Å for t_{Fe}=2, 5, 10, and 15 Å, respectively. No pure bcc-Fe Bragg peaks could be detected. However, a shoulder (near $2\theta\approx40°$) on the low-angle side of the Rh(111) peak observed for the thicker Fe films (10 and 15 Å) may be assigned to a bcc (110) reflex with a corresponding bcc-lattice parameter which is enhanced (relative to that of pure bcc Fe) by 11.4% (for t_{Fe}=10 Å) and 10.0% (for t_{Fe}=15 Å). In view of the small-angle XRD and Mössbauer results (below) the observed reduction or increase in lattice parameter is interpreted by the main effect of interface-fcc-alloy formation or bcc-alloy formation, respectively. For fcc Fe-Rh alloys, our interpretation is qualitatively supported by the known decrease of a_0 with rising Fe content in the bulk.[3]

Mössbauer spectra measured at 4.2 K (Fig. 2) indicate magnetic hyperfine (hf) splitting at all Fe thicknesses. These spectra were least-squares fitted using a histogram distribution,[4] $P(B_{hf})$, of hyperfine fields B_{hf}. It was found necessary to include a small linear correlation between isomer shift δ and B_{hf}, given by about +0.004 mm s^{-1}/T.

For t_{Fe}=2 Å, the most-probable (peak) hf field, B_{hf}^{peak}, has a value of 16.8 T (Fig. 2) which is typical for that of a ~7 at. % Fe disordered fcc-Fe-Rh bulk alloy at 4.2 K.[5] This

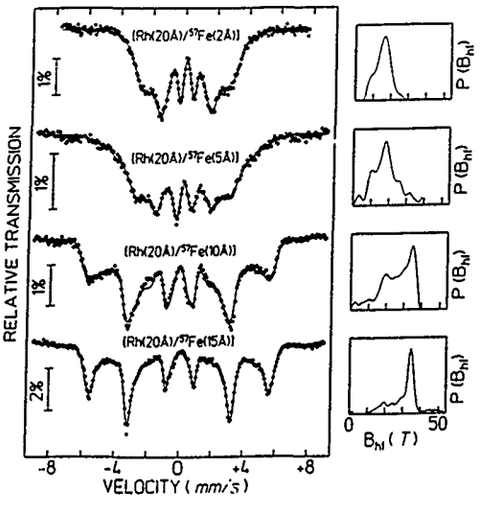

FIG. 2. Mössbauer spectra measured at 4.2 K and distributions $P(B_{hf})$ of Rh(20 Å)/^{57}Fe(t_{Fe}) multilayers for t_{Fe}=2, 5, 10, and 15 Å (from top).

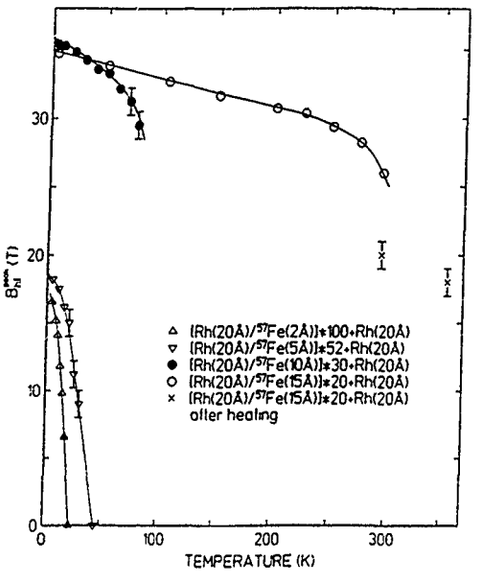

FIG. 3. Temperature dependence of B_{hf}^{peak} for t_{Fe}=2 Å (△), 5 Å (▽), 10 Å (●) and 15 Å (○). Crosses (×): for t_{Fe}=15 Å after annealing at 355 K.

suggests that the 2 Å ^{57}Fe film [~1 monolayer (ML) bcc Fe(110)] is completely alloyed with Rh resulting in an fcc-Fe-Rh alloy of average Fe concentration $c_{Fe}^{B_{hf}}$ of ~7 at. %. In the case of t_{Fe}=5 Å, $P(B_{hf})$ in Fig. 2 shows a pronounced peak at 18.2 T which demonstrates that this is also a pure fcc-RhFe multilayer. This hf field corresponds to $c_{Fe}^{B_{hf}}$ ~ 19 at. %, according to Ref. 5. We have also estimated the Fe concentration ($c_{Fe}^{a_0}$) in the fcc-alloy layer by comparing the measured lattice parameters (a_0) with those of bulk alloys.[3] Table I shows that $c_{Fe}^{a_0}$ values for 2 and 5 Å Fe are in rough agreement with corresponding $c_{Fe}^{B_{hf}}$ values. The calculated Rh thicknesses, $t_{Rh}^{fcc\ alloy}$, required for explaining the obtained $c_{Fe}^{B_{hf}}$ or $c_{Fe}^{a_0}$ values are given in Table I, too. (It was assumed that t_{Fe}=2 and 5 Å are completely alloyed). The $t_{Rh}^{fcc\ alloy}$ values obtained from $c_{Fe}^{B_{hf}}$ appear somewhat too large as compared to the deposited 20 Å-Rh layer, while those values deduced from $c_{Fe}^{a_0}$ appear to be reasonable. Table I indicates also the Fe concentration ($c_{Fe}^{T_f}$) obtained by comparing the measured (average) magnetic transition temperature T_f of our films (T_f=23±4 K for t_{Fe}=2 Å and T_f=45±7 K for t_{Fe}=5 Å, respectively, see Fig. 3) with the T_f vs c_{Fe} behavior of disordered fcc-RhFe alloys;[5] however, the corresponding (calculated) $t_{Rh}^{fcc\ alloy}$ values (Table I) are unreasonably high (e.g., 34 Å for t_{Fe}=5 Å). This very likely indicates that the T_f vs c_{Fe} behavior in ultrathin RhFe alloy layers deviates from that in bulk alloys as is the case for other spin glasses.[6] From the Mössbauer-line-intensity ratios the Fe-spin orientation in these samples was found to be nearly random which can be expected for spin-glass-type magnetism where a magnetic shape anisotropy is absent.

TABLE I. Estimated Fe concentrations $c_{Fe}^{T_f}$, $c_{Fe}^{B_{hf}}$ and $c_{Fe}^{a_0}$ of the fcc and bcc Rh–Fe alloy phase in Rh/Fe multilayers. $t_{Rh}^{fcc\ alloy}$ is the calculated Rh thickness consumed in fcc-alloy formation.

Rh(20 Å)/Fe(t_{Fe})	t_{Fe}=2 Å	t_{Fe}=5 Å	t_{Fe}=10 Å	t_{Fe}=15 Å
fcc phase				
$c_{Fe}^{T_f}$/at. %	7	12	24	...
($t_{Rh}^{fcc\ alloy}$)	(25 Å?)	(34 Å?)	(9.4 Å?)	...
$c_{Fe}^{B_{hf}}$/at. %	~7	~19	>25	>25
($t_{Rh}^{fcc\ alloy}$)	(25 Å?)	(20 Å?)	...	...
$c_{Fe}^{a_0}$/at. %	10	24	50	62
($t_{Rh}^{fcc\ alloy}$)	(17 Å)	(14.3 Å)	(3.0 Å)	(1.2 Å)
bcc phase				
$c_{Fe}^{B_{hf}}$/at. %	...	...	~96	~96

One can notice in Fig. 2 that the $P(B_{hf})$ curves (and the spectra) change drastically with increasing Fe thickness: the fcc-alloy distribution peak near ~17 T decreases gradually in relative intensity and shifts to slightly higher values, while simultaneously a new peak near 36 T (35 T) evolves and dominates at t_{Fe}=10 Å (or t_{Fe}=15 Å). This new peak is assigned to a disordered ferromagnetic bcc-Fe-Rh alloy. This follows from a comparison of our B_{hf}^{peak} values with those of Fe-rich disordered bcc-Fe-Rh bulk alloys.[7] We may estimate the average composition c_{Fe} of the bcc alloy in our multilayers by using the B_{hf} vs c_{Fe} curve in Ref. 7 (with B_{hf} in Ref. 7 corrected by a factor of 1.03 for the low temperature (4.2 K) used in our case). This leads to c_{Fe} ~96 at. % for t_{Fe}=10 and 15 Å in the bcc alloy (Table I).

The shape of the distribution $P(B_{hf})$ for t_{Fe}=10 Å (Fig. 2) demonstrates that fcc and bcc alloy phases coexist in this multilayer, (with the fcc-alloy distribution peak located at 19.8 T). Even for t_{Fe}=15 Å, the fcc-alloy distribution peak (at 20.0 T) is still present, together with a low-field distribution part (for B_{hf}<28 T). The relative area of the low-field or high-field (B_{hf}>28 T) distribution part provides values for the relative phase content (fcc or bcc) in the multilayer. In the case of t_{Fe}=10 Å we find that (36±15)% of the Fe atoms form the fcc-interface alloy (and 64% the bcc phase); for

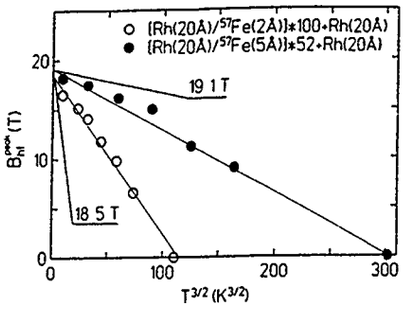

FIG. 4. B_{hf}^{peak} vs $T^{3/2}$ for t_{Fe}=2 Å (○) and 5 Å (●).

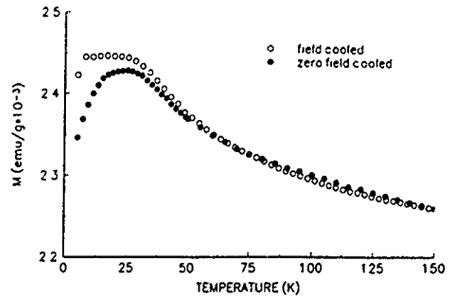

FIG. 5. Temperature dependence of magnetization in a Rh(20 Å)/^{57}Fe(2 Å) multilayer measured in B_{ext}=0.5 T, zero-field cooled (●) and field cooled (○).

t_{Fe}=15 Å, the corresponding values are (30±5)% (fcc) and 70% (bcc). This means that in the average a thickness of 3.6 Å Fe of the original 10 Å bcc-Fe layer is transformed to the fcc-interface alloy by interdiffusion; for the 15 Å Fe film, the corresponding value is 4.5 Å Fe. The Fe-spin direction of the bcc phase was observed to be preferentially oriented in the film plane indicating a shape anisotropy due to ferromagnetism.

It follows from the temperature dependence of B_{hf}^{peak} (Fig. 3) that the magnetic transition temperatures of the bcc phase (in multilayers with t_{Fe}=10 and 15 Å) are much higher than those of the fcc phase (with t_{Fe}=2 and 5 Å). For t_{Fe}=2 and 5 Å, $B_{hf}^{peak}(T)$ follows closely a $T^{3/2}$-spin wave law over the whole temperature range (Fig. 4). For t_{Fe}=15 Å, B_{hf}^{peak} shows a remarkable linear T dependence over a wide T range. It has been suggested that such a behavior is related to superparamagnetic relaxation of bcc-phase clusters.[8] However, as we have not observed a remarkable change at 150 K in the central component of the spectrum (not shown) even by applying fields up to 1 T, we may exclude superparamagnetism. Therefore, the linear T dependence observed can be explained by quasi-two-dimensional behavior of the bcc phase in the 15-Å sample, as predicted theoretically.[9] In contrast, the t_{Fe}=10 Å multilayer has been observed to be superparamagnetic by applying a magnetic field. After a measurement at 355 K and recooling to 295 K, an irreversible drop of B_{hf}^{peak} at 295 K occured. As we did not observe a change in $P(B_{hf})$ at 4.2 K after annealing, this drop in B_{hf}^{peak} could be due to a change in bcc Fe-film morphology (island formation) and a resulting change in the T dependence of B_{hf}^{peak} (possibly due to superparamagnetism).

The temperature dependence of the magnetization in the multilayer with t_{Fe}=2 Å (Fig. 5) indicates typical spin-glasslike behavior, i.e., different branches after zero-field cooling and during field cooling. It can be seen that the temperature of the maximum in the zero-field cooled magnetization (23±2 K) is in very good agreement with the magnetic transition temperature obtained from Mössbauer spectroscopy. This proves that interface fcc alloys with spin-glasslike properties can be obtained in Rh/Fe multilayers.

We are grateful to U. von Hörsten for technical assistance and sample preparation. This work was supported by the DFG (SFB166).

Heat treatment to control the coercivity of Pt/Co multilayers

J. Miller, P. G. Pitcher, and D. P. A. Pearson
Johnson Matthey Tech. Center, Sonning Common, Reading RG4 9NH, United Kingdom

We report on controlled changes in the coercivity of sputter deposited Pt/Co multilayer films by thermal treatment under controlled atmospheres. The as-sputtered coercivities of typically 3.3 kOe can be increased to 10.5 kOe by annealing in air, however for coercivities greater than 6 kOe the rectangular ratio of the multilayer decreases with increasing coercivity. The loop shape can be regained and the coercivity decreased by annealing in a H_2/N_2 atmosphere.

I. INTRODUCTION

Pt/Co multilayers are a promising candidate for the next generation of magneto-optical recording material.[1,2] These multilayers have been found to have large polar Kerr rotations and coercivities in both evaporated and sputtered films.[3,4]

In this article we report on the effect on annealing in controlled atmospheres on the coercivity of sputtered Pt/Co multilayers.

II. EXPERIMENT

Pt/Co multilayers were magnetron sputtered using dual source deposition in an Ar atmosphere onto glass substrates. The multilayers all consisted of 9.5 periods of 8 Å Pt/3 Å Co (the Pt layer was deposited first and last). Pt/Co individual layer thicknesses were confirmed using x-ray diffraction and inductively coupled plasma emission spectrometry.

The magnetic and magneto-optical properties of the multilayers were examined using a polar Kerr loop plotter and a vibrating sample magnetometer (VSM), the maximum applied field was 8 kOe so VSM measurements could not be done on the higher coercivity samples. The multilayer microstructure was examined using x-ray diffraction (XRD) and transmission electron microscopy (TEM).

A post-deposition anneal was performed on the multilayers, the atmosphere was either air or 10% H_2 in N_2, the annealing temperature was varied between 100 and 400 °C. The air annealed multilayers were heated by placing on a heater block at the required temperature. The transition from room temperature to the anneal temperature was achieved in under 2 min. Samples were cooled to room temperature by placing them on a large aluminum block. Cooling took less than a minute. The multilayers annealed in H_2/N_2 atmospheres typically reached the anneal temperature in under 5 min and were force cooled reaching room temperature in under 5 min.

III. RESULTS AND DISCUSSION

The as-sputtered multilayers typically had coercivities of 3.3 kOe and hysteresis loops with a high rectangular ratio $r(=H_n/H_c)$, as shown in Fig. 1(a). The coercivity was found to increase on heating the multilayer in an atmosphere containing oxygen. Figures 1(b)–1(d) show the room temperature polar Kerr hysteresis loops obtained after the multilayers had been heated in air to 200 °C for 2, 8, and 240 min. Initially both the coercivity (H_c) and the nucleation field (H_n) increase with annealing time and the hysteresis loops maintain a high rectangular ratio (r), however the H_n reaches a maximum at 6.2 kOe while the H_c continues to increase to a maximum of 10.5 kOe (Fig. 2) resulting in a skewing of the hysteresis loop. The H_c increase could be reversed and the loop's original rectangular ratio regained by heating in a reducing atmosphere of 10% H_2/90% N_2. An as-sputtered multilayer had its coercivity increased from 3.3 to 8.2 kOe by heating in air to 160 and 185 °C for 20 and 27 min, respectively. The before and after polar Kerr loops being almost identical to those of Figs. 1(a) and 1(c). The coercivity was then reduced from 8.2 to 3.3 kOe and the original loop shape regained by heating for 30 min at 185 °C in a 10% H_2/90% N_2 gas mix.

The mechanism for the coercivity increase is thought to be related to oxygen incorporation into the film structure. Coercivity increases after annealing the sample in air[5,6] and also in vacuum have previously been reported.[7] Yamane *et al.*[8] obtained increases from 0.2 to 2 kOe in the coercivity of sputtered Pt/Co multilayers with a 500 Å Pt capping film. They concluded from similar work with thicker Pd/Co multilayer films that oxygen incorporation at the grain boundaries of the columnar microstructure caused domain wall binding resulting in the increase in the multilayer coercivity.[5] The reversible nature of the coercivity in a reducing atmosphere suggests a similar mechanism causes the coercivity increases observed in our films. The saturation

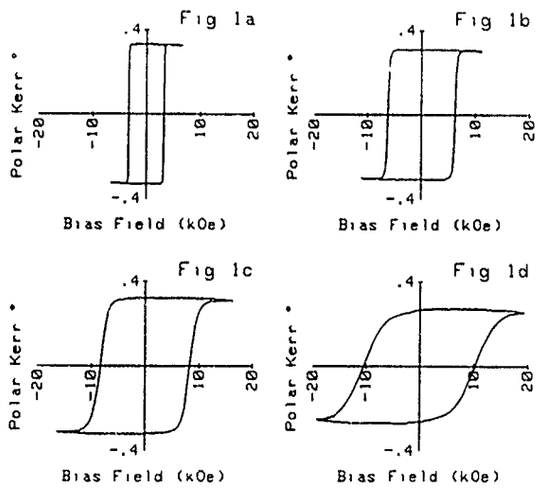

FIG. 1. Polar Kerr loops of Pt/Co multilayers after annealing at 200 °C, (a) as-sputtered, (b) 2 min, (c) 8 min, (d) 240 min.

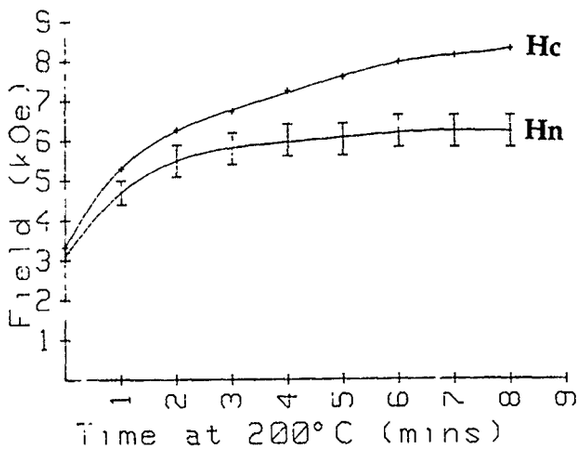

FIG. 2. Coercivity and nucleation variation with anneal time at 200 °C.

magnetization of our multilayers decreased as the multilayer coercivity increased from 3 to 6 kOe, this further suggests cobalt oxide formation as the cause of the increased coercivity.

A bright field TEM image of an as-sputtered multilayer is shown in Fig. 3. The multilayers are polycrystalline with a grain size of approximately 10 nm.

To examine the effect of the coercivity increase on the magnetization reversal mechanism initial magnetization curves were examined. A set of multilayers was demagnetized by heating to 400 °C for 15 s, the dwell time had to be short to avoid damaging the multilayer structure. Hashimoto *et al.*[1] have previously found that a 30 min anneal at 400 °C resulted in loss of perpendicular magnetic anisotropy and multilayer structure. However XRD measurements of our demagnetized multilayers showed that the satellite peaks of the multilayers were unchanged after thermal demagnetization. Figure 4 shows the initial magnetization curves for these multilayers. In Figs. 4(a)–4(c) the coercivity is a result of the difficulty in creating a reversed domain, since the magnetization initially increases from the demagnetized state at

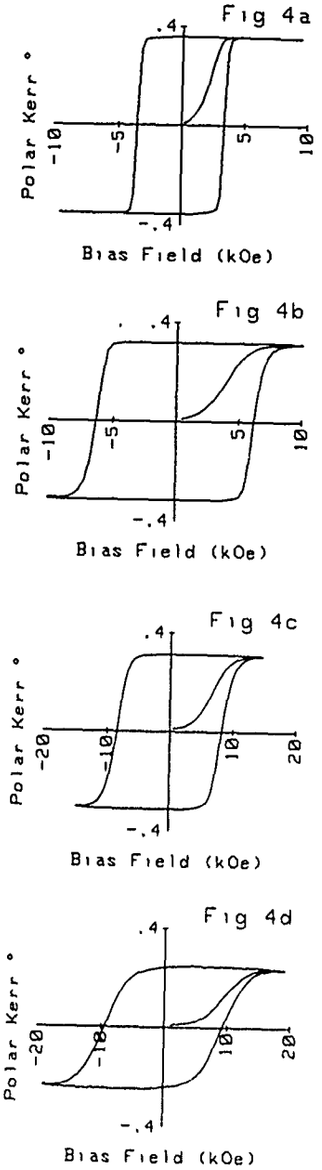

FIG. 4. Initial magnetization curves of thermally demagnetized Pt/Co multilayers.

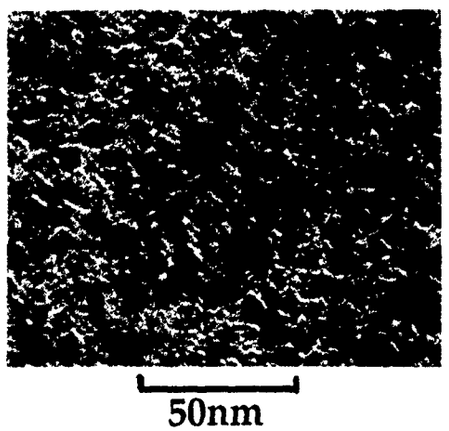

FIG. 3. TEM bright field image of an as-sputtered Pt/Co multilayer.

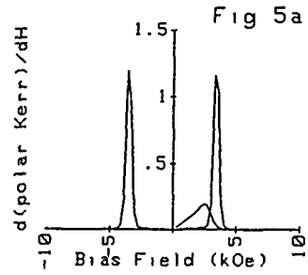
fields smaller than the nucleation field. In contrast the coercivity of the high coercivity multilayer in 4*d* is dominated by domain wall pinning. This is demonstrated by differentiating the polar Kerr signal with respect to the applied field, Figs. 5(a) and 5(b) are the differentials of Figs. 4(a) and 4(d) respectively. The rate of change of the initial magnetization as a function of applied field is different to that of the magnetization reversal in Fig. 5(a), where as in Fig. 5(b) both distributions are the same.

In summary the initial magnetization loops show that the coercivity increase is initially caused by an increase in the nucleation field. As the coercivity increases further, wall pinning becomes the dominant effect in determining the multilayer coercivity.



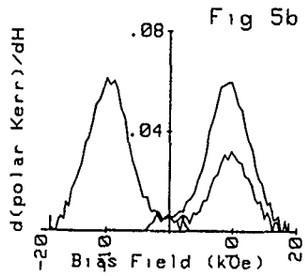


FIG. 5. Differential with respect to applied field of the initial magnetization curves.

IV. CONCLUSION

We have found that we can increase the coercivity of sputtered multilayers by annealing in air. The coercivity increase can be reversed by annealing in a 10% H_2 in N_2. The cause of the coercivity increase is thought to be oxygen incorporation in the multilayer, initially the effect is to increase the nucleation field of the multilayer however further coercivity increases are caused by domain wall pinning.

Commercially available Fe-Co alloys with Co contents of 50 and 24 wt. % have been rf sputtered to produce multilayers with noble metal (Ag or Cu) interlayers. Series with fixed Fe-Co or noble metal thicknesses have been produced, as have plain Fe-Co films. In all cases, the coercivities of the multilayers are significantly reduced from those exhibited by the plain alloy films. For example, a film of the alloy containing 50 wt. % Co had H_c=6.9 kA m^{-1}, whereas a multilayer with 12 nm Fe-Co layers and 2 nm Ag layers had H_c=480 A m^{-1}. The saturation magnetostriction is also enhanced, in some cases increasing by 60% over the expected bulk polycrystalline alloy value. For example, the literature λ_s value for a Fe-Co alloy containing 24% Co is about 28 ppm; in a multilayer with 12 nm alloy layers and 8 nm Ag layers, λ_s=45 ppm. The combination of high magnetostriction and low coercivity makes such materials as these attractive for their potential as stress sensor and actuation transducer elements.

I. INTRODUCTION

There is currently interest in many aspects of magnetic multilayers (e.g., giant magnetoresistance and magnetic and magneto-optic recording media). For sensor and transducer applications, high saturation magnetostriction, λ_s, in soft materials is desirable. Our investigations began with an iron-cobalt alloy of a composition known to have a value of λ_s($\approx$53 ppm) comparable with most conventional soft materials. Ag and Cu were chosen as the interlayers because they are noble metals, immiscible with Fe and Co, nonmagnetic, and are larger than Fe or Co atoms. We found that Ag interlayers in films sputtered from this alloy softened them considerably and, in some cases, caused enhancement of the magnetostriction.[1] Here, we report further investigations into the Fe-Co alloy/noble metal multilayer systems, including two types of alloy and various thicknesses. Results for Ag interlayers will be compared to those for multilayers containing Cu in order to give the first indication of an explanation for the observations.

II. EXPERIMENTAL METHODS

The multilayers were rf magnetron sputtered from alternate targets of commercially available alloys: HiSat50® (50% Fe, 50% Co with less than 0.2% Ta) or Permendur24® (24% Co, 75.4% Fe, 0.6% Cr) (Telcon Metals Ltd., U.K.); and Ag (99.99%) at 75 W. The background pressure was 2–5$\times10^{-7}$ Torr; during sputtering, the Ar pressure was 5 mTorr. The substrates were 26-μm-thick Kapton® polyimide (DuPont Ltd., U.K.); the substrate platen was water cooled. Typically 50 bilayers were deposited on each side of the substrate to equalize any film stresses. Two series types were made: (1) t_{Ag}=2 nm, $t_{HiSat50}$=2–12 nm or $t_{Permendur24}$=2–15 nm; (2) t_{Ag}=0.5–10 nm, $t_{HiSat50}$=12 nm, or $t_{Permendur24}$=10 nm. Results for the first HiSat50 series will be compared with those from multilayers with Cu in place of Ag interlayers (Cu target 99.99%). Plain alloy films were also deposited, 600 nm thick for HiSat50 on one side of the substrate and 2$\times$600 nm thick for Permendur24, i.e., 600 nm on each side of the substrate. These thicknesses are comparable to the typical total thickness of Fe-Co alloy in the multilayers.

In-plane magnetic hysteresis loops were measured using a quasi-dc inductive magnetometer,[2] H_{max}=22 kA m^{-1}. Saturation magnetostriction was measured by small angle magnetization rotation (SAMR)[3] (see Ref. 1 for application to deposited samples) and strain-modulated ferromagnetic resonance (SMFMR).[4] The films were examined structurally using high-angle x-ray diffraction (XRD) in the θ-2θ mode with Cu-$K\alpha$ radiation.

III. RESULTS AND DISCUSSION

Electron probe microanalysis of sputtered HiSat50 films shows that they contain 45 wt % Fe, 55 wt. % Co, and approximately 0.2 wt. % Ta. A bulk polycrystalline alloy of this composition would have $\lambda_s\approx$53 ppm; this is true for compositions $\approx\pm$5% of the nominal.[5]

XRD traces of the Fe-Co/Ag and Fe-Co/Cu multilayers show that the alloy layers are polycrystalline, with bcc structure and no significant crystallographic texture. Peaks due to fcc Ag generally coincide with alloy peaks, so it is not possible to say whether the Ag layers are textured. No XRD satellite peaks are seen, indicating that the alloy-noble metal interfaces are rough. This is supported by low-angle XRD and kinematic modeling. Ag layers are possibly not continuous for $t_{Ag}<\approx$5 nm.[6]

The Scherrer equation[7] has been used with the bcc (110) peak widths to estimate the grain sizes in the films. (No account was taken of any possible inhomogeneous lattice strains, which also contribute to peak broadening.) Grain sizes in the HiSat50/2 nm Ag multilayers are 3–14 nm; in

HiSat50/2 nm Cu, 5–14 nm. Thicker alloy layers produce larger grains in both cases.

Average lattice strain was calculated from the XRD peak positions by comparison with bulk Ag d_{111} or the d_{110} spacing for the thick Fe-Co films. In the series with constant t_{Ag}=2 nm, for thinner alloy layers, the average Fe-Co d_{110} spacing perpendicular to the film plane is expanded (up to 1.0% for HiSat50, 1.6% for Permendur24). The spacing relaxes towards the plain film value for thicker alloy layers. The Ag(111) spacings show no trend with $t_{Fe\text{-}Co}$ but the lattice is contracted up to −1.0%. In multilayers with fixed $t_{Fe\text{-}Co}$ and varied t_{Ag}, there is contraction up to −1.0% in thinner Ag layers, tending weakly towards the bulk value as t_{Ag} increases. The Fe-Co d_{110} spacings follow the same pattern as Ag d_{111} as t_{Ag} varies. The HiSat50 d_{110} strain rises to +0.3% as t_{Ag} increases; similarly, the Permendur24 d_{110} strain rises to +1.1%. Please note that although these strains are perpendicular to the film plane, it does not follow that the in-plane strains are necessarily of opposite sign.[8]

We have already reported some results on HiSat50/2 nm Ag multilayers.[1] Here we add λ_s data obtained SMFMR measurements (Fig. 1), which confirm the validity of the SAMR technique for such samples. Enhancement of λ_s is observed for multilayers with thicker $t_{HiSat50}$ and t_{Ag}=2 nm; 83 ppm is the highest seen, compared with 53 ppm for bulk.[5] A significant reduction of H_c is seen for all the multilayers, compared to that of a plain 600 nm HiSat50 sputtered film.[1] H_c=450 A m^{-1} is observed for a multilayer containing 12 nm HiSat50 layers and 2 nm Ag layers (this is also the most magnetostrictive sample) compared to 6.9 kA m^{-1} for the plain HiSat50 film. H_c values for plain alloy films given here are underestimates, since these films were not saturated in the field available in the dc magnetometer. The values given are those for which M=0 on reducing the applied field from H_{max}=22 kA m^{-1}.

H_c and λ_s for HiSat50/2 nm Cu multilayers are presented in Fig. 2. The softening effect of interlayers is again seen with similarly low coercivities obtained, although the trend is opposite to that seen in the HiSat50/2 nm Ag multilayers (i.e., for Cu interlayers, *thinner* HiSat50 layers, with *smaller* grain sizes, give the softer films). λ_s is slightly enhanced over the bulk value[5] but the increase is not as large as that seen for thicker HiSat50 layers with Ag interlayers.

Figure 3 shows the effects of different thicknesses of Ag interlayers on the properties of multilayers with $t_{HiSat50}$=12 nm. It is thought that Ag layers become continuous only for $t_{Ag}>\approx$5 nm[6] and this may account for the dip in λ_s at around that value. The maximum H_c in this series occurs around t_{Ag}=8 nm.

These results are to be compared with those for multilayers containing Permendur24 (Figs. 4 and 5), which contains a greater proportion of Fe and has a lower bulk polycrystalline λ_s than HiSat50 (around 28 ppm).[5] Again, the alloy films are softened by the presence of Ag interlayers and λ_s is enhanced. H_c=560 A m^{-1} for a multilayer with 12 nm Permendur24 layers and 2 nm Ag layers, compared with 4.6 kA m^{-1} for a 2×600 nm plain film. The highest λ_s value observed is 45±3 ppm an increase of about 60% over the bulk value, for the multilayer 2×40 (10 nm Permendur24/10 nm Ag). A similar value is found for 2×50(10 nm Permendur24/2 nm Ag), which has low H_c. The differences in behavior between the Ag and Cu series may result from

atom than Cu (Ag a_0=0.41 nm, Cu a_0=0.36 nm) Cu has a larger Young's modulus (E_{Cu}=118 GPa, E_{Ag}=76 GPa)[9] so it strains less readily, forcing the alloy layer to strain more. The data we have do not permit a comparison of the roughness of the interfaces in the two systems, although we can state that neither is smooth. It appears that lattice strain is not the mechanism for enhancing λ_s; work is in progress regarding magnetization orientation effects.

IV. SUMMARY

Both Ag and Cu interlayers of various thicknesses reduce the coercivity of Fe-Co alloy sputtered films by up to an order of magnitude. In certain cases, λ_s is enhanced by nearly 60% over the value expected for bulk polycrystalline alloys of similar compositions. Some λ_s results taken by SAMR have been independently confirmed by SMFMR. Greater effects are seen in multilayers containing Ag interlayers than in those containing Cu interlayers; this difference is tentatively attributed to the difference in wetting of Ag and Cu on Fe and Co. It has been demonstrated that multilayers can be deposited which are simultaneously magnetically soft and highly magnetostrictive, a characteristic desirable in sensor and transducer applications.

The structure of thin cobalt films sputtered on a rhenium buffer was analyzed from room temperature to 963 K, using the perturbed angular correlation technique with the $^{111}In/^{111}Cd$ probe. The hyperfine field corresponding to the fcc phase, which is the stable one above 704 K, is never observed, and the measured hyperfine field follows closely a theoretical prediction for the hcp phase. This is a consequence of the good match between the cobalt and the Re hcp lattices that leads to the stabilization of the hcp phase up to 963 K.

I. INTRODUCTION

As the structure of magnetic thin films and superlattices (SLs) determines their magnetic properties, it becomes important to control it on a microscopic level, leading to the tailoring of materials with prespecified properties. Cobalt is one of the elements more frequently used in magnetic SLs. While its stable phase has a hcp structure below 704 K, above that temperature a phase transition to fcc is observed.[1] Total-energy band structure calculations at 0 K predict correctly the hcp phase as the stable one,[2] with the fcc and bcc phases slightly higher in energy. The small energy differences suggest however the possibility of occurrence of the fcc and bcc metastable phases, even at room temperature. The bcc phase was first obtained[3] by epitaxial growth of Co on (110) GaAs, and later[4] by epitaxial growth on (100) Fe. The fcc structure is generally presented in samples submitted to mechanical or thermal treatments.[1] Although the mechanism of the phase transition at 704 K is well known[5] and explained as corresponding to the slip of planes normal to the $\langle 0001 \rangle$ hcp and $\langle 111 \rangle$ fcc axes, its cause is still not yet understood. Temperature-dependent calculations of the total energy should be able to determine whether an energy crossover between the hcp and fcc phases exists.

In this work, the 704 K phase transition in Co thin films grown on a hcp rhenium buffer is investigated. Re was chosen due to the small mismatch $\Delta(c/a)=0.5\%$ relative to the Co hcp lattice. Measurements were carried out at temperatures up to 963 K, using the perturbed angular correlation (PAC) hyperfine interactions technique, based on the observation of the spin rotation of a ^{111}Cd probe implanted in the film. Since the magnetic hyperfine fields (HFFs) are well known for both Co phases, the method is very sensitive for following the phase transition in a microscopic way.

II. EXPERIMENTAL DETAILS

Co thin films on a Re buffer grown on glass and silicon substrates were produced with a modified argon sputtering apparatus (Alcatel SCM 540). The pressure in the target chamber before the introduction of argon was 5×10^{-8} Torr. Co was deposited by rf magnetron sputtering at 5 mTorr and Re was deposited by dc magnetron sputtering at 2.5 mTorr. The deposition rates were 0.04 and 0.1 nm/s, respectively. Film thickness was monitored *in situ* by the vibrating quartz crystal method, and checked with Rutherford backscattering (RBS) analysis.[6] The Co layers were 22, 34, and 40 nm thick for the films studied in this work. The Re buffer layer was 30 nm thick in all cases.

The Re buffer is highly structured with the c axis normal to the film surface, and the same orientation is observed by x-ray diffraction and cross-sectional high resolution transmission electron microscopy for the Co films.[7,8] This is a consequence of the good lattice match between the Co and Re hcp structures, where $\Delta(c/a)=0.5\%$.

The ^{111}Cd probe atom has been introduced in the films by implantation with 80 keV energy of the ^{111}In parent isotope to doses of about 10^{13} at./cm^2. The implantation range and width are 16 and 6 nm, respectively, so the probe is confined to the Co layers. The PAC technique measures the Larmor nuclear spin precession frequency induced by the magnetic HFF at the probe site. The Larmor frequency is observed in the oscillating anisotropy amplitude of the coincidence spectra of the 173–247 keV γ-γ cascade of ^{111}Cd. This is done by measuring the number of coincidences as a function of time, $N(\theta,t)$, using four detectors in the same plane at 90° angles, and calculating the usual anisotropy function $R(t)=2.[N(180^0,t)-N(90^0,t)]/[N(180^0,t)+2.N(90^0,t)]$. For a pure magnetic interaction, the $R(t)$ function is a sum of cosines with the Larmor frequency $\omega_L=-\mu B/I\hbar$ and its $2\omega_L$ harmonic, where B is the local field at the ^{111}Cd probe and μ the magnetic moment of the $I=5/2$ intermediate state of the cascade. The known weak electric field gradient of the hcp Co lattice leads to a small damping of the spectra,[9] and was taken into account in the calculations. In this way the experimental data have been fitted with a theoretical function using ω_L and the percentage

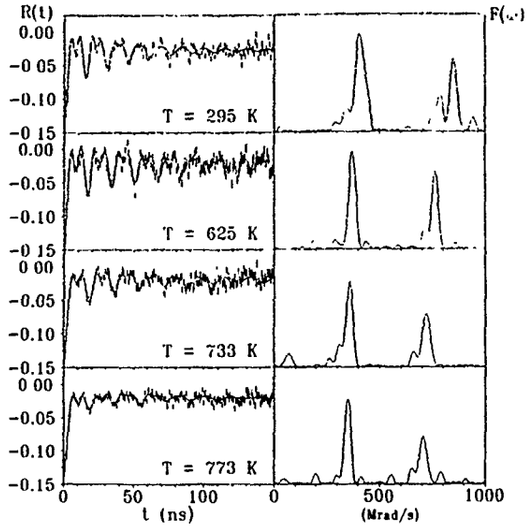

FIG. 1. PAC time spectra and corresponding Fourier transforms for one of the films.

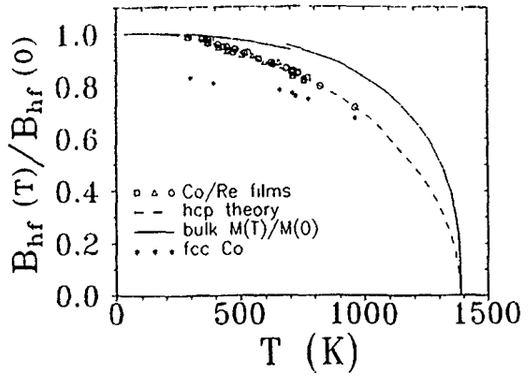

FIG. 3. Temperature dependence of the reduced hyperfine field at ^{111}Cd in Co, in Co/Re thin films. The full line represents the bulk magnetization. The dashed line is a theoretical prediction for the hcp field above the phase transition temperature (Ref. 13). The temperature dependence of the hyperfine field at ^{111}Cd in fcc Co (Refs. 13–15) is also shown.

of probe nuclei with a particular hyperfine interaction as adjustable parameters. The magnetic frequencies obtained following this analysis are also observed in the Fourier spectra, where the linewidth is broadened due to the quadrupole splitting.

Two setups were used, one with NaI(Tl), and the other with BaF_2 detectors. The time resolution of 2.3 ns for NaI(Tl) and 0.7 ns for BaF_2 allows the observation of the precession frequencies, with a 1% error mainly due to the error in the time calibration. The measurements have been performed as a function of temperature under 10^{-6} Torr pressure. The maximum temperatures reached for each of the films were, respectively, 963, 759, and 773 K. In each of the films several runs were done starting at room temperature. The frequencies obtained for the same temperature in different runs were the same within experimental errors, and the temperature dependence of the frequency was also the same in the three films, so the results obtained will be treated as a single experiment.

RBS experiments were done using a 1.6 MeV He^+ beam detected by a 15 keV energy resolution detector located at 160° with the incidence direction in the Cornell geometry.

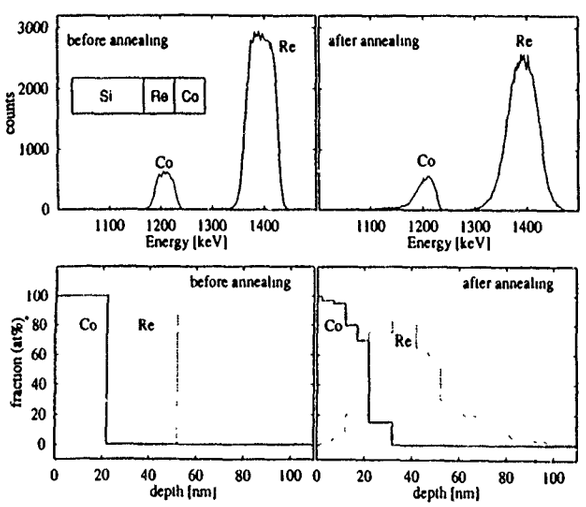

FIG. 2. RBS spectra and derived depth profiles of a Si/Re 30 nm/Co 22 nm film taken before and after 1 h annealing at 923 K.

III. RESULTS

In Fig. 1 the spin rotation curves and their corresponding Fourier transforms are shown for one of the films, measured with the BaF_2 detectors setup at different temperatures. The normal to the plane of the film was in the detector plane, at 45° with two of the detectors. The field orientation is clearly reflected in the relative amplitudes of the ω_L and $2\omega_L$ frequencies. It is in the plane of the film, as already seen in Co/Re multilayers.[10] Separate experiments were done at room temperature with the film in different positions, leading to different ω_L and $2\omega_L$ amplitudes, confirming that orientation of the HFF. In Co single crystals the HFF is along the c axis at room temperature, and turns slowly to the basal plane between 500 and 600 K.[9] This reorientation of the magnetic moments does not occur in these thin films, due to the demagnetizing field.

The clearly separated satellites observed at the left of the ω_L and $2\omega_L$ peaks correspond to a well-known stacking fault defect.[11,12] This defect is due to the sputtering process and does not interfere with the determination of ω_L. Its fraction is maximum at room temperature, and decreases with annealing.

At temperatures higher then 800 K, new frequency components (not shown) are seen in the Fourier spectra. However, the ^{111}CdCo peaks are still clearly defined. RBS studies of the 22 nm Co film were done as function of annealing temperature. Below 823 K no change could be observed. The RBS spectra taken before and after 1 h annealing at 923 K are shown in Fig. 2, together with the derived depth profiles, showing clearly that diffusion occurred between the Co and Re layers. Therefore, the new frequency components are

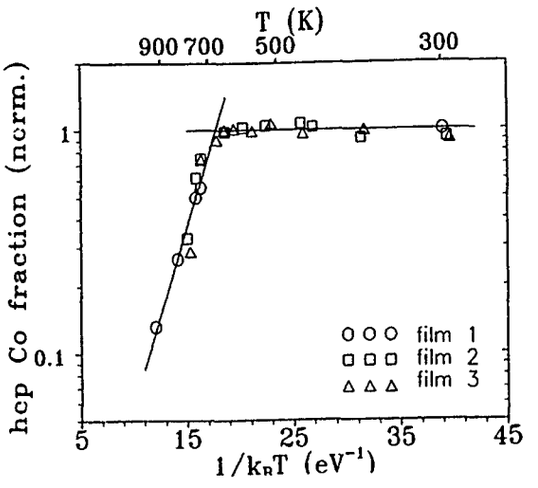

FIG. 4. Temperature dependence of the fraction of probes feeling a well-defined hyperfine field, normalized to the room temperature value.

likely to be related with a fraction of probes in the mixed region, while some remain in a pure Co environment, leading to the ^{111}CdCo field.

IV. DISCUSSION

The temperature dependence of the reduced HFF $B_{HF}(T)/B_{HF}(0\ K)$ is shown in Fig. 3 together with the bulk Co magnetization $M(T)/M(0\ K)$[1] and the HFF of ^{111}Cd in fcc Co.[13–15] It is clear that throughout the temperature range of this experiment, the temperature dependence of the measured field is smooth and in very good agreement with the one expected for hcp Co; indeed, the fcc field is never observed, and the known 10% discontinuity of the HFF that takes place at the phase transition is not present, which proves that no fcc phase is present. Also, the deviation from the bulk magnetization of the HFF of Cd and other 4 *sp* impurities in Co has been explained previously by Lindgren *et al.*[13] In this model a temperature dependent *sd* hybridization contributes a local field at the probe site adding up with the conduction electron contribution. Their calculation for the HFF of Cd in hcp Co is given as the dashed line in Fig. 3. The HFF obtained in the present study is in very good agreement with the predicted values above the phase transition temperature, confirming that the hcp structure was retained as a metastable phase throughout the temperature range attained.

The fraction of probes feeling the well-defined HFF of Cd in hcp Co is shown in Fig. 4 as function of temperature, normalized to its room temperature value. The solid line is a fit to the data above 625 K assuming an Arrhenius law. The extrapolation of the fit to a 1.0 normalized fraction of probe nuclei in substitutional positions in a pure Co environment yields $T(f=1.0)=$ 655 K. This is 150 K below the occurrence of mixing between the Co and Re layers, so the decrease observed must be related to diffusion of the probes out of the Co layer.

V. CONCLUSIONS

The hcp structure of Co was retained above the fcc phase transition temperature and up to 963 K, as a metastable phase, by growing thin Co films on Re substrates. No fcc phase was observed, and the temperature dependence of the hyperfine field at the Cd site in the Co films above the usual phase transition temperature of 704 K follows closely a theoretical prediction for the hcp field.

Observation and computer simulation of static magnetization process in soft magnetic thin film

Zhigang Wang, Ikuya Tagawa, and Yoshihisa Nakamura
Research Institute of Electrical Communication, Tohoku University, Sendai 980-77, Japan

We have developed a new numerical micromagnetic simulator based on the curling particle assembly model and the finite element method which describes the static magnetization process in soft magnetic films successfully, and which exhibits many details of that process. Compared to conventional numerical treatment of the magnetic structure in soft magnetic films, e.g., the Landau–Lifshits–Gilbert equation method, recently proposed Monte Carlo method, our approach has the following advantages: high calculation speed, arbitrary meshing size, and good agreement with experiment.

I. INTRODUCTION

Studying the static magnetization process in soft magnetic thin film is of interest for domain-control technology. As a conventional analytic method, the Landau–Lifshits–Gilbert (LLG) equation method has been well used.[1,2] Recently a Monte Carlo method was proposed[3] which uses random numbers to calculate an approximate result for eventual phenomena such as unknown magnetization distribution in soft magnetic films.

In this article a new numerical micromagnetic simulator based on the curling particle assembly model[4] and the finite element method (FEM) is developed. Compared to the other methods, our approach has the following advantages: high calculation speed, arbitrary meshing size, and good agreement with experiment.

Magnetic structures of rectangularly striped permalloy film, which can be typically used for magnetoresistive head, are modeled. The easy magnetic axis is aligned in the transverse direction. At the beginning, the spontaneous subdomain configuration for a stripe of a given length/width ratio is simulated by determining the minimum free energy. The static magnetization process due to a slowly changing external field is then simulated. The above simulation results are generally in agreement with Bitter pattern experiments.

II. OBSERVATION

The sample for the Bitter pattern experiment is a rectangular $Ni_{80}Fe_{20}$ film (thickness=100 nm, width=10 μm) formed by rf sputtering, photolithography, and ion-etching process. An anisotropic field H_k=4.2 Oe is induced along the width direction by applying a field of 15.5 Oe in the same direction while sputtering. The samples were coated by a thin magnetic colloidal solution and the domains were observed under an optic microscope.

The static magnetization process for a stripe with the length/width ratio of 2:1 is shown in Fig. 1. Based on the equilibrium ground state of the closure domain pattern, a uniform external field H is applied along the transverse and longitudinal directions. The common rule is that those domains with magnetizations parallel to H grow whereas those domains with magnetizations antiparallel to H shrink and therefore magnetic walls move. Eventually a single domain state is achieved at a field H_s. We find that H_s along the longitudinal direction is about 10 Oe, and is much smaller than the value of 50 Oe determined for H_S along the transverse direction.

III. DESCRIPTION OF SIMULATOR

The flow chart of our simulator is shown in Fig. 2. A soft magnetic film is divided into an array of $n \times m$ square cells, where each cell is assumed to be an assembly of a certain number of magnetic particles. The angle of the magnetization in each particle is chosen such that it minimizes the energy function which covers the exchange, anisotropy, demagnetizing, and external field terms according to the curling model. The magnitude and direction of the magnetization (magnetization vector) of each cell is determined by computing the arithmetic mean of those of all particles in that cell. The magnetic properties of each particle are determined by forcing the calculated hysteresis curve, with the aid of our hysteresis curve simulator,[4] to resemble the measured curve in shape. The parameters to be adjusted for the curling model are shown in Table I. The adjusted parameters are as follows:

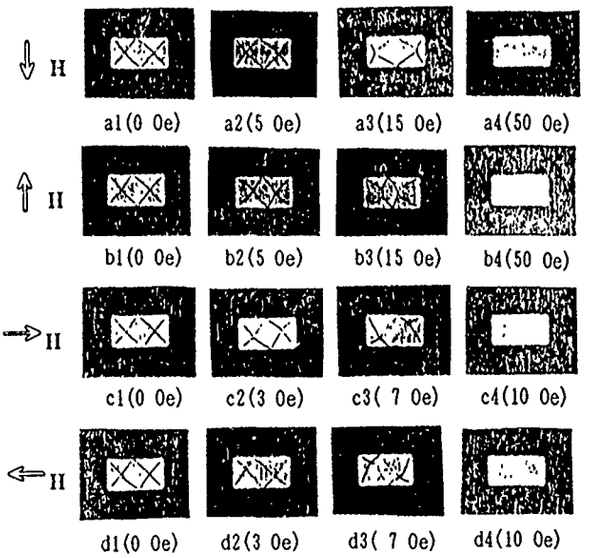

FIG 1. The Bitter pattern experiment

 0021-8979/94/76(10)/6540/3/$6.00 © 1994 American Institute of Physics

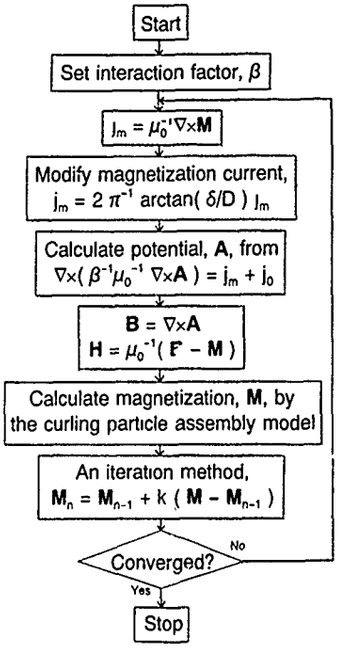

FIG. 2. Flow chart.

the curling model parameter $S=(1.08H_k/H_c)^{1/2}=3.37$, $M_s=700$ emu/cc, $H_c=0.4$ Oe, $\sigma_{H_c}/H_c=0.1$, $H_k=4.2$ Oe, $\sigma_{H_k}/H_k=0.1$, $\sigma_\theta=10$ deg.

In general two-dimension model the thickness of the film is assumed as large enough. To realize the quasi-three-dimension (FEM) simulation of very thin film, we have to correct the demagnetizing field by a factor $(2/\pi)\arctan(\delta/D)$, where δ and D are the thickness and width of the film, respectively. This is because the demagnetizing factor of a long stripe thin film with the thickness δ and the width D is appropriately $(2/\pi)\arctan(\delta/D)$ in the transverse direction. In FEM program, however, we cannot separate the demagnetizing field from the total field, so that we modified the magnetization current j_m instead of the demagnetizing field, as shown in Fig. 2.

TABLE I. The adjusted parameters for the curling model.

Magnetic property	Distribution function	Parameters to be adjusted
Curling model parameter		S
Saturation magnetization		M_s
Coercive field	Gauss distribution	Average H_c, standard deviation σ_{H_c}/H_c
Anisotropic field	Gauss distribution	Average H_k, standard deviation σ_{H_k}/H_k
Direction distribution of easy axis	Gauss distribution	Average θ, standard deviation σ_θ

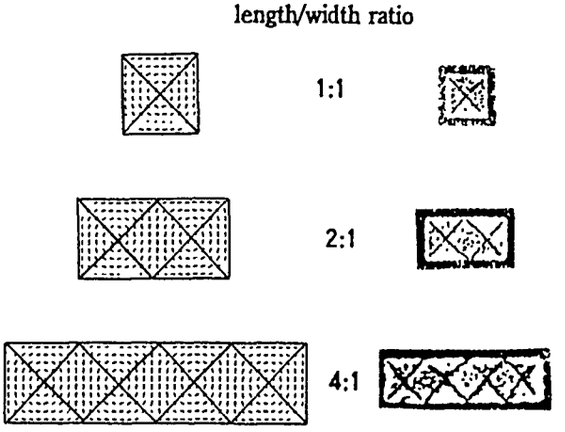

FIG. 3. The spontaneous subdomain configuration.

It is taken for granted to assume a mean field interaction[5] between particles for permalloy. The mean magnetic field is assumed to be proportional to the intensity of the mean magnetization in the surroundings of the particle. For simplicity, we take the mean field as $H_{\text{mean}}=\alpha B/\mu_0$, where B is the magnetic flux density and α is a constant. The effective field in a soft magnetic film is then expressed as

$$H_{\text{eff}}=H+H_{\text{mean}}=H+\alpha B/\mu_0=(1+\alpha)H+\alpha M/\mu_0. \tag{1}$$

Here H is the magnetostatic field which consists of the externally applied field and the demagnetizing field. The equation expressing the relationship between the flux density B and the field H then results in

$$B=\mu_0 H_{\text{eff}}+M=(1+\alpha)(\mu_0 H+M)=\beta(\mu_0 H+M), \tag{2}$$

where $\beta=1+\alpha$ which represents the interparticle mean field interaction. Applying Ampere's law $\nabla\times H=j$, the essential equation of FEM becomes

$$\nabla\times\left(\frac{1}{\beta\mu_0}\nabla\times A\right)=j_0+j_m, \tag{3}$$

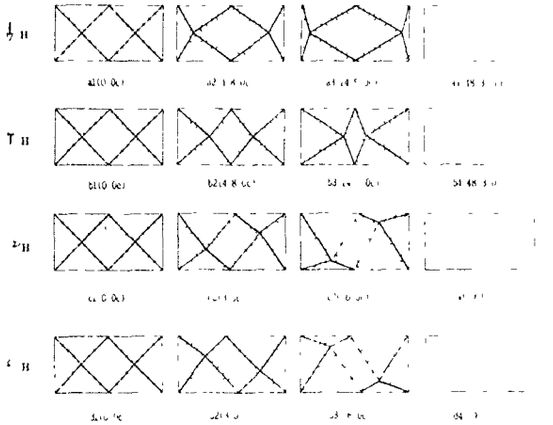

FIG. 4. The simulated static magnetization process.

where A ($B=\nabla\times A$) is the vector potential. The solved magnetization M in every cell is converted into an equivalent magnetization current by $j_m=\mu_0^{-1}(\nabla\times M)$ and the substituted into the magnetization current term j_m in Eq. (3). This procedure is repeated until the final equilibrium state is reached.

IV. SIMULATED RESULTS

By making use of the above micromagnetic model, the spontaneous states of the well-known closure domain pattern are given in Fig. 3 for various length/width ratios. For comparison, the corresponding Bitter patterns are also shown in the same figure.

Then the static magnetization process due to a slowly changing field is simulated. The uniform external field H is induced by a pair of Helmholtz coils. Figure 4 is a example for a 2:1 stripe which demonstrates good agreement with the Bitter pattern experiment in Fig. 1. Further, this simulation can explain the phenomenon that the walls of the main domain become less well defined in Fig. 1(c3) and Fig. 1(d3) and finally disappear completely in the Bitter pattern experiment. It is because of the large-angle rotation of the moments in the main domain, as shown in Fig. 4(c3) and Fig. 4(d3). In other words, from this simulation we can observe clearly the two major magnetization mechanisms: wall displacement and magnetization rotation.

V. CONCLUSION

Attempts to simulate the static magnetization process in soft magnetic film using the particle assembly model yield good agreement with experiment. In the future it may be interesting to find a direct microscopic evidence in physical structure.

The structural and magnetic properties of sputtered Fe/Fe-O films were studied by x-ray photoelectron spectroscopy (XPS), Rutherford backscattering spectroscopy, transmission electron microscopy, and superconducting quantum interference device. XPS studies showed the presence of FeO and Fe_2O_3 on the surface of as-made samples. Microstructure studies showed a uniform nanostructure with the grain size in the range of 50–150 Å with smaller grains corresponding to thinner films. The coercivity at 10 K was found to increase substantially with decreasing film thickness below 60 Å. A high H_c (2.7 kOe) was observed in samples with a thickness about 20 Å. Magnetization curves showed a planar anisotropy with a shifted hysteresis loop characteristic of an exchange anisotropy between the Fe and Fe-O coating. The coercivity was found to drop steeply with increasing temperature. This may be attributed to the superparamagnetic behavior of the Fe-O surface layer.

I. INTRODUCTION

During the last several years, iron oxide thin films have been extensively investigated because of their unusual magnetic properties and potential application in high density recording media.[1–5] In these studies, iron oxide thin films were prepared by a variety of methods, including reactive rf sputtering from iron targets in a mixed O_2 and Ar atmosphere. The structural and magnetic properties of the films were found to strongly depend on the oxygen flow rate, the substrate temperature and the thickness of the film. Different iron oxides (FeO, Fe_3O_4, α-Fe_2O_3, and γ-Fe_2O_3) were found in films with thickness in the range from several hundred to several thousand angstroms.

Very few studies have been conducted on iron-iron oxide systems.[6–8] Schneider *et al.*[7] found a high coercivity in Fe-Fe_2O_3 annealed at 200 °C. However, Ruf and Gambino[8] observed a strong exchange anisotropy in sputtered Fe-FeO layered films instead of a high coercivity. Recent studies on Fe-Fe oxide fine particles showed a high coercivity and exchange anisotropy at low temperatures consistent with a core-shell particle morphology.[9]

In this study we extended the studies on Fe-Fe oxide particles to bilayer films made by dc magnetron sputtering. Iron oxide was formed by direct oxidation of the surface of the as-made Fe film.

II. EXPERIMENTAL PROCEDURE

A dc planar magnetron sputtering system was used to prepare the Fe-Fe oxide bilayers. The sputtering target used was a 99.9% Fe disk 2 in. in diameter and 0.053 in. in thickness. The distance between the target and the water cooled substrate holder was 13.5 cm. The sputtering chamber was initially pumped down to 7×10^{-8} Torr by a crypopump and then the Fe film was deposited onto a kapton substrate by sputtering in a 5 mTorr Ar atmosphere. Aluminum and carbon-coated copper grids were also used as substrates to study the structural and microstructural properties of the film. The thickness of the films was between 20 and 200 Å. Soon after the film was made, a small amount of ambient air was introduced into the system to passivate the surface of Fe films under three different pressures (335, 735 and 1070 mTorr) for 2 h at the ambient room temperature (we use the same passivation conditions as in Fe particles[9]). The as-made samples were protected by depositing a 100 Å Ag coating layer on top of the bilayers.

The Fe-Fe oxide bilayer thickness was measured by Rutherford backscattering spectroscopy (RBS) and the surface composition and depth profile were studied by x-ray photoelectron spectroscopy (XPS). The crystal structure of bilayers was determined from selected area electron diffraction (SAD) data and the microstructure was studied using a JEOL JEM-2000 FX transmission electron microscope (TEM). The magnetic properties were studied using a superconducting quantum interference device (SQUID) magnetometer.

III. RESULTS AND DISCUSSION

Figure 1 shows two bright field micrographs and a selected area diffraction pattern of a 112 Å sample sputtered at 1.0 Å/s and oxidized at 1.07 Torr air. A uniform and continuous distribution of grains could be seen from the bright field pictures. The grain size determined by the line intercept method was observed to increase from 50 to 150 Å as the thickness of the samples increased from 20 to 200 Å. For films with the same thickness but with different sputtering rates and oxidation pressures, the grain size was found not to vary significantly. From selected area electron diffraction patterns, bcc α-Fe and fcc Ag were recognized. The apparent absence of reflections from the oxide layer in the diffraction pattern is probably due to the very small grain size and the small thickness of the oxide layer.

Figure 2 shows a typical XPS spectrum of an Fe-Fe oxide sample. The asymmetric broadening of the higher energy

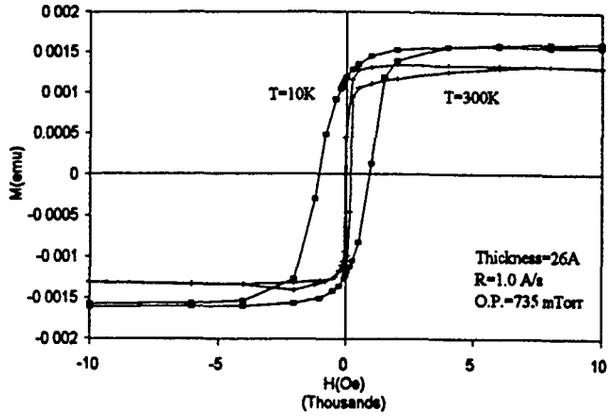

FIG. 3. Hysteresis loops of an Fe-Fe oxide sample at 10 and 300 K.

edge of the metallic Fe peak was deconvoluted to determine the type and amount of Fe oxides present. After argon etching for about 40 Å, the peak due to Fe became stronger, indicating that the oxides were on the surface of the Fe film. Figure 3 shows typical hysteresis loops for an Fe-Fe oxide sample at 10 and 300 K. The shifted loop (shift by about 120 Oe) indicates the presence of exchange anisotropy at the interface of α-Fe and Fe-O phases. The loop shift was found to be smaller in thicker films.

Magnetization studies perpendicular and parallel to the film plane showed an anisotrop · in the film plane in a sample of thickness of 112 Å, which had been sputtered at 1.0 Å/s and passivated at 1.07 Torr (Fig. 4). The lack of perpendicular anisotropy is consistent with previous studies[10] which showed that oxygen contamination reduces the uniaxial surface anisotropy in Fe films having a thickness of several monolayers. With the increasing thickness, the surface anisotropy energy is further reduced and the easy axis becomes planar.

The coercivity of Fe-Fe oxide bilayers was found to depend strongly on both the total film thickness and temperature. H_c showed a large increase in samples with thickness below 60 Å reaching a value about 2.7 kOe in a 20 Å thick film (Fig. 5). In samples with a larger thickness, the coercivity was almost a constant, ~250 Oe. The thickness depen-

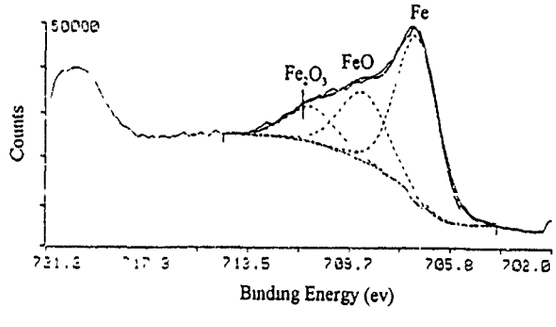

FIG. 2. XPS spectrum of an Fe-Fe oxide bilayer sample with thickness of 80 Å.

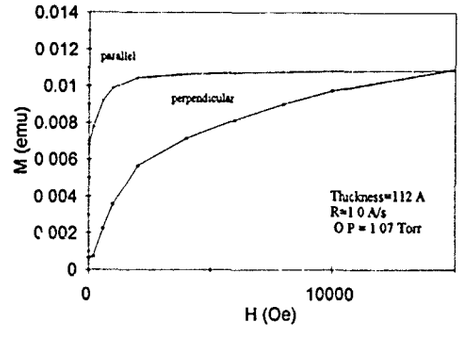

FIG. 4. Magnetization curves parallel and perpendicular to the film plane in an Fe-Fe oxide sample.

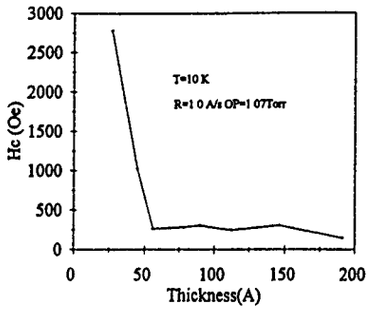

FIG. 5. Thickness dependence of H_c in Fe-Fe oxide bilayers.

dence of H_c may be influenced by both the grain size and the amount of iron oxide in the sample. The grain size is larger in thicker films and this may lead to a multidomain structure with a reduced coercivity. However, the grain size is well below the single domain size of iron particles (200 Å) even in the 200 Å thick sample, and therefore the size does not play a significant role here. On the other hand the relative amount of iron oxide present in the bilayers is much higher in thinner films leading to a stronger effective exchange coupling between the iron and iron-oxide layers and therefore a higher coercivity. The latter assumption is consistent with the fact that the coercivity of films with less oxidation is lower. The quantitative aspect of this interaction remains to be further investigated.

The coercivity decreases substantially with increasing temperature, as shown in Fig. 6. At room temperature, the coercivity is small but at lower temperature it increases substantially. This behavior may be caused by the magnetic behavior of the Fe-O coating which may become superparamagnetic at temperatures above 100 K. This is further supported by the thermomagnetic data (Fig. 7) which show a magnetic transition below room temperature possibly associated with the blocking temperature of Fe-O.

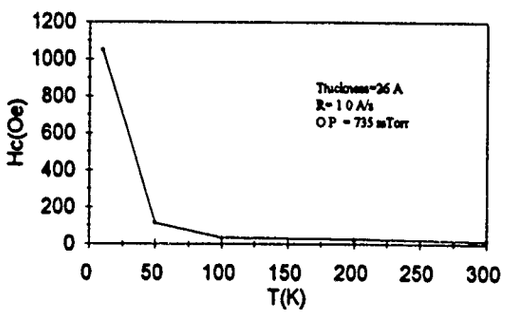

FIG. 6. Temperature dependence of H_c in an Fe-Fe oxide sample.

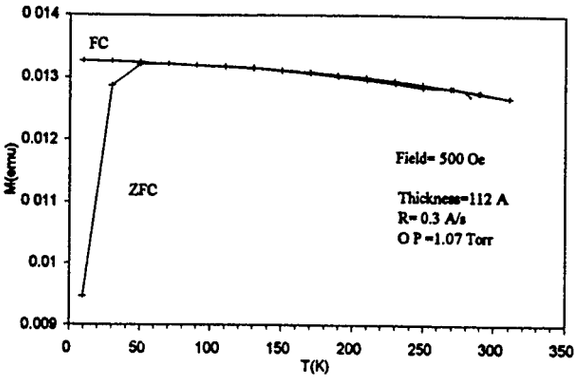

FIG. 7. Magnetization as a function of temperature of an Fe-Fe oxide sample at an applied field of 500 Oe. (ZFC: zero field cooled; FC: field cooled.)

IV. CONCLUSIONS

Fe-Fe oxide bilayers were made by dc magnetron sputtering method. The oxide layer was formed by passivating the surface of Fe film. The thin film was observed to have a uniform distribution of grains and the grain size increased with the increasing thickness from 20 to 200 Å. A high coercivity (2.7 kOe) was observed in a sample of 20 Å, deposited at 1.0 Å/s and passivated at 1.07 Torr air. A displaced hysteresis loop was observed in samples indicating a strong anisotropy at the iron-iron oxide interface. The coercivity was found to decrease substantially when the film thickness increased above 60 Å and the temperature increased above 100 K. The latter behavior was attributed to the superparamagnetic behavior of the Fe-O coating which might consist of very fine grains that had a blocking temperature around 100 K.

Ferromagnetic-ferromagnetic tunneling and the spin filter effect

P. LeClair,[a] J. S. Moodera, and R. Meservey
Francis Bitter National Magnet Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Tunneling characteristics of a ferromagnetic-antiferromagnetic-ferromagnetic (FM-AFM-FM) thin film tunnel junction were studied in high magnetic fields with a view to investigate magnetic coupling by the tunneling process. Gd_2O_3, a stable oxide which undergoes antiferromagnetic ordering below about 3.9 K, was chosen as the tunnel barrier between the ferromagnetic electrodes Gd and permalloy. Tunnel characteristics showed as much as 32% decrease in junction resistance in an applied field of 20 T, below 4.2 K. The resistance behavior as a function of H can be explained by two different effects: firstly, the change in tunnel conductance due to change in the relative magnetization of the two FM electrodes in low H; secondly, the spin filter effect in high fields, due to the exchange splitting of the Gd_2O_3 conduction band.

I. INTRODUCTION

In the past few years, there have been many investigations with multilayer magnetic thin films. For example, if two magnetic films are separated by a thin nonmagnetic layer, then the current flowing in such a trilayer depends on the relative magnetization direction of the magnetic film.[1] This is the case whether the current flow is by the tunneling process or in plane through the entire length of the trilayer. Several trilayer systems in non-tunneling work (generally, with a metallic film interlayer) have shown the characteristics needed to fabricate field-activated devices.[1] When tunneling occurs between two ferromagnets, interesting effects can be expected if it is assumed that spin is conserved in the tunneling process.[2] Having two ferromagnetic electrodes with different coercive fields, one can expect the tunnel conductance to be dependent on the relative magnetization of the two electrodes.[3–7] When the two electrodes are aligned parallel, a maximum in conductance is expected; the opposite is true for an antiparallel arrangement. The effects of FM-I-FM tunneling and the change in the relative magnetization direction have been observed to bring up to 2%–3% change in junction resistance.[4,6] A simple model[4] gives the change in tunnel conductance due to the change in the relative magnetization directions equal to $2P_1P_2$, where P_1 and P_2 are the conduction band spin polarizations of the electrodes. For example, taking P_1=34% for Gd and P_2=30% for NiFe, one expects a change of 20% in the tunnel conductance. However, the observed change for various combinations of FM electrodes and barriers is far less than the expected value based on the simple model. Earlier, using a NiO_x barrier in FM-FM tunneling showed limited success.[4–6] This deviation can be partially accounted for by impurities in the tunnel barrier, magnetic domain walls, and insufficient field to align the electrodes fully.[6] Recent theoretical studies have also indicated a small effect.[7] The present work is about the study of an antiferromagnetic layer intervening two ferromagnetic layers, with a view to investigate magnetic coupling by the tunneling process. Gd_2O_3, a stable oxide which undergoes antiferromagnetic ordering below ~3.9 K,[8] was chosen for this study. In Gd/Gd_2O_3/NiFe tunnel junctions, a large effect on the junction resistance is observed upon the application of a magnetic field. The present experiments show that the latter effect is related to the spin filter effect, similar to that observed by Moodera *et al.*[9] Nowak and Rauluszkiewicz have recently reported excellent domain structure study in the tunnel junction area and about 2.5%–7.7% change in tunneling resistance for Gd/GdO_x/Fe junction in a field of ~80 Oe which they partially attribute to the spin filter effect.[10] However, the exchange splitting due to the applied field, $2\mu H$, in their case is only ~7 μeV and is too small compared to the reported barrier height of 0.276 eV to effectively show significant spin filter effect.

II. EXPERIMENT

Thin film junctions of Gd/Gd_2O_3/NiFe were prepared on LN_2 cooled glass substrates by vacuum evaporation. Metal masks were used to obtain the tunnel junction cross pattern. Initially, 40 nm cross strips of Gd were deposited. The Gd_2O_3 barrier was then created by oxygen glow discharge of the Gd film surface. NiFe long strips of 18 nm were then deposited. The preparation process was entirely *in situ*. Two out of the 72 junctions were selected to be mounted on a probe to measure the resistance as a function of magnetic field and temperature down to liquid helium temperatures. The magnetic field was applied parallel to the junction plane. Two kinds of measurements were done: R_J was measured as a function of applied field up to 20 T; second, I-V characteristics were plotted at H=0 and H=20 T up to 300 mV bias across the junction. The four terminal resistance measurement was used to avoid contact and lead resistance.

III. RESULTS AND DISCUSSION

Tunnel junction resistance was observed to increase as temperature decreased, showing the semiconducting nature of the Gd_2O_3 tunnel barrier. At temperatures 4.2 K and below, a significant drop in junction resistance was seen with applied magnetic field. Figure 1 shows the variation of tunnel junction resistance as a function of magnetic field, taken at 1.1 K for a representative sample. As seen in Fig. 1, junction resistance showed a sharp initial decrease of ~6%, in low fields, region A(A′), followed by a slight increase in region B(B′) where it nearly regains its original value. Some

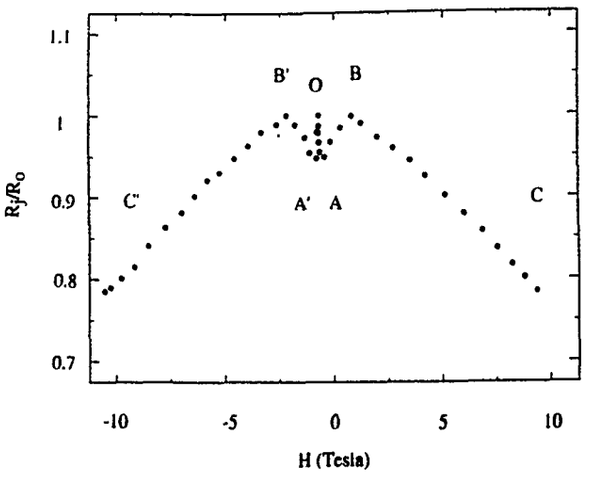

FIG. 1. Tunnel junction resistance variation with magnetic field. Data taken at $T=1.1$ K.

other junctions did not show this rise after the first decrease in resistance. In higher H, a more gradual and greater change in R_J is seen, and by $H=10$ T, the change is ~20% [region C(C′)]. As seen in Fig. 1, R_J variation is not simple and straightforward. However, invoking the phenomena of tunneling conductance dependence on the relative magnetization directions of the two electrodes and the spin filter model, one can try to explain the general trend of the data. Although not shown in Fig. 1, R_J vs H was measured up to 20 T, where R_J decreased by ~32%. The magnetoresistance of the electrodes alone was measured and found to have a negligible contribution to the junction resistance change.

The I-V characteristics of the junctions were measured in $H=0$ and $H=20$ T at various temperatures. Data reported here is for $T=1.1$ K; data at 4.2 K or less showed qualitatively similar behavior, while at higher temperatures R_J varied only a few percent. Shown in Fig. 2 is current density (J) versus voltage at 1.1 K, in $H=0$ and $H=20$ T. The J-V curves are typical of junctions with good barriers. The current-voltage characteristic of a tunnel junction has been theoretically derived by Simmons,[11] based on a trapezoidal tunnel barrier. The tunnel current density is given approximately by

$$J=J_0\left\{\left(\phi-\frac{V}{2}\right)\exp\left(-A\left(\phi-\frac{V}{2}\right)^{1/2}\right]-\left(\phi+\frac{V}{2}\right)\times\exp\left(-A\left(\phi+\frac{V}{2}\right)^{1/2}\right]\right\}, \quad (1)$$

where $J_0=(e^2/2\pi h)s^{-2}$ and $A=(4\pi s/h)(2m)^{1/2}$, with s being the barrier thickness, and ϕ is the barrier height. By fitting the J-V curves to Eq. (1), tunnel barrier height (ϕ) was obtained for $H=0$ and $H=20$ T separately. This fit is also shown in Fig. 2. The barrier thickness (s) was found to be 3.05 nm. In $H=0$, the mean barrier height was 0.4105 eV, while at $H=20$ T it was found to be 0.4006 eV. Thus the mean barrier height decreased by 9.9 meV in 20 T field.

R_J variation seen in Fig. 1 may now be explained as follows. At low H, the ~6% decrease in R_J(A,A′) can be due to ferromagnetic-ferromagnetic tunneling with the relative magnetization of the electrodes changing from antiparallel to parallel direction. Region O represents the antiparallel alignment. This change is still quite low when compared to the expected 20% change[4] as discussed above, but the values in this region are quite similar to those observed by others.[3–7] The effects due to the relative magnetization direction dominate at low H. The increase in region B(B′) is not fully understood at this time; for example, exchange anisotropy at the AFM-FM interface may be at least partially responsible.

In high fields, the change in junction resistance is more gradual and greater as well. Simmons' tunneling theory shows that a decrease in R_J is possible when ϕ or s is decreased. In the present case, the change cannot be due to a decreasing barrier thickness, since s is Gd_2O_3 thickness, which is fixed. Such behavior was observed recently by Moodera *et al.*[9] in tunnel junctions with antiferromagnetic EuSe barriers. There, the variation of the barrier height was

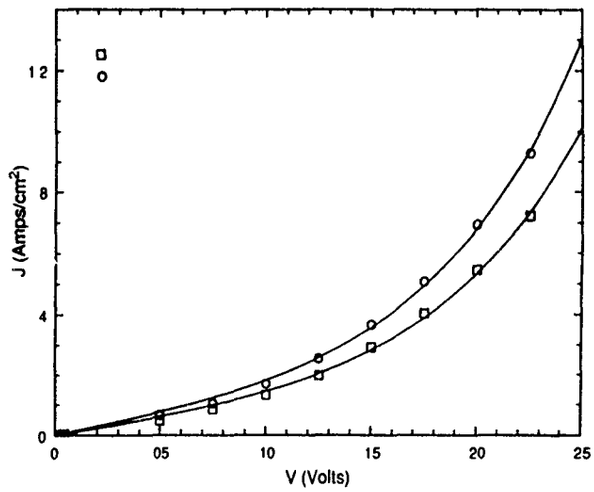

FIG 2 J-V characteristics taken at 1.1 K in $H=0$ and 20 T (□ and ○, respectively) applied field. Solid line is the fit to Simmons' theory [Eq. (1)].

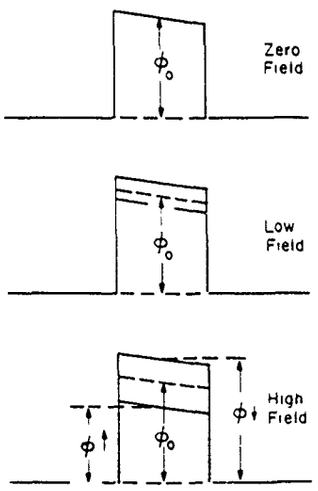

FIG. 3 Schematic of conduction band exchange splitting of the antiferromagnetic Gd_2O_3 tunnel barrier and the spin filter effect.

attributed to the AFM to FM phase change in EuSe in an applied H, leading to exchange splitting in EuSe and resulting in an energy separation of spin up and spin down bands (see Fig. 3). Since Gd_2O_3 is antiferromagnetic, applying a strong magnetic field can be expected to drive it towards a ferromagnetic phase. The magnetic moment of the Gd^{3+} ion, $7.8\mu_b$,[12] is conductive to such a phase change. The exchange splitting (2Δ) in a field is given by the Zeeman energy, $2\ \mu H$, where μ is the magnetic moment of Gd^{3+} ions in Gd_2O_3. The exchange splitting value is for the splitting of the bottom of the conduction band in Gd_2O_3, similar to europium chalcogenides.[13,14] The change in barrier height as expected from the exchange splitting, $2\ \mu H$, is 9.03 meV at 20 T, which is in close agreement with the observed change of 9.9 meV from $H=0$ to $H=20$ T. This clearly shows that the change in barrier height is closely associated with the conduction band splitting in Gd_2O_3. This energy separation causes the spin up band to be at a lower energy than the spin down band, resulting in preferential selection of spin up electrons in the tunneling process, and thus decrease in resistance as well as spin polarization of the tunneling electrons (Fig. 3), leading the tunnel barrier to serve as a "spin filter." Applied field effectively "tunes" the barrier height. The spin filter effect dominates at high H and temperatures close to and below the Neél temperature of Gd_2O_3, $T_n=3.9$ K.

Simmons' tunnel current equation [Eq. (1)] can be modified for the spin up and spin down current densities as follows:

$$J_{\downarrow,\uparrow}=\frac{J_0}{2}\left\{\left(\phi_{\downarrow,\uparrow}-\frac{V}{2}\right)\exp\left[-A\left(\phi_{\downarrow,\uparrow}-\frac{V}{2}\right)^{1/2}\right]-\left(\phi_{\downarrow,\uparrow}+\frac{V}{2}\right)\exp\left[-A\left(\phi_{\downarrow,\uparrow}+\frac{V}{2}\right)^{1/2}\right]\right\}, \quad (2)$$

where $\phi_{\downarrow,\uparrow}$ are the barrier heights, respectively, for the spin up and spin down tunneling electrons. The barrier heights for spin up and spin down tunneling electrons are $\phi-\mu H$ and $\phi+\mu H$ respectively. So, at 20 T, $\phi_\downarrow$ was taken to be 0.4096 eV, and $\phi_\uparrow$ was taken to be 0.3916 eV. Now that spin up and spin down barrier heights are known, spin polarization can be found by evaluating J for the spin up and spin down energy bands. Spin polarization was found by defining $P=(J_\uparrow-J_\downarrow)/(J_\uparrow+J_\downarrow)$,[9] which gave values of 17%–23%. This does not take into account spin scattering or other effects.

IV. SUMMARY

In conclusion, FM-FM tunneling has been studied. The present work shows that the junction resistance variation with H of the $Gd/Gd_2O_3/NiFe$ tunnel structure can be explained by two distinct effects; namely, FM-FM tunneling and the spin filter effect. Exchange splitting in H, given by the Zeeman energy, explain the J-V characteristics quite well. This latter effect also causes spin polarization of the tunneling electrons. The low H results are in agreement with previous studies,[3–7] and the high H results are similar to those seen in EuSe junctions by Moodera *et al.*[9]

An analytic Green-function theory is developed for the dipole-exchange spin waves and their Brillouin light-scattering spectra in perpendicularly magnetized magnetic multilayers and superlattices. We consider periodic structures consisting of a large number of similar ferromagnetic layers separated by nonmagnetic spacers. The dipole-dipole and exchange coupling are included between magnetic layers, as well as within the layers.

We extend our previously developed analytic theories of Brillouin light scattering from dipole-exchange spin waves in magnetic films[1] and double layers[2] to the cases of perpendicularly magnetized magnetic superlattices consisting of alternating layers of a ferromagnet and a nonmagnetic spacer. The effects of dipole-dipole and exchange interactions (both intralayer and interlayer) are included. We obtain explicit approximate expressions for the spectrum of the collective spin wave modes of a superlattice. Numerical examples for Fe/spacer superlattices are presented.

We assume a perpendicularly magnetized multilayer structure consisting of N identical magnetic layers separated by identical nonmagnetic spacers. The energy density W of the system can be written as

$$W=\frac{1}{4VN}\sum_{i,j}\int d\mathbf{r}\,d\mathbf{r}'\mathbf{M}^*_{\mathbf{r}i}(2\hat{G}_{\mathbf{r}\mathbf{r}'ii}\delta_{ij}+\hat{G}_{\mathbf{r}\mathbf{r}'ij})\mathbf{M}_{\mathbf{r}'j}$$
$$-\frac{1}{VN}\sum_{j}\int d\mathbf{r}H_{\mathbf{r}j}M^z_{\mathbf{r}j}, \tag{1}$$

where V is the volume of each magnetic layer (labeled by i and j) and $\mathbf{M}_{\mathbf{r}i}$ is the total magnetization at position $\mathbf{r}$ in layer i. The second term describes the Zeeman interaction with the static magnetic field, assumed to be $H\hat{\mathbf{z}}$ in all layers. The tensor $\hat{G}_{\mathbf{r}\mathbf{r}'ij}$ represents dipole and exchange interactions, with the diagonal term $\hat{G}_{\mathbf{r}\mathbf{r}'ii}$ corresponding to a single film case. We take the dipole and intralayer exchange interaction tensors in the same form as for a single film[1] and assume for the interlayer exchange

$$W_{ile}=-\frac{\pi\alpha}{\tilde{L}NV}\sum_{i,j}\beta\int d\mathbf{r}\,d\mathbf{r}'\mathbf{M}^*_{\mathbf{r}i}\mathbf{M}_{\mathbf{r}'j}\delta(\rho-\rho'), \tag{2}$$

where $\tilde{L}$ is the superlattice periodic length (i.e., the sum of a spacer thickness and a magnetic layer thickness), and α is a constant of intralayer exchange[3] related to exchange constant $\mathcal{A}$ by $\alpha=\mathcal{A}/(2\pi M_0^2)$, where M_0 is the saturation magnetization (assumed to be the same in all layers). Also $\beta=\mathcal{A}_{12}/\mathcal{A}$ is an effective interlayer exchange parameter defined as in Ref. 2. The sum is over the adjacent layers, and ρ and ρ' are the in-plane components of $\mathbf{r}$ and $\mathbf{r}'$.

Next we rewrite W, using the linearized Holstein–Primakoff representation[4] as before,[3] and we transform the spin-wave (SW) polarizations $a_{\mathbf{r}i}$ and $a^*_{\mathbf{r}i}$ with respect to any complete orthonormal basis $\phi_k(\mathbf{r},i)$, indexed by label k

$$a_{\mathbf{r}i}=\sum_k a_k\phi_k(\mathbf{r},i),\quad a^*_{\mathbf{r}i}=\sum_k a^*_k\phi^*_k(\mathbf{r},i). \tag{3}$$

The quadratic part W_2 of the energy density is then

$$W_2=\sum_{12}A_{12}a^*_1a_2+\tfrac{1}{2}\left(\sum_{12}B^*_{12}a_1a_2+\text{c.c.}\right) \tag{4}$$

where, defining g as a gyromagnetic ratio,

$$A_{12}=\frac{gM_0}{2VN}\sum_{i,j}\int d\mathbf{r}\,d\mathbf{r}'\Big[\phi^*_1(\mathbf{r},i)\phi_2(\mathbf{r}',j)$$
$$\times(\hat{G}^{++}_{\mathbf{r}\mathbf{r}'ij}+\hat{G}^{--}_{\mathbf{r}'\mathbf{r}ji})(1+\delta_{ij})-2\delta(\mathbf{r}-\mathbf{r}')$$
$$\times\delta_{ij}\left(\sum_j\int d\mathbf{r}'\hat{G}^{zz}_{\mathbf{r}\mathbf{r}'ij}+\frac{H}{M_0}\right)\Big], \tag{5}$$

$$B_{12}=\frac{gM_0}{VN}\sum_{i,j}\int d\mathbf{r}\,d\mathbf{r}'\phi_1(\mathbf{r},i)\phi_2(\mathbf{r}',j)$$
$$\times\hat{G}^{+-}_{\mathbf{r}\mathbf{r}'ij}(1+\delta_{ij}). \tag{6}$$

Here indices 1 and 2 stand for k_1 and k_2, and the superscripts $+$, $-$, and z denote the corresponding components of the interaction tensor in terms of $M^{\pm}=M^x\pm iM^y$ and M^z.

To choose the orthonormal basis $\phi_k(\mathbf{r},i)$ we assume that: (i) the interlayer interaction is weak, so that the SW modes of a single layer (SWSL) do not differ significantly from the corresponding modes S_n of a single magnetic film;[3] and (ii) the individual layers are thin enough for the different SWSLs to be well separated in frequency. With these two assumptions the SW modes of a multilayer can be represented as SW composite modes (SWCM) of the following form:

$$\phi_k(\mathbf{r},i)\equiv\phi_{\mathbf{k}nQ}(\mathbf{r},i)=L_{niQ}S_n(\xi_i)\exp(-\mathbf{k}\cdot\rho), \tag{7}$$

where $\mathbf{k}$ is the in-plane wave vector, and ξ_i is the spatial coordinate perpendicular to the layers measured from the center of layer i. The orthonormality condition is

$$\sum_{nj}L^*_{njQ}L_{njQ'}=N\delta_{QQ'}. \tag{8}$$

 0021-8979/94/76(10)/6549/3/$6.00 © 1994 American Institute of Physics

We now substitute the above expressions into Eqs. (5) and (6) to obtain A_{12} and B_{12} in terms of the coefficients L_{njQ}, which we take to have the form

$$L_{njQ}=R_{nQ}\exp(-iQ_j)+T_{nQ}\exp(iQ_j), \tag{9}$$

where Q, which generally depends on the mode number n, is a (dimensionless) superlattice Bloch wave number for the SWCM.

By analogy to the single film case,[3,5] the values of R_{nQ}, T_{nQ}, and Q depend on the effective "macroscopic pinning" at the top and bottom magnetic layers of the multilayer structure. These macropinning parameters may depend on the different effective anisotropy fields in the top, bottom, and bulk layers as well as on the anisotropy of interlayer exchange. Details will be given elsewhere,[6] but in the simple case of no multilayer boundary anisotropy we get

$$L_{njQ}=(2-\delta_{0m})^{1/2}\cos\left[\frac{\pi m}{N}\left(j-\frac{1}{2}\right)\right], \tag{10}$$

where $Q\equiv\pi m/N$, and $m=0,1,2,\ldots,N-1$. For any given $\mathbf{k}$ and n, we can eventually rewrite the coefficients A and B and the lowest nonhybridized SWCM frequencies ω_{knQ} as

$$A_{kn,QQ'}=\delta_{QQ'}[\omega_H+\alpha\omega_M(\mathbf{k}^2+q_n^2)+(\beta Q^2/2\tilde{L})]+\tfrac{1}{4}\omega_M U_{kn,QQ'}, \tag{11}$$

$$B_{kn,QQ'}=\tfrac{1}{4}\omega_M U_{kn,QQ'}, \tag{12}$$

$$\omega_{knQ}^2=A_{kn,QQ}^2-|B_{kn,QQ}|^2=\Omega_{knQ}(\Omega_{knQ}+\tfrac{1}{2}\omega_M U_{kn,QQ}). \tag{13}$$

Here $\omega_M=4\pi gM_0$, $\omega_H=g(H-4\pi M_0)\equiv gH_i$, q_n is the single-film transverse wave number for mode n, and

$$\Omega_{knQ}=\omega_H+\alpha\omega_M[\mathbf{k}^2+q_n^2+(\beta Q^2/2\tilde{L})], \tag{14}$$

$$U_{kn,QQ'}=\frac{1}{N}\sum_{i,j}L_{niQ}^{*}L_{njQ'}P_{nnij}(\mathbf{k})+P_{nn}(\mathbf{k}L)\delta_{QQ'}. \tag{15}$$

The dipole matrix elements $P_{nnij}(\mathbf{k})$ and $P_{nn}(\mathbf{k}L)$ are defined analogously to the single film case.[3] The following factorization is possible:

$$P_{nnij}(\mathbf{k})=\mathcal{G}_{\mathbf{k}}(i,j)P_n(kL), \tag{16}$$

where $P_n(kL)$ depends only on the single-layer parameters and

$$\mathcal{G}_{\mathbf{k}}(i,j)=\frac{k}{2}\exp(-k\tilde{L}|i-j|) \tag{17}$$

is a discrete analog of the dipole Green function[3] (denoting $k\equiv|\mathbf{k}|$). For $N\gg1$ we can write[6] $U_{kn,QQ}\sim P_{QQ}(\mathbf{k}\tilde{L}N)P_n(kL)$ where the function P_{QQ} is given by the same formal expression as the matrix element P_{nn} for a single film.[3]

Now, using Eqs. (11)–(15), we can calculate the frequencies of the nonhybridized composite modes in a similar way to the single film case. Equations (13)–(15) constitute a description of the multilayer in an effective-medium approximation. In particular, Eq. (13) has the same form as for a single film, but with renormalized parameters. By analogy with the single-film results we conclude that, if the multilayer has no "macrosurface" anisotropy, i.e., the interaction between the first (or last) layer and its neighboring one is the same as for any adjacent layers in the bulk, there are no pseudosurface ($\mathrm{Im}\,Q>0$) composite modes. In this case the lowest frequency excitation will be the uniform precession (constant L_{njQ}) mode, which also will be the only one excited in FMR experiments. If there is a macrosurface anisotropy on the edges of a multilayer, the consistency equation to determine the composite modes transverse wave numbers Q will be similar to that for a film:[1,3]

$$(Q^2-D_1D_2)\tan(QN\tilde{L})=Q(D_1+D_2) \tag{18}$$

with the parameters D_1 and D_2 characterizing the boundary-layer anisotropy of the interlayer exchange. The solutions of Eq. (18) for Q with imaginary values correspond to the pseudosurface excitations while real values produce the pseudobulk solutions.

We first relate the above results to some recent FMR measurements.[7] The two branches of FMR can be associated with the hybridized pseudosurface and first pseudobulk composite modes. The hybridization occurs as the spacer thickness becomes greater than 5 Å and is due to mixing of the branches with different q_n but close SWCM frequencies. We expect low value of macropinning constant as the first pseudobulk composite mode has relatively small resonance amplitude. We assume that $D_2=0$ and $D_1\equiv D$, which roughly matches assumptions in Refs. 7 and 8. Using Eq. (18) we can write that far from the hybridization area for small D

$$\frac{\Delta\omega}{\omega_M}=\frac{\alpha}{2N\tilde{L}}[\pi^2+4D+\pi(\pi^2+4D)^{1/2}]. \tag{19}$$

Equation (19) enables the value of D to be deduced from the experimental values of $\Delta\omega$. Although our approach is capable of predicting the behavior of the FMR dispersion relationships, there is no simple way to include hybridization in our formalism. The reason is that the possible mechanism for hybridization is mixing of single film modes with different transverse wave vectors but close frequencies, occurring due to the micropinning dependence on the spacer thickness. It would be worth developing a numerical perturbation theory of the kind used in Refs. 9 and 10 that would use our analytical expressions as a zero-order approximation.

For the case of Brillouin light scattering (BLS) experiments, where $k\sim10^5\ \mathrm{cm}^{-1}$, the above-mentioned effects will be much less important as the main role in the hybridization will be played by dipole interlayer interaction. Hence we apply the SWCM formalism to Fe/spacer multilayers with the parameters: $\alpha=1.15\times10^{-13}\ \mathrm{cm}^2$, $4\pi M_0=21$ kOe, $H=22.5$ kG, $L=100$ Å, spacer thickness 10 Å, and zero macro- and micropinning. It is straightforward to confirm numerically that for these parameters there is no noticeable hybridization of the modes with different n. In Fig. 1 we display the boundaries of the bulk bands for multilayers with $\beta=10^5\ \mathrm{cm}^{-1}$ and different values of N. One of the boundaries (at $Q=\pi$), is independent of N within the given $\mathbf{k}$ interval. This can be explained by the vanishing of the dipolar

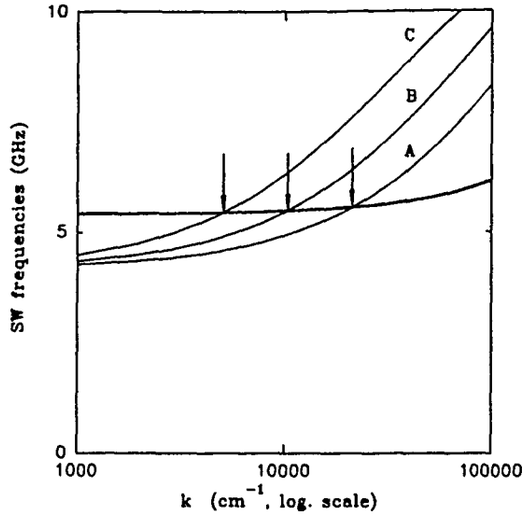

FIG. 1. Dispersion relationships for Fe/spacer multilayers with number of layers $N=10$ (A), 20 (B), and 40 (C). The flat curve represents the purely exchange branch ($Q=\pi$); curves A, B, and C represent the purely dipole branch ($Q=0$). $\beta=10^5$ cm^{-1}. See the text for the other parameters.

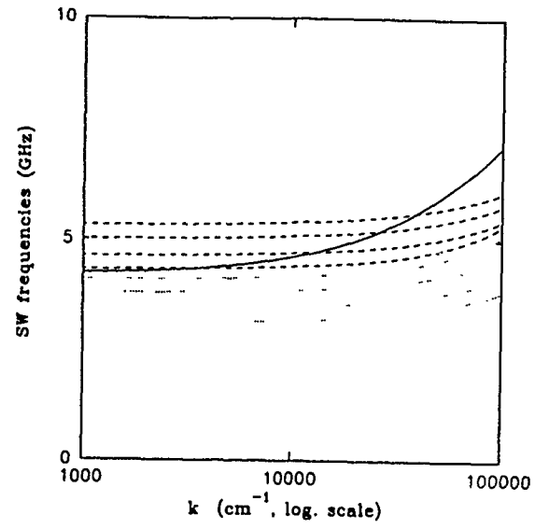

FIG. 2. The dispersion relationships for a five-layer structure. The solid line corresponds to the purely dipole branch, while the dashed and broken lines refer to $\beta=10^5$ and -10^5 cm^{-1}, respectively.

contribution for the modes with high Q. The other boundary (at $Q=0$) does not depend on the interlayer exchange. The dipolar contribution to this branch is significant and it depends on N. From our analysis we expect a scaling behavior with the dimensionless universal variable being $k\tilde{L}N$. Indeed, in Fig. 1 we see that the crossings, denoted by arrows are equidistant in the logarithmic k scale. In Fig. 2 we show the dispersion branches for Fe/spacer multilayers with $N=5$ and different values of β corresponding to ferromagnetic and antiferromagnetic interlayer exchange. The branch separation for the low k region, which is directly measurable from the BLS spectrum, is directly proportional to $|\beta|$. This provides a convenient way of measuring β.

The extension of the above to obtain the BLS intensities follows a well-established procedure, generalizing our results[1,2] for thin films and double layers. Basically, the scattering cross section can be expressed in terms of a weighted summation over magnetization-dependent Green functions $\langle\langle m^{\mu}_{n\mathbf{k}}; m^{\nu}_{n'\mathbf{k}}\rangle\rangle$ with $\mu,\nu=x,y$. The weighting factors depend on temperature, magneto-optical coupling, electric-field polarizations, scattering geometry, and optical transmission coefficients at the various surfaces and interfaces. Once the appropriate Green functions have been calculated from the formalism described earlier (by linear-response methods), it is straightforward to determine the BLS intensities associated with the various SWCM modes. Details will be presented elsewhere.[6] In general, it is necessary to take account of the various internal multiple reflections of the incident and scattered light at the surfaces and interfaces of the sample,[1,2] but we avoid this difficulty by restricting attention to the case where the optical penetration depth of the light in the sample is smaller than L (e.g., as would be typically in the case of Fe/spacer multilayers).

Spin wave spectra in semi-infinite magnetic superlattices with nonuniaxial single-ion anisotropy

E. L. Albuquerque
Departamento de Física, Universidade Federal do Rio Grande do Norte, 59072-970-Natal, RN, Brazil

A microscopic theory, based on the Heisenberg model, is employed to investigate the spin wave spectra in a semi-infinite superlattice made up of two ferromagnetic materials, where the constituents may present both the uniaxial and nonuniaxial components of the single-ion anisotropy. Our calculations are carried out for the exchange-dominated regime, and a transfer-matrix approach is used to simplify the algebra, which otherwise could be quite heavy. The calculated spectra show that, in addition to bulk spin wave modes, there may be surface modes associated with the truncation of the superlattice.

I. INTRODUCTION

As a result of recent advances in fabrication techniques, there has been a continuing interest in investigating the properties of spin waves that propagate in multilayer magnetic microstructures. Many of these works have been concerned with these excitations at the low-temperature regime, where at least one of the components is a ferromagnetic or an antiferromagnetic material (for a review see Ref. 1). Further, depending on the relative importance of the magnetic dipole-dipole and exchange interactions, different models for the magnetic behavior can be employed. For instance, for sufficiently small values of the excitation wave vector, dipolar effects are dominant and magnetostatic modes should propagate in such superlattices.[2–4] On the other hand, at large excitation wave vectors typically greater than 10^8 m^{-1} in a ferromagnet, exchange interaction, which is the restoring force for spin waves, will be dominant.[5–10]

In this article we are concerned with the spin wave spectra in exchange-dominated magnetic superlattices. We intend to extend previous work[7,11,12] by considering surface effects in a semi-infinite magnetic superlattice, whose constituents have nonuniaxial ("easy-plane") single-ion anisotropy, besides the uniaxial ("easy-axis") single-ion anisotropy. Nonuniaxial anisotropy exists in many magnetic materials, like the ferromagnet $CrBr_3$ and the antiferromagnet NiO, and it can be different at a surface or interface because the crystalline electric fields are different there. We employ a microscopic theory to investigate the spin wave spectra based on the Heisenberg model, together with a transfer-matrix approach. This method was used with success in dealing with the theory of superlattice plasmon-polaritons (for a review see Ref. 13), and it leads to a compact expression for the spin wave dispersion relation of the magnetic superlattice. Experimental systems are likely to be more complicated than the model described here, with less simple crystal structures and possible different ordering at interface layers.[14] However, these details would influence only the detailed form of the transfer matrix, and neither the general method nor the qualitative form of the dispersion relations should be affected.

II. THEORY

As indicated in Fig. 1, we consider a superlattice in which n_a layers of material A alternate with n_b layers of material B. Both materials are taken to be simple cubic nonuniaxial Heisenberg ferromagnets, having bulk exchange constants J_A and J_B with nearest-neighbor exchange interaction. The size of the superlattice unit cell is $L=(n_a+n_b)a$, where a is the lattice constant of both materials. A static applied magnetic field $\mathbf{H}_0$ is assumed to be in the z direction. The superlattice is truncated at $z=0$, with vacuum occupying the region $z<0$.

The two materials are characterized by single-ion uniaxial anisotropy parameters D_A and D_B, as well as single-ion nonuniaxial anisotropy parameters F_A and F_B. At the interfaces, between constituents, these values are D_{SJ} and F_{SJ} ($J=A$ or B), while at the free surface (material A), defined by $z=0$, we have D_0 and F_0, respectively. The exchange constant across each interface A-B is equal to I.

The Heisenberg Hamiltonian for a bulk specimen of component $J=A$ or B is

$$H=-(1/2)\sum_{i,j} J_J \mathbf{S}_i\cdot\mathbf{S}_j - g\mu_B H_0 \sum_i S_i^z + H_{\text{anis}} \tag{1}$$

with

$$H_{\text{anis}}=-\sum_i D_J (S_i^z)^2 - \sum_i F_J[(S_i^x)^2-(S_i^y)^2]. \tag{2}$$

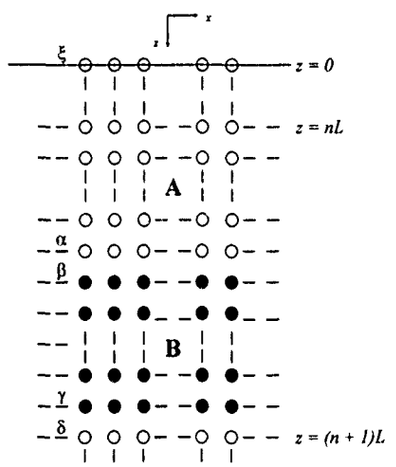

FIG. 1 The semi-infinite nonuniaxial ferromagnetic superlattice discussed in this article.

 0021-8979/94/76(10)/6552/3/$6.00 © 1994 American Institute of Physics

Here, $\mathbf{S}_i$ denotes the spin operator at magnetic site i, g is the usual Landé factor, and μ_B is the Bohr magnetron.

The dispersion equation for a bulk spin wave in medium J is found within the random-phase-approximation (RPA) from the equation of motion for the operator $S_i^{\pm}=S_i^x \pm iS_i^y$. This equation is

$$(\pm\hbar\omega-\Delta_J)S_i^{\pm}=S\sum_J J_J(S_i^{\pm}-S_j^{\pm})+2F_JS\eta^{1/2}S_i^{\mp}, \quad (3)$$

where we have made a Fourier transform to frequency ω. Also, $\eta=[1-(2S)^{-1}]$, and S is the RPA approximation for S_i^z. The value of Δ_J is

$$\Delta_J=g\mu_BH_0+2D_JS\eta. \quad (4)$$

Considering plane-wave solution for the operators $S_i^{\pm}$, and either by diagonalizing the Hamiltonian (1) or by solving Eq. (3) directly, we can find that the spin-wave dispersion relation in a nonuniaxial ferromagnet J is[15]

$$\cos(k_za)=(\Delta_J/2J_JS)+[3-\gamma(\mathbf{k}_p)] \pm[(\Omega_J/2)^2+F_J^2\eta/J_J^2]^{1/2}. \quad (5)$$

Here, $\Omega_J=\hbar\omega/J_JS$ and $\gamma(\mathbf{k}_p)=\cos(k_xa)+\cos(k_ya)$, with $\mathbf{k}_p=(k_x,k_y)$.

We now turn to the semi-infinite magnetic superlattice depicted in Fig. 1. At nonzero temperature the equilibrium configuration must exhibit the analog of surface reconstruction. This implies that the mean spin S in both materials is a function of its distance from the nearest A-B interface. However, although this effect is important, we can overcome it by restricting our attention to the low temperature regime, that is $T\ll T_c$, at which the spins are fully ordered. The spin wave dispersion equation can then be found by solving the RPA equations of motion for the spin operators $S_J^{\pm}$. A spin that is not in an interface layer, labeled α, β, γ, δ and ξ in Fig. 1, has the same nearest-neighbor environment and therefore the same equation of motion as a spin in the corresponding bulk medium. Thus, the spin wave amplitudes should be given, within each bulk material, by a linear combination of the positive- and negative-going solutions, i.e.,

$$S_J^+=\zeta_{1J}+F_{JJ}\zeta_{2J}, \quad (6)$$

$$S_J^-=Q_{1J}F_{JJ}\zeta_{1J}+Q_{2J}\zeta_{2J}, \quad (7)$$

where

$$\zeta_{1J}=A_1^n\exp(ik_{1J}z)+A_2^n\exp(-ik_{1J}z) \quad (8)$$

and ζ_{2J} is equal to ζ_{1J} provided we replace A_1^n, A_2^n, and k_{1J} by A_3^n, A_4^n, and k_{2J}. Also, ($J=A$ or B):

$$F_{JJ}=F_J\eta_J^{1/2}/J_J, \quad (9)$$

$$Q_{1J}=-2[\Omega_J+(\Omega_J^2+4F_{JJ}^2)^{1/2}]^{-1}=-(Q_{2J})^{-1}. \quad (10)$$

The wave vectors k_{1J} and k_{2J} are related to Ω_J by Eq. (5).

The equations of motion for layers α and β relate the amplitudes A_j^n, ($j=1-4$) of medium A with the corresponding amplitudes B_j^n ($j=1-4$) of medium B. Similarly, the equations of motion for layers γ and δ relate the amplitudes A_j^{n+1} ($j=1-4$) of medium A with the corresponding amplitudes B_j^n ($j=1-4$) of medium B. If one defines the column vectors $|A^n\rangle$, $|B^n\rangle$ and $|A^{n+1}\rangle$ formed by the corresponding undetermined amplitudes A_j^n, B_j^n and A_j^{n+1} ($j=1-4$), these equations can be cast in matrix forms as

$$\mathbf{M_A}|A^n\rangle=\mathbf{N_B}|B^n\rangle$$

and (11)

$$\mathbf{N_A}|A^{n+1}\rangle=\mathbf{M_B}|B^n\rangle,$$

where the 4×4 matrices $\mathbf{M}$ and $\mathbf{N}$ can be found elsewhere.[16]

Now, making use of the transfer-matrix treatment and Bloch's theorem, as in previous works,[7,12] we find that

$$\mathbf{T}|A^n\rangle=\exp(iQL)|A^n\rangle, \quad (12)$$

where Q is the Bloch wave vector, and the 4×4 transfer matrix $\mathbf{T}$ is defined by

$$\mathbf{T}=\mathbf{N_A}^{-1}\mathbf{M_B}\mathbf{N_B}^{-1}\mathbf{M_A}. \quad (13)$$

Also, as $\mathbf{T}$ is a unimodular matrix, the eigenvalues of Eq. (12) occur in pairs (t_i,t_i^{-1}), $i=1, 2$, and they are related to the two Bloch waves vectors Q_i by $t_i=\exp(iQ_iL)$. Thus, once $\mathbf{T}$ is evaluated, the required eigenvalues can be determined in a standard way. This calculation generalizes those presented in a previous paper,[12] where we discussed two limiting cases, namely first the nonuniaxial parameter F in each medium has the same value at the interface as in the bulk, and second the nonuniaxial anisotropy is considered only at the interfaces.

Now we consider the truncation of the superlattice at the plane $z=0$, with vacuum occupying the half space $z<0$. This allows us to investigate the occurrence of surface spin waves for this superlattice structure. For these modes Eq. (12) still holds, provided we replace the Bloch wave vector Q by $i\beta$, with $\mathrm{Re}(\beta)>0$ to guarantee a localized mode. Further we should take into account the equations of motion (3) for layer ξ at $z=0$, considering the single-ion anisotropy parameters D_0 and F_0. This provides an implicit dispersion relation for the surface spin waves and in fact, once the equations are solved, we can obtain a value of β which satisfies Eq. (12), with $\mathrm{Re}\,(\beta)>0$. The details of this calculation can be found elsewhere.[16]

III. NUMERICAL RESULTS AND DISCUSSIONS

In Fig. 2 we show the spin wave spectra for the surface and bulk modes which can propagate in a semi-infinite nonuniaxial ferromagnetic superlattice. We have plotted a reduced frequency $\Omega_A=\hbar\omega/J_AS_A$ against a reduced wave number k_xa across the whole Brillouin zone. The wave vector $\mathbf{k_p}=(k_x,k_y)$ is taken in the [10] direction.

The bulk superlattice bands of spin waves are shaded and they are bounded by the curves $QL=0$ and π. There are frequency gaps where no bulk superlattice modes exist, and the locations and widths of these gaps are influenced by the nonuniaxial anisotropy, being more pronounced for small values of k_xa where exchange effects are small. As a consequence, surface modes may propagate in these forbidden region, and indeed, as shown dashed in Fig. 2, there are surface spin waves occurring as discrete branches to the spectrum, in the gap regions between the continuum bulk mode bands. It is important to notice that some of the surface modes emerge

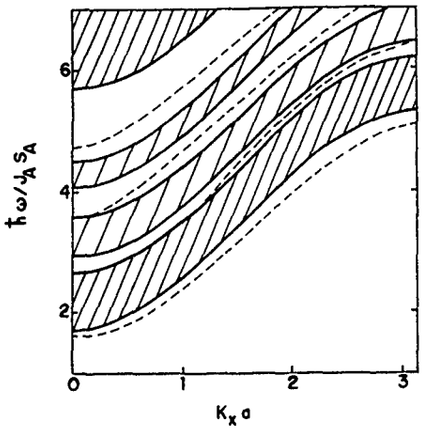

FIG. 2. Surface (dashed lines) and bulk (shaded bands) spin wave superlattice modes. The physical parameters used here are $J_A=2J_B=0.8I$, with $g\mu_B H_0=J_A$, and the spin average $S_A=S_B=1$. The anisotropy parameters were taken to correspond to $D_J/J_J=0.9$, $F_J/J_J=0.6$, while $D_{SJ}/I=0.9$, $F_{SJ}/I=0.6$, for $J=A$ or B. At the outermost interface we took $D_0/F_0=1.2$.

from the bulk continuum at a nonzero wave vector. For instance, the second and third surface spin-wave branch emerge from the bulk bands at the values of $k_x a$ equal to 0.12 and 1.2, respectively. For large values of $k_x a$, all surface modes tend to merge with the bulk bands.

Appropriate experimental technique for studying the superlattice spin waves would include light scattering spectroscopy of Raman and Brillouin type, and magnetic resonance. They have previously been successfully applied to surface and bulk spin waves in various magnetic microstructures.[1]

We also have extended the present ferromagnetic theory to take into account systems in which there is an antiparallel magnetization between the ferromagnetic materials.[16] High quality antiferromagnetic superlattices have recently been fabricated,[17] and we have also interest to extent the present theory to Heisenberg antiferromagnets.

We determine the ground state of semi-infinite uniaxial antiferromagnets and films, in terms of a two-dimensional area-preserving map, where the surfaces are introduced as appropriate boundary conditions. For the film, the ground state is calculated in a very rapid and accurate way for any value of N, the number of planes. For the semi-infinite system, we show that the so-called surface spin-flop state does not exist, while a non-homogeneous ground state is found in the bulk spin-flop phase.

Recently, new materials made of ferromagnetic films antiferromagnetically coupled, were synthetized. Using Kerr and SQUID magnetometry, sharp cusps in dM/dH were detected for such an $N=22$ multilayer of Fe/Cr(211) with a magnetic field applied parallel to the easy axis.[1] The peak at the higher field H_B was attributed to the bulk spin-flop (BSF) transition, and the peak at the lower field H_S to the surface spin-flop (SSF) transition.[1]

For a semi-infinite antiferromagnet with the surface spins *antiparallel* to the magnetic field ($AF_{\uparrow\downarrow}$), the presence of the SSF instability was inferred some years ago,[2,3] by noting that the $k=0$ surface mode softens for $H=H_S\simeq H_B/\sqrt{2}$. In the SSF state, the spins were predicted[2] to turn by nearly $\pi/2$ near the surface and asymptotically reach the $AF_{\uparrow\downarrow}$ configuration in the bulk. It was also suggested[4] that the extension of the region of turned spins should increase with increasing H, until the onset, for $H=H_B$, of a uniform bulk spin-flop state, with all the spins rotated by nearly $\pi/2$. In contrast, for a semi-infinite system with the surface spins *parallel* to the field ($AF_{\uparrow\uparrow}$),[3] the only instability was found at $H=H_B$, as in the infinite system, in correspondence to the softening of a bulk mode.

A doubtful point of this description is that, in the semi-infinite system, the same uniform BSF phase would be achieved in different ways, depending on the parallel or antiparallel orientation of the surface spins with respect to H.

For a film with a finite number of planes, N, one finds an analogous behavior of the excitations. For N even, there are two surface modes, and for $H=H_S$ only the one localized at the surface with the spins antiparallel to H shows a complete softening.[5] For N odd, if the excitations are calculated with respect to the AF ground state with the spins on both the two surfaces parallel to the field, the only instability is found at $H=H_B$.[5]

In this article, the determination of the ground state of both the semi-infinite system and the film is formulated as a two-dimensional area-preserving map[6–8] where the surfaces are introduced with appropriate boundary conditions.[9] The mapping is characterized by the fixed points and the orbits of the infinite sistem, but the spin structures relevant for our problem are only those which satisfy the previous conditions, a very selective constraint. In this way we are able to calculate the inhomogeneous ground state very rapidly and with a high accuracy (within machine double precision). For films with zero anisotropy, so that $H_B=0^+$, we recover the results obtained by numerical self-consistent methods.[10]

For the semi-infinite system, we show that the SSF state does not exist; for $H<H_B$, the stable ground state is always the $AF_{\uparrow\uparrow}$ one. We show that the $AF_{\uparrow\downarrow}$ state is metastable for $H<H_S$, while for $H_S<H<H_B$ it is unstable with respect to the formation of a Bloch wall which makes the surface spins turn from antiparallel to parallel to the field. For $H>H_B$, a nonuniform bulk spin-flop ground state is found.

For a film with even N, if $H<H_S$, the ground state is the AF one, with zero magnetization. For $H_S<H<H_B$, the lowest free energy is accomplished by an inhomogeneous configuration carrying a finite magnetization. In fact, it consists of a domain wall separating two nearly antiferromagnetic regions, with the spins on the two surfaces almost parallel to the applied field. In contrast, for a film with odd N, the ground state is the AF one with the spins on both the two surfaces parallel to H for any $H<H_B$. This explains why a peak in dM/dH was observed[1] at $H=H_S$ only for films with an even number of planes. For $H>H_B$, in both cases one has a nonuniform BSF configuration, owing to the surfaces effect.

The energy of the system is given by

$$\frac{E}{N_{\parallel}S}=\sum_n \left[H_E\cos(\phi_n-\phi_{n-1})-H_A\cos^2\phi_n - 2H\cos\phi_n\right], \tag{1}$$

where H_E and H_A are the exchange and anisotropy fields, respectively; n is the plane index, with $n\in\mathbb{Z}$ for the infinite system, $n\in\mathbb{N}$ for the semi-infinite one, and $n=1,2,\ldots,N$ for a film. By derivation we obtain

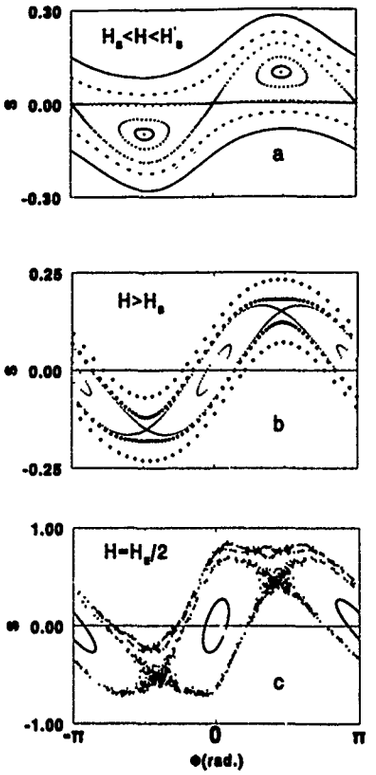

FIG. 1. Phase portraits obtained from mapping (3) for $H_A=0.9$ kG, $H_E=100$ kG ($\zeta=0.009$). (a) $H=10$ kG, (b) $H=15$ kG; full circles denote two nonhomotopic to zero trajectories pertinent to films with $N=20$ and $N=50$, respectively, (c) $H=50$ kG.

$$\sin(\phi_{n+1}-\phi_n)+\sin(\phi_{n-1}-\phi_n)+2\xi\sin\phi_n+\zeta\sin 2\phi_n=0 \quad \text{(infinite)}, \tag{2a}$$

$$\sin(\phi_{n+1}-\phi_n)+(1-\delta_{1,n})\sin(\phi_{n-1}-\phi_n)+2\xi\sin\phi_n+\zeta\sin 2\phi_n=0 \quad \text{(semi-infinite)}, \tag{2b}$$

$$(1-\delta_{N,n})\sin(\phi_{n+1}-\phi_n)+(1-\delta_{1,n})\sin(\phi_{n-1}-\phi_n)+2\xi\sin\phi_n+\zeta\sin 2\phi_n=0 \quad \text{(film)}, \tag{2c}$$

where $\xi\equiv H/H_E$ and $\zeta\equiv H_A/H_E$. We first consider Eq. (2a), valid for the infinite system. Introducing[8] $s_n=\sin(\phi_n-\phi_{n-1})$, it can be written as a two-dimensional mapping

$$\phi_{n+1}=\phi_n+\sin^{-1}(s_{n+1}), \tag{3a}$$

$$s_{n+1}=s_n-2\xi\sin\phi_n-\zeta\sin 2\phi_n. \tag{3b}$$

The mapping is area preserving (because the Jacobian is $J\equiv 1$), and invariant with respect to the transformation $(\phi,s)\rightarrow(-\phi,-s)$. Trajectories in (ϕ,s) space are associated with equilibrium configurations. In general, from the mapping (3) we obtain phase portraits [see Figs. 1(a)–1(c)] characterized by inflowing and outflowing orbits connecting the hyperbolic fixed points, elliptic orbits which encircle the homonymous fixed points and, finally, nonhomotopic to zero curves (i.e., curves which cannot be reduced to a point by a continuous deformation). The fixed points correspond to uniform ground states of the infinite system, and are second-order ones owing to its antiferromagnetic nature. Carrying out a stability analysis, it results that the AF fixed points $P_-^{AF}=(0,0)$, $P_+^{AF}=(\pi,0)$ are hyperbolic for $H\leqslant\sqrt{2H_EH_A+H_A^2}\equiv H_B$ [see Fig. 1(a)] and elliptic for higher fields [see Figs. 1(b) and 1(c)]. On the contrary, the BSF fixed points $P_-^{BSF}=(-\tilde{\phi},-\sin\tilde{\phi})$, $P_+^{BSF}=(\tilde{\phi},\sin\tilde{\phi})$, where $\cos\tilde{\phi}=H/(2H_E-H_A)$, are hyperbolic for $H\geqslant\sqrt{2H_EH_A-3H_A^2}\equiv H_B'$ [see Figs. 1(b) and 1(c)] and elliptic for lower fields[11] [see Fig. 1(a)].

In order to take care of the presence of surfaces in the film [see Eq. (2c)], we introduce two fictitious planes for $n=0$ and $n=N+1$, so that the boundary conditions are given by

$$s_1=\sin(\phi_1-\phi_0)=0, \tag{4a}$$

$$s_{N+1}=\sin(\phi_{N+1}-\phi_N)=0. \tag{4b}$$

For the semi-infinite system, only one fictitious plane must be introduced for $n=0$ [see Eq. 2(b)], and the boundary condition is given by Eq. 4(a). Among all trajectories obtained from the mapping (3), only those satisfying Eqs. (4) represent equilibrium configurations for the system in presence of surfaces. This is a very selective constraint; e.g., for a film, the physical trajectories must have two intersections with the $s=0$ line, separated by exactly N steps of the recursive mapping.

From the analysis of the phase portrait at different values of the field, we have found the ground state configurations for the semi-infinite system and for a film with even N.

(1) For $H<\sqrt{H_EH_A+H_A^2}\equiv H_S$, the phase portrait does not show peculiar features: the ground state is the $AF_{\uparrow\uparrow}$ one for the semi-infinite system, and the AF one for the film.

(2) For $H_S<H<H_B'$ [see Fig. 1(a)], the surface spin-flop state is not an equilibrium one for the semi-infinite system. This happens because none of the inflowing orbits, converging to one of the hyperbolic fixed points, P_-^{AF} and P_+^{AF}, is found to cross the line $s=0$ at $\phi\neq 0,\pi$.[5] It will be shown later, by energetic arguments, that the configuration assumed by the semi-infinite system in this field regime is the $AF_{\uparrow\uparrow}$ one. For the film, the ground state configuration is provided by one of the non homotopic to zero curves, since they are the only ones crossing the $s=0$ line in two different points which are not fixed points. In Fig. 2 we show the ground state configuration of an $N=50$ film for different values of H. It results that there is only one trajectory which is able to satisfy the boundary conditions (4), and the corresponding energy turns out to be smaller than that of the AF one. For $H_S<H<H_B'$, we find an inhomogeneous configuration consisting of a domain wall separating two nearly antiferromagnetic regions, with the spins on the two surfaces almost parallel to the applied field. Thus for $H=H_S$, the magnetization of a film with an even number of planes presents a jump from zero to a finite value. Such a field-induced phase transition was experimentally revealed as a peak in dM/dH in Fe/Cr multilayers.[1]

(3) For $H>H_B$ [see Fig. 1(b)], the uniform bulk spin-flop state is never an equilibrium one since the hyperbolic fixed points, P_-^{BSF} and P_+^{BSF}, do not lie on the line $s=0$, as

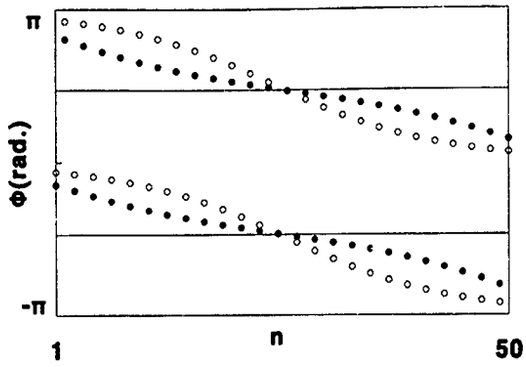

FIG. 2. Ground state configuration for an $N=50$ film with $H_A=0.9$ kG, $H_E=100$ kG. Open circles: $H=10$ kG. Full circles: $H=15$ kG. The solid horizontal lines show the canting angles for an infinite system in the bulk spin-flop phase fo $H=15$ kG.

required by the boundary conditions. For the semi-infinite system, an inhomogeneous ground state is found since all the inflowing orbits, converging to one of the hyperbolic BSF fixed points, intersect the $s=0$ line. For the film, the nonhomotopic to zero trajectories giving the ground state configuration, are closer and closer to $P_{\pm}^{\mathrm{BSF}}$ as N increases: then, for $H>H_B$ and moderate fields, only the middle planes present a configuration similar to the BSF one, while the spins in the planes near the surfaces are rotated by angles significantly different from $\pi/2$ (see Fig. 2). For $H>H_B$ and high fields ($H\gtrsim H_E/2$), the phase portrait becomes chaotic [see Fig. 1(c)]. It is important to note that evidence for chaotic behavior is also found[5] for those high values of the H_A/H_E ratio ($\zeta=0.25$) pertinent to Fe/Cr multilayers.[1]

At this point we put forward an energetic, though approximate, argument to confirm that for the semi-infinite system in the field range $H_S<H<H_B$, the SSF state (or any other nonuniform configuration) cannot exist. We rewrite Eq. (1) as

$$\frac{E}{N_{\|}S}=\sum_{n=1}^{\infty}\left[H_E\cos(\phi_n-\phi_{n-1})-H_A\cos^2\phi_n\right]$$

$$-H\sum_{n=1}^{\infty}\left[\cos\phi_n+\cos\phi_{n+1}\right]-H\cos\phi_1. \qquad (5)$$

Only systems in which $(\cos\phi_n+\cos\phi_{n+1})$ goes to 0 when n goes to ∞ will be considered. It is so both in the $AF_{\uparrow\downarrow}$ state and in the $AF_{\uparrow\uparrow}$ state, since $(\cos\phi_n+\cos\phi_{n+1})$ is identically zero for any n in both cases. Therefore, in both states, the Zeeman energy reduces to $-H\cos\phi_1$ which is minimum in the $AF_{\uparrow\uparrow}$ state, but maximum in the $AF_{\uparrow\downarrow}$ state! Since the $AF_{\uparrow\downarrow}$ state is not the ground state, but it is stable with respect to spin waves for $H<H_S$, we conclude that it is metastable for $H<H_S$. However, for $H_S<H<H_{\mathrm{BSF}}$ the situation is different. We are going to argue that the $AF_{\uparrow\downarrow}$ state is unstable with respect to the formation of a Bloch wall which will form at the surface and sink into the bulk, thus transforming the system in its $AF_{\uparrow\uparrow}$ state. Performing in Eq. (5) a $T=0$ decimation procedure in order to eliminate the even spins,[12] we obtain, for small H_A and H

$$\frac{E}{N_{\|}S}=\sum_{n=1}^{\infty}\left[\frac{H_E}{4}(\phi_{2n-1}-\phi_{2n+1})^2\right.$$

$$\left.-\left(2H_A-\frac{H^2}{H_E}\right)\cos^2\phi_{2n-1}\right]-H\cos\phi_1, \qquad (6)$$

where the last term is due to the existence of a free surface at $n=1$. Equation (6) has the well-known sine-Gordon form. In order to investigate the transformation of the $AF_{\uparrow\downarrow}$ state into the $AF_{\uparrow\uparrow}$ state, and also the stability of the SSF state, it is of interest to minimize this energy for a given value of ϕ_1 and for fixed $\cos\phi_{2n+1}=-1$ at $n=\infty$. The solution of this problem is given by the Euler–Lagrange equation of a domain wall

$$\frac{H_E}{2}(2\phi_{2n+1}-\phi_{2n+3}-\phi_{2n-1})$$

$$+\left(2H_A-\frac{H^2}{H_E}\right)\sin 2\phi_{2n+1}=0. \qquad (7)$$

Inserting its solution into Eq. (6), we have

$$\frac{E}{N_{\|}S}=\sqrt{(2H_AH_E-H^2)}(\cos\phi_1+1)-H\cos\phi_1. \qquad (8)$$

For weak fields, the coefficient of $\cos\phi_1$ is positive, so that the energy presents a minimum for $\cos\phi_1=-1$ or $\phi_1=\pi$. Thus, the $AF_{\uparrow\downarrow}$ state is a metastable one, in agreement with the spin wave argument. In other words, if a Bloch wall is introduced into the $AF_{\uparrow\downarrow}$ state from the surface, the system expels it through the surface. This occurs if $H^2<H_AH_E$, i.e., if $H\lesssim H_S$. On the other hand, if $H_S\lesssim H<H_B$, the energy (8) is minimum for $\phi_1=0$. In this case, if a Bloch wall is introduced into the $AF_{\uparrow\downarrow}$ state from the surface, the system swallows it and transforms progressively into the $AF_{\uparrow\uparrow}$ state. In particular, the SSF state corresponds to $\cos\phi_1=0$, and it is unstable, in agreement with the mapping argument.

Magnetoresistance of ultrathin Co films grown in UHV on Au(111): Crossover from granular to continuous film behavior versus Co thickness (abstract)

C. Dupas, E. Kolb, J. P. Renard, and E. Vélu
Institut d'Electronique Fond, Université Paris-Sud, 91405 Orsay, France

M. Galtier, M. Mulloy, and D. Renard
Institut d'Optique Théorique et Appliquée, Université Paris-Sud, 91405 Orsay, France

Co/Au(111) is a model system for magnetoresistance (MR) studies due to abrupt interfaces without intermixing between Co and Au and perpendicular magnetization of Co films for Co thickness below nine atomic monolayers (AL). The high quality of Co/Au(111) multilayers is revealed by highly contrasted MR oscillations versus Au spacer thickness.[1] We report here a detailed study of the effect of cobalt thickness done to 0.2 AL on the MR of various Au/Co structures. Experiments were performed on single Co layer sandwiched between two Au(111) films, Au/Co/Au, and on double Co films, Au/Co/Au/Co/Au, in the T range 1.5–300 K and in magnetic fields up to 10 T. For the sandwiches, two series were studied, each including eight samples grown in UHV in a single run, with Co thicknesses t_{Co} from 0.2 to 1.6 and from 1.4 to 4 AL. The MR in the perpendicular and transverse configurations show that the easy magnetization axis is perpendicular to the films, even for low t_{Co}. The MR value increases with t_{Co} to the high value of 5% at low temperatures for a noncontinuous Co film and decreases afterwards, clearly evidencing the transition from islandlike to continuous-like character of the Co film. In the islandlike regime, the magnetic domain size is limited by the island size and is thus smaller than in the continuous Co films, leading to higher MR values. In the double Au/Co/Au/Co/Au samples, different Au spacer thicknesses were chosen in order to ensure either FM or AFM coupling between the magnetic layers, and t_{Co} was varied up to 10 AL. We did not observe coupling oscillations versus t_{Co}. Moreover, the lack of any significant variations of the MR value shows that the electronic mean free path in Co is larger than 10 AL at any T.

The micromagnetics of periodic arrays of defects in trilayers with interlayer exchange coupling (abstract)

H. A. M. van den Berg
Siemens A G, Erlangen, P.O. Box 3220, Germany

A significant loss in the giant magnetoresistive signal of magnetic stacks with antiferromagnetic coupling across nonmagnetic intermediate layers is caused by regions with a ferro- rather than an antiferromagnetic coupling. The impact of these ferromagnetic coupling regions extends itself into the lateral direction due to the bulk exchange coupling. The present micromagnetic model provides a tool by which a detailed quantitative evaluation of the impact of periodic arrays of parallel line defects is possible. These defects have deviating exchange-coupling constants, and/or anisotropy constants or directions, bulk exchange constants, saturation magnetization, etc., in specific regions. Previously, we developed a phenomenological model of trilayers with two magnetic films separated by a nonmagnetic interlayer[1] that contains one such defect. This model, with a relatively small number of free parameters, allows one to trace complete hysteresis curves. A large number of mode branches reveal themselves and jumpwise transitions between these modes frequently occur along the hysteresis loops. The present micromagnetic model requires a sufficiently accurate assessment of the starting magnetization configuration in order to get a convergence of the code. In general, the micromagnetic code is not capable of overcoming the above irreversible mode conversions. The mode branches evaluated by the phenomenological model are applied to provide the micromagnetic model with appropriate starting configurations after meeting a situation of nonstability. The micromagnetic theory of Brown[2] constitutes the basis of the present approach. The micromagnetic effective field is calculated at grid points and the torque exerted by it on the magnetic dipole is made zero at each grid side by an iteration scheme. The long ranging magnetostatic fields are given by convolution integrals and are evaluated in the Fourier space by using two-dimensional fast Fourier transforms. The single defect is micromagnetically studied by zero padding techniques. Depending on the course of the external field, two different wall regions reveal themselves, to wit, the wall core and the so-called Néel tails. These tails were not incorporated into the phenomenological model. Provided that the defects are sufficiently wide spaced, the agreement between both models is rather good in the core regions. The impact on the GMR signal, in particular of the Néel tails, will be discussed with emphasis on systems with weak interlayer coupling, e.g., the decoupled systems.

FMR doublet in two-layer iron garnet films (abstract)

A. M. Grishin, V. S. Dellalov, E. I. Nikolayev, V. F. Shkar, and S. V. Yampolskii
Donetsk Phystech, Donetsk 340114, Ukraine

Multilayer epitaxial iron garnet films have been investigated very intensively in the recent past. The dipole and exchange couplings of spins lying in different layers results in the existence of new types of oscillations in these structures and give rise to the characteristic resonance properties of them.[1,2] Resonance microwave absorption in two-layer iron garnet films, of which one layer is in a saturated state and the other is in a demagnetized state, is investigated. The films were prepared by the epitaxial method on a gallium-gadolinium substrate with (111) orientation. The first layer on the substrate was the doped iron yttrium garnet with the easy plane magnetization. The second easy axis layer was the bubble domain layer. The resonant field of the first layer FMR line versus the external in-plane magnetic field was investigated. It was determined that the FMR line is doubled when the external field is applied along the [112]-type axes. The lines of the FMR doublet merge into a single line and the resonance intensity is doubled if the magnetic field is oriented in the [110] directions. It was established that the FMR line splitting is conditioned by the layer exchange interaction, the cubic anisotropy, and the domain dissipative field. The magnetic and anisotropy of the resonance fields agrees with the model of an isolated layer magnetized by the domains of the neighboring layer.

Influence of the dipole interaction on the direction of the magnetization in thin ferromagnetic films (abstract)

A. Moschel and K. D. Usadel
Theoretische Tieftemperaturphysik, Universität Duisburg, Lotharstrasse 1, 47048 Duisburg, Germany

The magnetization of thin films depends in a very sensitive way on surface anisotropy fields which often favor a perpendicular orientation and on the dipole interaction which favors an in-plane magnetization. A temperature driven transition from one to the other orientation has been observed experimentally.[1] In order to understand this behavior theoretically we performed detailed calculations of the magnetization of very thin films (thickness of up to 5 layers) within a quantum mechanical mean field approach. A surface anisotropy that favors a perpendicular orientation and a long range dipole interaction were taken into account. It is shown that these competing interactions for certain values of the parameters may result in a temperature driven switching transition from an out-of plane to an in-plane ordered state. Varying the strength of the dipole interaction we found that the switching temperature is a very sensitive function of the ratio of these two competing interactions. A perpendicular ground state magnetization of the film is only found for values of the surface anisotropy which are larger than a critical surface anisotropy value. The reorientation of the magnetization vector has its physical origin in an entropy increase of the system when going from a perpendicular to an in-plane ordered state.

Coercivity and switching field of single domain γ-Fe_2O_3 particles under consideration of the demagnetizing field

Paul L. Fulmek and Hans Hauser
Institut für Werkstoffe der Elektrotechnik, Technische Universität Wien Gusshausstrasse 27-29, A-1040 Vienna, Austria

The coherent rotation of the spontaneous polarization in ellipsoidal ferromagnetic single domain particles is calculated under consideration of the magnetocrystalline anisotropy and the true, inner field. Magnetization curves and switching fields are computed for uniaxial and cubic magnetocrystalline and shape anisotropy. Considering only the magnetic energy inside the particle, the resulting switching fields are lower than those predicted by the Stoner–Wohlfarth theory, and they are qualitatively and quantitatively comparable to the results of other models. The comparison to measurements on isolated γ-Fe_2O_3 particles shows excellent agreement.

I. INTRODUCTION

The idealized particles discussed are small, perfect single crystals of exactly ellipsoidal shape. They consist of one single domain only.[1] The magnetization process happens by coherent rotation of the spontaneous polarization. This rotation need not happen continuously, switching occurs for critical field strengths.[2]

It is further assumed that all processes happen at temperatures far below the Curie temperature, where the spontaneous polarization of the material is constant. The analysis assumes static and isothermal ferromagnetism. Effects associated with the time rate of change of magnetization are not considered.

The coherent rotation of the spontaneous polarization is determined by the behavior of the minima of the total energy density. Therefore, only anisotropic contributions have an influence. The energies taken into account are the magnetocrystalline energy E_c and the energy of the fields in connection with the applied field $\mathbf{H}_a$ and the demagnetizing field $\mathbf{H}_d$. All other energies are neglected. As single domain particles are always in the state of saturation, the demagnetizing field has a strong influence on the true field and on the energy due to the field. Stoner–Wohlfarth (SW) calculations demand that the particle does not interact with surrounding magnetic material. Completely neglecting the field outside the particle, however, yields results that agree perfectly with measurements on single γ-Fe_2O_3 particles.

Magnetization curves are calculated by tracing the minima of the energy areas (the three-dimensional space variation of the total energy) as the applied field is changed continuously.[2–6]

II. ANISOTROPIC ENERGIES

To calculate magnetization curves we have to find the minimum energy configuration for a given applied field. Only the direction of $\mathbf{I}_s$ can vary. Under this assumption the energy is a function of only two variables, of the direction of $\mathbf{I}_s$. For searching the minima we have to take into account only anisotropic energies.

In crystalline ferromagnetic materials $\mathbf{I}_s$ prefers certain directions of the crystal lattice to minimize the *magnetocrystalline energy* E_c. For cubic crystal structures (bcc, fcc) we use a series expansion of the directional dependence (direction cosines α_i) with respect to the crystal axes

$$E_c = K_0 + K_1(\alpha_1^2\alpha_2^2 + \alpha_1^2\alpha_3^2 + \alpha_2^2\alpha_3^2) + K_2\alpha_1^2\alpha_2^2\alpha_3^2. \quad (1)$$

Three coefficients $K_{0,1,2}$ are sufficient to describe this property. Uniaxial magnetocrystalline anisotropy is described by

$$E_u = K_{u0} + K_{u1}\sin^2\varphi + K_{u2}\sin^4\varphi, \quad (2)$$

where φ is the angle between the easy axis and $\mathbf{I}_s$.

The general expression for the power density of the magnetic field in any material, especially in nonlincar and anisotropic materials,[8] is

$$P_m = \frac{\partial E_m}{\partial t} = \mathbf{H}\frac{\partial \mathbf{B}}{\partial t}. \quad (3)$$

The time integral supplies the general formula for the energy density of any general magnetic field configuration[9,10]

$$E_m = \int \mathbf{H}d\mathbf{B}. \quad (4)$$

The true $\mathbf{H}$ acting in the material is the vectorial sum of the applied field $\mathbf{H}_a$ and the demagnetizing field $\mathbf{H}_d$. In the special case of a specimen surface of second order (e.g., a general ellipsoid) all fields in the volume of the specimen are homogeneous, and therefore, the demagnetizing field can be determined by a demagnetizing matrix $\underline{N}$

$$\mathbf{H}_d = -\frac{1}{\mu_0}\underline{N}\mathbf{I}_s, \qquad \mathbf{H} = \mathbf{H}_a + \mathbf{H}_d = \mathbf{H}_a - \frac{1}{\mu_0}\underline{N}\mathbf{I}_s. \quad (5)$$

Demagnetizing factors are determined in the directions of the axes of the ellipsoid.[11] This diagonal matrix has to be transformed for general ellipsoids in arbitrary orientations.

 0021-8979/94/76(10)/6561/3/$6.00 © 1994 American Institute of Physics

The induction $\mathbf{B}$ in the specimen results from the vacuum induction of the magnetic field $\mathbf{H}$ and the polarization of the material:

$$\mathbf{B}=\mu_0\mathbf{H}+\mathbf{I}_s=\mu_0\mathbf{H}_a+(\underline{1}-\underline{N})\mathbf{I}_s. \tag{6}$$

As an approximation for the total energy we integrate Eq. (4) with Eqs. (5) and (6) over the volume of the specimen only. The variation of the energy density is due to the variation of the polarization vector $\mathbf{I}_s$ only. The energy density of the material is therefore reduced by

$$-E_m=-\int \mathbf{H}\left(\frac{\partial\mathbf{B}}{\partial\mathbf{H}_a}\,d\mathbf{H}_a+\frac{\partial\mathbf{B}}{\partial\mathbf{I}_s}\,d\mathbf{I}_s\right)$$

$$=(\underline{1}-\underline{N})\left(-\mathbf{H}_a\mathbf{I}_s+\frac{1}{2\mu_0}(\underline{N}\mathbf{I}_s)\mathbf{I}_s\right). \tag{7}$$

For a given applied field the energy can be expressed as a function of two variables, the direction of $\mathbf{I}_s$. A minimum energy for constant $\mathbf{H}_a$ yields stable solutions of $\mathbf{I}_s(\mathbf{H}_a)$. Two interesting properties of the magnetization curve will be discussed here. The point of magnetization reversal—the coercive force—and the point(s) of instability—the switching field strength. As single domain particles are always in the state of saturation, we have to define the magnetization curve as projection of $\mathbf{I}_s$ in the applied field $\mathbf{H}_a$ versus the value of the applied field H_a.

III. UNIAXIAL CALCULATIONS

For comparison to other models it is convenient to calculate the coercive force and the critical field (switching field) in the case of simple uniaxial anisotropies (magnetocrystalline and shape anisotropy, $K_{u2}=0$) for prolate ellipsoids. The polar axis of the ellipsoid is identical to the axis of uniaxial magnetocrystalline anisotropy. The angles α of the applied field and φ of the polarization are denoted with respect to the axis of uniaxial anisotropy.

As we need the energy expressions Eqs. (2) and (7) to find the minimum energy only, we can reduce the total energy E to E^*

$$E=E_u-E_m\rightarrow E^*=\sin^2\varphi-h\left[\cos\alpha\cos\varphi+\frac{1}{2}\left(\frac{1+N}{1-N}\right)\sin\alpha\sin\varphi\right], \tag{8}$$

$$h=H_a\frac{1}{K_{u1}/[I_s(1-N)]+I_s(1-3N)/(8\mu_0)}, \tag{9}$$

$$\frac{dE^*}{d\varphi}=\sin(2\varphi)-h\left[-\cos\alpha\sin\varphi+\frac{1}{2}\left(\frac{1+N}{1-N}\right)\sin\alpha\cos\varphi\right], \tag{10}$$

$$\frac{d^2E^*}{d\varphi^2}=2\cos(2\varphi)+h\left[\cos\alpha\cos\varphi+\frac{1}{2}\left(\frac{1+N}{1-N}\right)\sin\alpha\sin\varphi\right]. \tag{11}$$

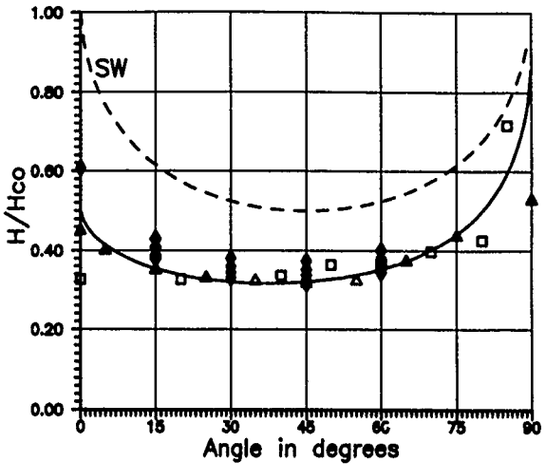

FIG. 1. Switching field of prolate ellipsoids (aspect ratio 4:1:1) with vanishing magnetocrystalline anisotropy. The dashed line gives H_c according to SW theory. All H_c values are related to SW$-H_{c0}=138$ kA/m. □ Measurements γ-Fe_2O_3 particles (Ref. 13); △ Micromagnetic calculations (parallelepiped) (Ref. 12); ◇ calculations for additional cubic anisotropy ($K_1=-4600$ kJ/m^3).

In the SW model the influence of shape and magnetocrystalline anisotropy can be included as an *anisotropy field* $H_A\rightarrow h=H_a/H_A$. This reduction is impossible for our calculations. To find a direction φ for the polarization with minimum energy, we have to find the value for h [Eq. (9)] that gives $\partial E^*/\partial\varphi=0$ [Eq. (10)]. With a second derivative Eq. (11) greater than zero, h gives a stable minimum, a stable point on the magnetization curve. When Eq. (11) is zero, the corresponding field is a critical field; the solution is an unstable one. This critical, switching field strength is important for magnetic storage.

Figure 1 shows the switching field strength depending on the direction of the applied field calculated by the formulas from above. In comparison to our results Fig. 1 shows the switching field curve according to SW calculations, results from a micromagnetic approach by Yan and Della Torre using a parallelepiped as model geometry (aspect ratio 6:1:1, length 300 nm, uniaxial magnetocrystalline anisotropy),[12] and measurements of the switching field on small isolated γ-Fe_2O_3 particles (aspect ratio ≈4:1:1) by Knowles.[13]

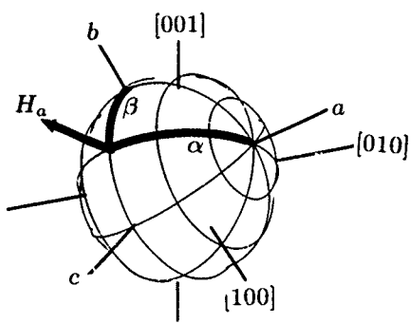

FIG. 2 Coordinate system for magnetocrystalline anisotropy ⟨100⟩, shape anisotropy (a,b,c), and the direction of the applied field (α,β)

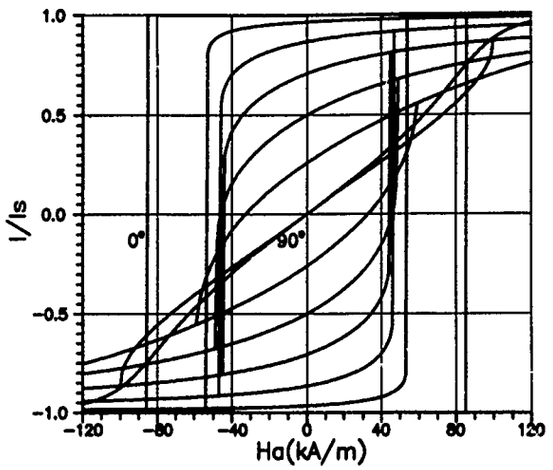

FIG. 3. Magnetization curves for γ-Fe_2O_3 particles (aspect ratio 4:1:1) in dependence of the angle α (β=0) of the applied field with respect to the easy axis of shape and cubic magnetocrystalline anisotropy. α is varied from 0° to 90° in steps of 15°.

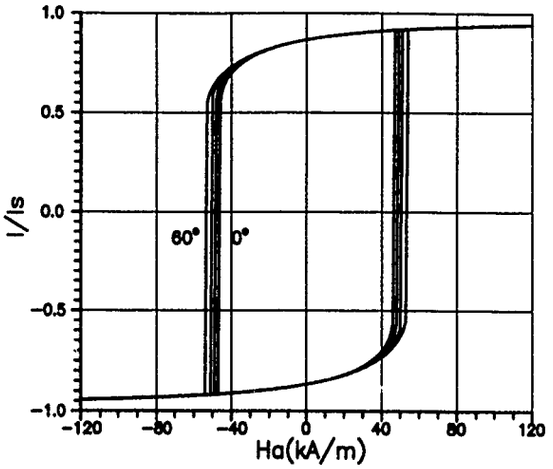

FIG. 4. Magnetization curves for γ-Fe_2O_3 particles (aspect ratio 4:1:1) in dependence of the angle β for α=30°.

For uniaxial considerations, we did our calculations for γ-Fe_2O_3 particles with I_s=0.45 T, K_{u1}=0, and an ellipsoid shape with an aspect ratio of 4:1:1. The demagnetizing factor in the direction of the longer axis is N=0.075.

For an angle of the applied field of 0°, our calculations yield exactly half the value for the switching field of SW when the uniaxial anisotropy constant K_{u1} is zero. In this case are both angles $\alpha=\varphi=0$

$$E^*_{SW}=\sin^2\varphi-h_{SW}\cos(\alpha-\varphi),$$
$$h_{SW}=4H_a\mu_0/[I_s(1-3N)], \qquad (12)$$
$$h/h_{SW}=2\rightarrow H_c/H_{c0}=0.5.$$

IV. CUBIC CALCULATIONS

For cubic anisotropies the two-dimensional minimum search on the surface of the energy areas was realized by a numerical algorithm implemented on a computer.

The calculations have been carried out for elongated ellipsoids of γ-Fe_2O_3 with an aspect ratio of 4:1:1. We assume that the long axis of the ellipsoid lies in the [111] direction of the crystal lattice.[4] The material parameters are: I_s=0.45 T, $K_1=-4600$ J/m^3, K_2=0 J/m^3.[14]

As we calculate magnetization curves for cubic anisotropies, we have to consider two angles of the applied field with respect to the axes of the ellipsoid. The angles are denoted according to the angles in a spherical-coordinate system with the long axis of the ellipsoid as polar axis (i.e., the [111] direction). The first angle α is always the angle between the direction of the applied field and the long axis of the ellipsoid. The second angle β is the angle between the $(1\bar{1}0)$ plane and the field vector (see Fig. 2).

Figure 3 shows the resulting magnetization curves when the direction of the applied field is changed in the $(1\bar{1}0)$ plane by 15° steps (α=0°···90°, β=0). The magnetization curve for α=0° calculated by SW theory would have a coercivity of 138 kA/m. For $\alpha<60°$ the switching field is identical to the coercivity.

The influence of the second angle β is shown in Fig. 4: the angle α between the applied field and the easy polar axis of the ellipsoid is constant 30°. The coercive force varies by 15%, as the secondary angle β changes from 0° to 90°.

Values of the coercive force variation due to the cubic anisotropy are plotted in Fig. 1 in comparison to pure uniaxial shape anisotropy. The values of switching fields for $\alpha>60°$ could not be determined precisely, as with increasing angle the continuous rotation yields steeper slopes of the magnetization curve, numerically indistinguishable from a real instability (compare Fig. 3).

Co fine particles coated with Ag have been synthesized through the microemulsion method in an inert atmosphere. The size of the particles is controlled by the water droplets of the microemulsions. Fine particles prepared by this method, consist of a magnetic core of Co covered by a layer of Ag. Samples containing from 3.3 to 40.5 vol % Co have been prepared. The average size of the particles obtained is in the nanometer range. The magnetic properties were studied by dc magnetization at 77 K and room temperature. The data show a strong dependence of the magnetic properties on the annealing temperature.

I. INTRODUCTION

Single domain magnetic particles show very interesting properties, such as high coercivity and remanence, which are of special interest to several applications in magnetic recording and permanent magnets. Different methods can be used in order to obtain small particles in the submicrometric range. Among these, chemical reactions and vacuum deposition are the most usual ones. Most studies of ultrafine metallic particles have been performed on granular materials in nonmetallic matrices.[1–3] Interest in single domain particles immersed in a nonmagnetic metallic matrix has increased recently.[4,5] The interest in granular materials, such as Fe-Ag, Co-Ag, $Ni_{81}Fe_{19}$-Ag, etc., is because they present a giant magnetoresistance (GMR).[6,7] Although much effort has been devoted during the last years studying the origin of their properties, a quantitative understanding of the phenomenon is still lacking.[8,9]

In this work we describe a new chemical method for the preparation of ultrafine Co particles covered by metallic silver. This method consists in mixing two water-in-oil (W/O) microemulsions containing the reactants dissolved in the aqueous phase in order to produce the Co core. The reaction takes place inside the droplets, which controls the final size of the particles. Subsequently, silver ions are adsorbed onto these particles and finally are reduced to produce a silver metallic shell.

II. EXPERIMENT

The microemulsions employed in the production of the particles were composed of *n*-heptane, aqueous solution, and aerosol-OT (AOT, sodium dodecylsulfosuccinate). The droplet size of these microemulsions was controlled by the ratio $R=[H_2O]/[AOT]$. This ratio was set to 10. The whole process for obtaining the particles, that was carried out in an inert glove box, can be divided into two stages.

(1) Formation of the magnetic cores: To carry out this first stage, two different microemulsions were prepared. The first one consisted in an aqueous solution of $Co(NO_3)_26H_2O$ (0.1 M) and the second one contained $NaBH_4$ (0.2 M). The two microemulsions were mixed and the magnetic particles were formed inside the microdroplets. The microparticles, separated from the microemulsion by ultracentrifugation, were washed later with *n*-heptane and ethanol several times and finally dried with acetone.

(2) Coating with Ag: The magnetic particles were redispersed with AOT in an aqueous solution containing $AgNO_3$ and EDTA (ethylendiaminetetracetic). Silver ions were then absorbed on the particles which acted as nucleation centers. This solution was later irradiated with UV light during 30 min to obtain a metallic cover of silver on the magnetic particles.[10] The amount of EDTA and $AgNO_3$ used depends on the Ag/Co ratio to be obtained. The coated microparticles were separated again from the solution by ultracentrifugation, washed several times with *n*-heptane and ethanol in order to remove the AOT surfactant, and finally dried with acetone. Then, the microparticles were examined before and after annealing in flowing Ar.

Most of the organic impurities were eliminated after annealing, followed by a process of oxidation and reduction. These were observed by differential thermogravimetric analysis measurements.

The samples were characterized analytically by inductive coupled plasma-atomic emission spectroscopy and the final composition of Co, Ag, and impurities were determined. The structural characterization was carried out by x-ray powder diffraction. These measurements were performed at room temperature, and matched with diffraction patterns from the total access diffraction database. In order to determine the size distribution, measurements of transmission electron microscopy (TEM) and dynamic light scattering (DLS) were carried out. For both TEM and DLS measurements, particles were dispersed in water using AOT. The average crystallite sizes were calculated from the shape of the x-ray diffraction peaks using the Debye–Scherrer formula. The magnetic properties of the samples were measured with a vibrating sample magnetometer in the temperature range of 80 K$<T<$300 K. The powder was introduced, loosely packed, in a cylindrical sample holder.

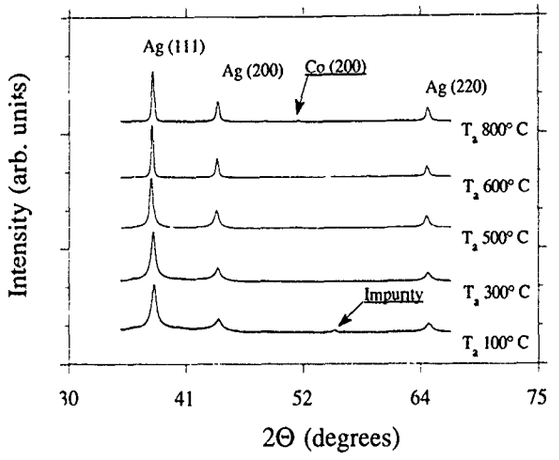

FIG. 1. X-ray diffraction pattern for $Co_{0.5}Ag_{0.5}$ after annealing at different temperatures. The arrows show the position of cobalt reflections.

III. RESULTS AND DISCUSSION

A. Structural characterization

X-ray diffraction on as-prepared Co particles (first chemical stage) shows a typical amorphous spectrum. Figure 1 shows the x-ray diffraction pattern for a typical Co/Ag sample at five temperatures of annealing (T_A=100, 300, 500, 600, and 800 °C). Long measurement times, counting times of 20 s per 0.002° step in 2θ, were needed in order to observe cobalt peaks in samples with high concentration of Co and high treatments of temperature. Only one Co peak is visible (200) because the others overlap with those due to silver. In Fig. 1 it can be observed how the width decreases with annealing temperature. Studies of the width of Ag (111) and Ag (220) peaks done as a function of annealing temperature yields the size of the Co/Ag particles grows from 15 to 60 nm.

Figure 2 shows the TEM electron micrograph for the sample with x=0.12 of Co_xAg_{1-x} treated at 500 °C. To obtain the micrograph, the samples were dispersed in water and then deposited onto Cu grid substrates. The average diameter was of about 30 nm, similar to the results obtained by DLS.

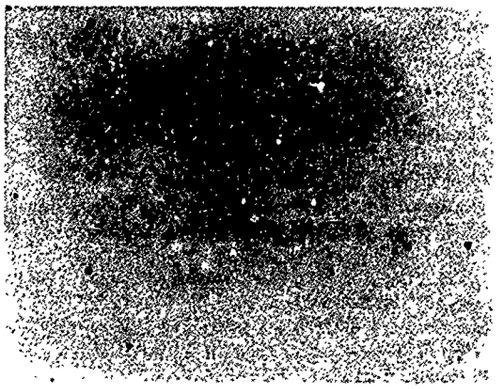

FIG. 2. TEM microphotograph of a sample of $Co_{0.12}Ag_{0.88}$.

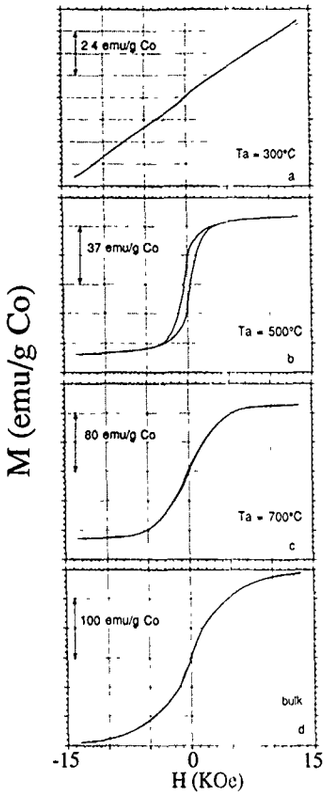

FIG. 3. In plane M-H loops at room temperature of Co_xAg_{1-x} with $x \approx 0.12$ at different annealing temperatures in series A. (a) T_A=300 °C, (b) T_A=500 °C, (c) T_A=700 °C, and (d) bulk Co.

B. Magnetic properties

The temperature dependence of the magnetization has been measured after cooling in zero magnetic field (ZFC) and also after cooling in a field (FC). The M-T data show a splitting between the FC and ZFC curves. For the as-prepared samples, this splitting occurs close to room temperature (RT). For annealed samples, the sizes of cobalt cores grow and this splitting point is shifted towards higher temperature.

The magnetic hysteresis loops have been measured in three series of Co_xAg_{1-x} (A, B, and C). Series A and B are two separate fabrication runs with the same Co concentration (x=0.12±0.02) but with different annealing temperatures, 100 °C<T_A<800 °C. Series C are samples of different compositions, from x=0 to x=0.66 annealed at T_A=500 °C. Figure 3 shows magnetization (M) as function of magnetic field (H) at RT for T_A=300 °C [Fig. 3(a)], 500 °C [Fig. 3(b)], and 700 °C [Fig. 3(c)]. Figure 3(d) is the M for cobalt powder (d<250 μm) and reflects the bulk properties of the material. The coercive field (H_c) as function of T_A is plotted in Fig. 4(a). The squareness, SQ, defined as M_r/M_s where M_r is the remanence magnetization and M_s is the magnetization at H=13.5 kOe, vs T_A, is shown in Fig. 4(b).

According to Fig. 4, for series A and B, it is possible to define three regions of annealing temperature. The first for low T_A, between 100 and 300 °C, shows a reversible M-H behavior. The second region, for 300<T_A<600 °C shows a hysteresis loop [Fig. 3(b)]. The dramatic change of the mag-

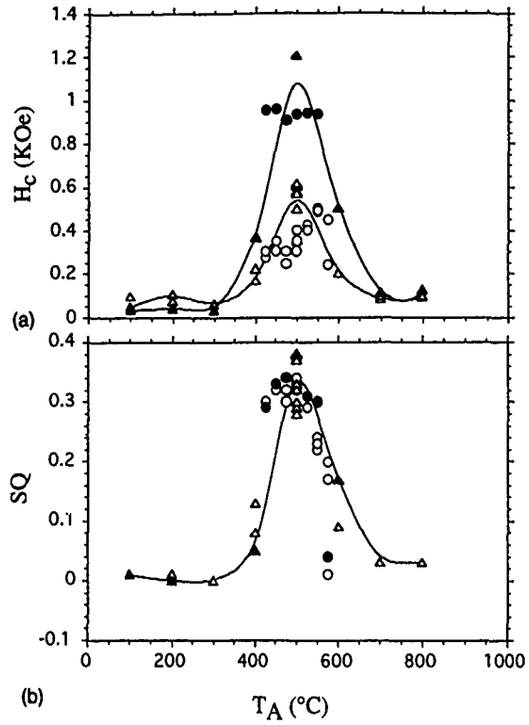

FIG. 4. (a) H_c vs T_A and (b) SQ vs T_A for two different runs of Co_xAg_{1-x} ($x \sim 0.12$). Series A (△) RT, (▲) 77 K, series B (○) RT and (◔) 77 K.

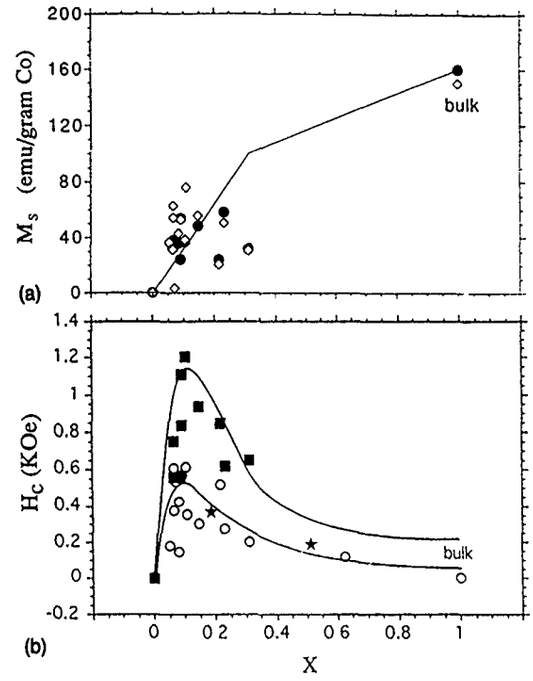

FIG. 5. Co_xAg_{1-x} samples (a) M_s vs x (experimental composition) after annealing at 500 °C (the solid line comes from Co_xCu_{1-x} in Ref. 5) and (b) H_c vs x. The solid lines are guides to the eye. Open and filled symbols show measurements at RT and 77 K, respectively. The filled stars are data from Ref. 11 of Co_xAg_{1-x} films.

netic properties in this range could be due to an increase of the Co nuclei and/or the crystallization of some amorphous portions of the Co cores as T_A increases. For $T_A \approx 500$ °C, H_c and SQ have maximum, as seen in Fig. 4. This maximum is similar to the one found by other authors in $Co_{19}Ag_{81}$ and $Co_{50}Ag_{50}$ granular magnetic thin films.[11] The third region ($T_A > 600$ °C) shows that the H_c and SQ decrease as T_A increases. The reason for it is that the interaction between the particles is strong and they are no longer single domains so their magnetic behavior approaches the one found for bulk Co.

Finally, in Fig. 5, we show M_s and H_c as function of experimental Co composition. The solid line is the data of Ref. 5 about Co_xCu_{1-x}. For the samples with low Co concentration ($x < 0.12$), the magnetization does not saturate and the coercive field has a value close to zero. The long range magnetic order appears at high Co concentrations. For samples with $0 < x < 0.12$ the magnetization was found to saturate more easily and the systems exhibit a monotonic increase of H_c with increasing Co content. For $x > 0.15$, the samples present a monotonic decrease of H_c with increasing x, which is consistent with a coupling effect of the Co particles.

IV. CONCLUSIONS

In summary, we have studied the structural and magnetic properties in a Co-Ag granular systems obtained by chemical reactions in microemulsions. The reaction takes place inside the droplets, which control the final size of the particles. By this method, magnetic ultrafine particles, in the nanometer range, of Co coated with Ag were obtained. From the x-ray analysis we observe that Ag crystallizes in the face centered cubic structure. The magnetic behavior of these samples after thermal treatments ($T_A \approx 500$ °C) shows coercive fields as high as $H_c \approx 600$ Oe at room temperature. These values are similar to those reported for granular materials which present GMR.[6,7] We are now in the process of measuring the MR in our samples.

Magnetic properties of Fe clusters in NaY zeolite

J. A. Cowen

Clusters of up to 28 Fe^0 atoms have been introduced into the "supercages" of NaY zeolite by ion exchange of Fe^{+2} for Na^+ followed by reduction to Fe^0 with solvated electrons and Na^{-1} ions. The temperature-dependent ac and dc susceptibilities, which exhibit Curie–Weiss behavior before reduction, change to something approximating superparamagnetic behavior afterwards. The blocking temperature, T_b, shows a strong dependence on magnetic field but weak dependence on frequency. There is at best a very weak remanence and coercive field while the onset of irreversibility occurs at temperatures well above T_b. In addition, the real and imaginary parts of the ac susceptibility show essentially similar temperature dependence. Some of this anomalous behavior can be attributed to a distribution of particle sizes. To the best of our knowledge these preliminary data—while poorly understood—represent the first measurements of the temperature, frequency, and field dependence of the magnetic properties of such small clusters.

I. INTRODUCTION

The study of the magnetic properties of small particles or clusters has been divided into two regimes. *Small clusters* consisting of between 10 and 600 atoms are produced in a "molecular" beam by laser vaporization. Particle size is selected by mass spectrometry and the magnetic properties are determined in a Stern Gerlach experiment.[1] *Large clusters*—nanocrystals—consisting of between 10^3 and 10^7 atoms are produced by sputtering, evaporation, or chemical techniques and are collected in quantity in an insulating matrix.[2] These larger particles can be characterized and their magnetic properties measured by using all of the standard techniques—x rays, extended x-ray-absorption fine structure, magnetic susceptibility, Mössbauer spectroscopy, NMR, electron spin resonance, etc.

By using conventional ion exchange methods, we have introduced up to 28 Fe^{+2} ions into NaY zeolite and reduced them to metallic Fe^0 particles that are presumably trapped in the supercages. According to the stoichiometry of this zeolite, an average of not more than 28 Fe^0 atoms can be present per supercage. We are thus able to measure for the first time the temperature, field and time dependence of the magnetic properties of such small clusters. Although these are preliminary measurements and the samples have not been completely characterized, our experimental results agree qualitatively with previous results on small clusters obtained at a single temperature and field. The overall magnetic behavior is quite complex and requires further experimental and theoretical study.

II. SAMPLE PREPARATION

Zeolites are alumino-silicates which are characterized by an open structure (about 50% of the volume is voids) in which charge unbalance in the structure is compensated for by the appropriate number of charged ions in the open holes or cages. NaY zeolite, with the chemical formula $Na_{56}Al_{56}Si_{134}O_{348}\cdot 240H_2O$ has an fcc structure in which "large" (1.2-nm-diam) "supercages" are connected by "small" (0.7-nm-diam) sodalite cages. The unit cell has a lattice parameter of 2.5 nm and contains one supercage and 56 Na^{+1} ions. These charges are balanced by negative charges produced by the substitution of Al^{+3} for Si^{+4} in the alumino-silicate framework.[3]

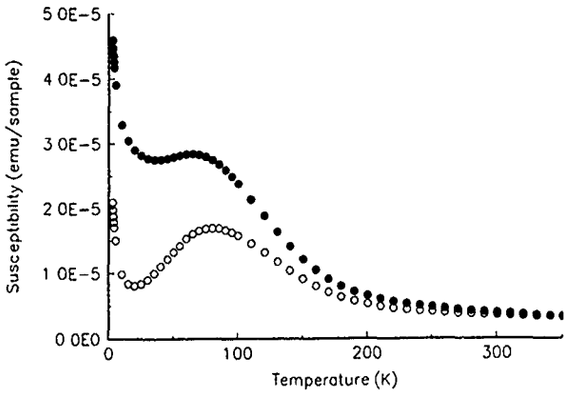

FIG. 2. The dc susceptibility of a sample after a single reduction to Fe^0 measured in a 10 G field. The upper curve is field cooled; the lower is zero field cooled.

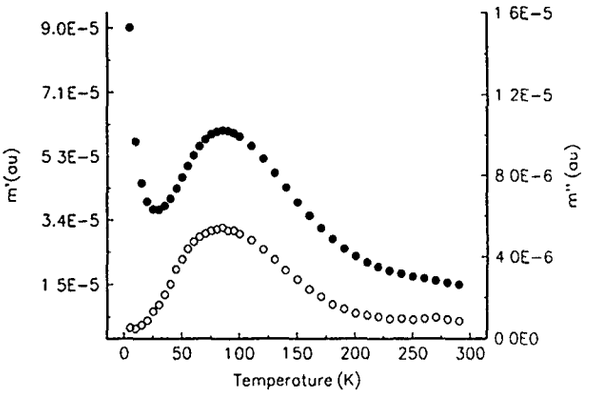

FIG. 4. The real (solid circles) and imaginary (open circles) parts of the ac magnetization of a reduced sample measured at 10 Hz.

By using conventional ion-exchange methods, we have introduced Fe^{+2} ions into the NaY zeolite and reduced it to Fe^0 with solvated electrons and Na^{-1} anions in an ether solvent.[4] The ion exchange process followed by the reduction is expected to yield iron clusters in the supercages with a maximum of 28 Fe atoms, with 56 K^{+1} and/or Na^{+1} ions reintroduced to maintain charge neutrality. Although we have tried to prevent exposure to oxygen we expect some oxidation of Fe atoms to occur yielding a mixture of Fe^0 and Fe^{+2} of unknown proportions. Although both multiple-exchange and multiple-reduction processes are possible, the samples used in these experiments were the result of one stage of each.

III. EXPERIMENTAL RESULTS

We are reporting here the temperature- and field-dependent dc susceptibility and the temperature- and frequency-dependent ac susceptibility which have been measured on a Quantum Design MPMS2 susceptometer. The dc magnetic susceptibility and reciprocal susceptibility of the zeolite sample after Fe^{2+} exchange but before reduction are shown in Fig. 1. The high temperature behavior is Curie—Weiss (CW) with $\Theta \approx 10$ K with small deviations from CW at low temperature.

The dc magnetic susceptibility measured after reduction to Fe^0 is shown in Fig. 2. The upper and lower curves are obtained from the field cooled (FC) and zero field cooled (ZFC) measurements, respectively. There are three interesting features in these data; the irreversibility which starts near 300 K, the peak near 100 K, and the Curie-like behavior at low temperatures. The Curie behavior arises from residual Fe^{+2} ions which were missed in the reduction process or were oxidized after reduction. Magnetic measurements made several months after sample preparation give essentially the same results implying no long term oxidation. The peak near 100 K can be attributed to a blocking temperature, T_b, associated with superparamagnetic behavior, although if this were a conventional superparamagnet the irreversibility would begin near T_b. Figure 3 shows the field dependence of the ZFC data for magnetic fields between 10 and 5000 G. The blocking temperature peak is first shifted to lower temperatures and then destroyed by fields of less than 1000 G. Hysteresis curves taken between T_b and the paramagnetic regime indicate remanence and coercive fields of about 1×10^{-6} and 5 G, respectively.

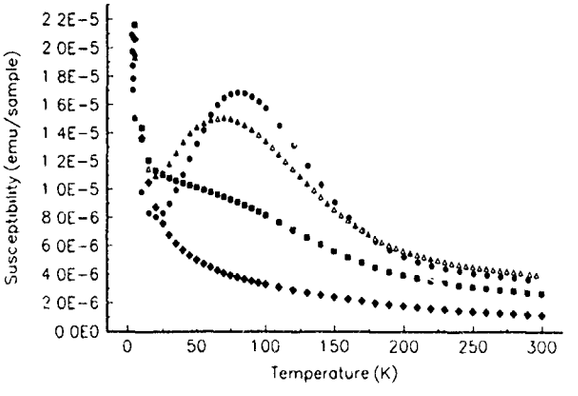

FIG. 3. The dc susceptibility of a reduced sample measured in. ●, 10, △, 100; ■, 500; and ◇, 5500 G.

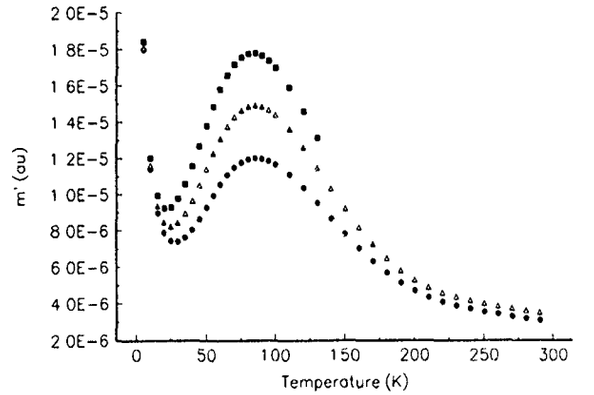

FIG. 5. The real part of the ac magnetization of a reduced sample measured at: ●, 0.1; △, 10; and ■, 100 Hz.

The real and imaginary parts of the ac susceptibility—χ' and χ'', respectively—were measured in an ac field of 1 G (with no static field) for frequencies between 0.1 and 1000 Hz. The temperature dependence of χ' and χ'' measured at 10 Hz is shown in Fig. 4. The absence of an imaginary component in the low temperature range confirms our suggestion that this is a paramagnetic regime—where there are essentially no losses. On the other hand, near the peak in the susceptibility of a superparamagnet (or a spin glass) where the measuring frequency and relaxation time are related by $\omega = 1/\tau$, the real part of the magnetization, χ', should have an inflection point while χ'' should have a maximum.[5] The data do not show this behavior at any measuring frequency. In addition there is a weak frequency dependence of T_b (Fig. 5).

IV. SUMMARY

The ion exchange and reduction techniques which we have developed to incorporate small clusters of Fe^0 into the supercages of NaY zeolite have produced novel samples whose magnetic properties can best be described as "nominally superparamagnetic." Some of the anomalous behavior which is observed is certainly due to a distribution of particle sizes or possibly to particles which consist of a mixture of Fe^0 and Fe^{+2} leading to a frustrated spin glass. Currently we are investigating the effects of multiple exchange and reduction on the magnetic properties and the use of Mössbauer spectroscopy to characterize the structure.

Spherical and monodisperse $Co_{20}Ni_{80}$ particles were prepared, in the micrometer and submicrometer size range, by the polyol process. X-ray diffraction showed crystalline particles with a fcc structure. From electron probe microanalysis a fairly homogeneous distribution of both elements within each particle was observed. Microwave properties of metal particles dielectric matrix composites were studied in the 0.1–18 GHz range for different filler concentrations. The intrinsic permeability of the metal powders was obtained using the Bruggeman effective medium theory. The control of the particle size allowed the study of its effect upon dynamic permeability. Whereas micrometer size particle permeability presents a single resonance band at low frequencies which can be correlated to the low magnetocrystalline anisotropy of the particles, submicrometer size particle permeability exhibits an original behavior, never reported before, with several resonance bands.

I. INTRODUCTION

One way to make electromagnetic absorbers is to disperse ferromagnetic powders in an insulating matrix. Previous studies[1,2] showed that the microwave properties of such materials depend on particle shape and granulometry. Spherical particles present an advantage in minimizing permittivity level of the composites whereas the maximum of the imaginary part of permeability decreases when the particle size increases.

The polyol process is a method for preparing fine metallic powders which has been developed over the last few years.[3] This process which applies to cobalt and nickel allowed the elaboration of spherical and monodisperse particles with an accurate control of the particle mean diameter in the micrometer and submicrometer size range.[4] Our aim was to adapt the polyol process to the preparation of fine bimetallic cobalt-nickel particles. We focused the study on the $Co_{20}Ni_{80}$ composition which corresponds to low magnetocrystalline anisotropy in bulk alloys. Composites were made with the $Co_{20}Ni_{80}$ powders and their microwave permeability was measured.

II. EXPERIMENTAL METHODS

A. General description of the polyol process

Finely divided metal powders (Co,Ni,Cu,Pb, precious metals) are obtained by precipitation in hot liquid polyols. The reaction proceeds according to the following scheme: progressive dissolution of a suitable powdered metallic compound (precursor), reduction of the dissolved species by the polyol itself; nucleation and growth of the metal particles from the solution.[4]

In standard conditions the metallic nuclei are formed spontaneously (homogeneous nucleation). However this homogeneous nucleation can be replaced by an heterogeneous one by the formation of seed particles acting as foreign nuclei. More generally, the kinetic control of the nucleation and growth steps allows the synthesis of powders made up of particles with a well-defined shape, a controlled size, and a narrow size distribution.[5]

B. Preparation of $Co_{20}Ni_{80}$ particles

CoNi particles were prepared as follows: cobalt and nickel acetate hydrate were used as precursors, they were dissolved in a NaOH-ethylene glycol solution; the NaOH concentration was in the range 0.5–2 mol dm^{-3}, the precursor concentration was typically 0.2 mol dm^{-3} with a Co/Ni molar ratio: 20/80. The solution was stirred and heated up to 195 °C; the water and the volatile organic products of the reaction were distilled off while the polyol was refluxed. After a few hours the metal was quantitatively precipitated from the solution, the metal particles were recovered by centrifugation, washed with ethanol, and dried in air at 50 °C. The use of a basic solution of ethylene glycol shortens the reaction time and allows one to obtain, by homogeneous nucleation, monodisperse particles more easily. CoNi particles were also obtained by heterogeneous nucleation, the seed particles being tiny metallic silver particles formed *in situ* by the admixture of silver nitrate dissolved in ethylene glycol to the original reactant solution.

C. Characterization techniques

Phase analysis was performed by x-ray diffraction (XRD) using a C.G.R. x-ray powder diffractometer (Co $K\alpha$ radiation). The form and the size of metallic particles were determined by scanning electron microscopy (Philips 505). The average diameter and the standard deviation were estimated from image analysis of ~250 particles. The distribution of the two elements within isolated particles was studied by energy dispersive x-ray spectrometry (EDS), the microprobe being associated with a scanning transmission electron microscope (STEM). Magnetization saturation of powders and composites were measured by a vibrating sample magnetometer.

Particles were randomly dispersed in epoxy resin with concentration ranging from 30% to 50% by volume. Particle concentrations were determined by saturation magnetization measurements. Microwave properties of composites were measured in 0.1–18 GHz frequency range with an APC7 coaxial line associated with a network analyzer.

III. RESULTS AND DISCUSSION

$Co_{20}Ni_{80}$ powders obtained are well crystallized as evidenced by XRD (Fig. 1). The pattern can be indexed as a fcc lattice. It is well known[6] that nickel crystallizes with a fcc lattice (a=0.352 38 nm) and that there are two cobalt polymorphs: Co(α) with a hexagonal lattice and Co(ϵ) with a fcc one (a=0.354 47 nm). From Fig. 1 it can be inferred that there is no Co(α) polymorph but it is not possible to ascertain if $Co_{20}Ni_{80}$ powders are solid solutions or mixtures of cobalt and nickels fcc phases owing to the very close values of the cell parameters of these two phases.

Typical examples of $Co_{20}Ni_{80}$ powders obtained by the polyol process are provided by the scanning electron microscopy micrographs in Fig. 2. The first sample [Fig. 2(a)] was obtained by homogeneous nucleation from a 2 mol dm^{-3} NaOH-ethylene glycol solution. The particles are quasi-spherical with a mean diameter d_m=1.4 μm, a narrow size distribution (standard deviation σ=0.2 μm), and a low degree of agglomeration. The second sample [Fig. 2(b)] was obtained by heterogenous nucleation (Ag/Co+Ni atomic ratio: 5×10^{-5}). The particles are smaller (d_m=0.33 μm, σ=0.05 μm). Heterogeneous nucleation gives particles in the submicrometer size range and allows their mean diameter to be controlled by varying the amount of $AgNO_3$ used to form the silver seed particles.

The Co/Ni ratio in the final metal powder is the same as in the starting solution: 20/80. Chemical analysis shows that the main impurities are carbon and oxygen at a level lower than 0.5% by weight.

The global composition $Co_{20}Ni_{80}$ is found again for each isolated particle analyzed by energy dispersive spectroscopy

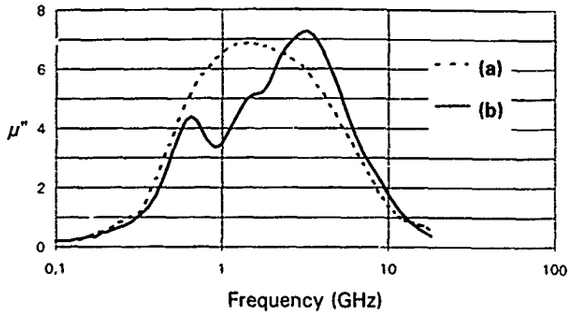

FIG. 5. Comparison of $\mu_i''(\omega)$ for two $Co_{20}Ni_{80}$ powders of different granulometry (a) d_m=1.5 μm; (b) d_m=0.3 μm.

(EDS). Moreover, the distribution of each element within one particle appears fairly homogeneous (Fig. 3). However, a small concentration gradient can be observed from the heart to the outer part of the particle, the heart being slightly poorer in nickel than the outer part. This difference in composition which cannot be estimated quantitatively is related to different kinetics of reduction and precipitation for the two metals.

Saturation magnetization values were typically 75 and 72 emu/g for micrometer and submicrometer size particles, respectively. These values are very close to bulk metal value and corroborate the low level of impurities.

Dynamic permeability of $Co_{20}Ni_{80}$ powders-epoxy resin composite materials presents a resonance in the 0.1–18 GHz range. The composite permeability $\mu_e(\omega)$ depends on the ferromagnetic particle concentration. It has been shown recently[1,2] that a homogenization law adapted from Bruggeman theory[7] can describe this effect. According to these studies intrinsic permeability $\mu_i(\omega)$ of our powders was inferred from composite permeability measurements. For a given powder the values $\mu_i(\omega)$, computed from $\mu_e(\omega)$ measurements for several composites of different volume fraction, were found weakly dependent on the volume fraction. Thus, $\mu_i(\omega)$ may be considered as an intrinsic property of the powders.

Figure 4 shows $\mu_i(\omega)$ for $Co_{20}Ni_{80}$, Ni, and Co powders of comparable granulometry in the micrometer range. The maximum of $\mu_i''(\omega)$ appears at 1.4, 1.8, and 6.5 GHz for $Co_{20}Ni_{80}$, Ni and Co powders, respectively. The shift of resonance bands observed with chemical composition can be correlated to a variation of the magnetocrystalline anisotropy. In the case of a monodomain and monocrystalline sphere Kittel[8] linked the resonance frequency to the magnetocrystalline anisotropy field: $f_r=(\gamma/2\pi)H_a$. H_a values computed from resonance frequency measurements by Kittel formula present a variation with chemical composition in qualitative agreement with the variation of the anisotropy constants reported for Ni, Co, and NiCo alloys.[9]

Effect of particle size upon microwave permeability were studied by Berthault *et al.* with permalloy particles in the 4–16 μm size range.[1] It was shown that the variation of the dynamic permeability with granulometry could be interpreted by the eddy current effects. We present here a comparison between $\mu_i''(\omega)$ for two $Co_{20}Ni_{80}$ samples of different granulometries in the micrometer and submicrometer size range (Fig. 5). Whereas micrometer size particles (d_m=1.5 μm) exhibit a permeability curve with a single resonance band the submicrometer size particles (d_m=0.3 μm) exhibit an original behavior with three resonance bands. This unexpected phenomena for particles exhibiting uniformity of shape, size, and composition, can be clearly related to their small size. Actually, we have observed a similar behavior with ferromagnetic fine particles of different composition but with a similar mean diameter. Results will be reported elsewhere.[10] To our knowledge such a phenomena has never been reported before. It can be tentatively related either to the magnetic domain structure of small particles or to a surface effect similar to the effect responsible for spin wave resonance in thin ferromagnetic films.

IV. CONCLUSION

The intrinsic permeability $\mu_i''(\omega)$ of $Co_{20}Ni_{80}$ particles having controlled and well-defined morphological characteristics have been measured. A size effect has been clearly evidenced. For particles in the micronic size range a single resonance band has been observed at low frequency as expected for a material with a low magnetocrystalline energy. Particles in the submicron range exhibit an original behavior, never reported before, with several resonance bands.

Coercivity of Fe-SiO_2 nanocomposite materials prepared by ball milling

Anit K. Giri, C. de Julián, and J. M. González
Departamento de Propiedades Ópticas, Magnéticas y de Transporte, Instituto de Ciencia de Materiales de Madrid—CSIC, c/Serrano 144, 28006 Madrid, Spain

Samples containing Fe nanoparticles dispersed in SiO_2 were prepared by high energy ball milling. We have studied the variation with the milling time of both the saturation magnetization and the coercive force of these samples. The rapid increase of coercivity with the decrease of temperature observed in the low temperature range suggested the presence of superparamagnetic particles in the samples. Nevertheless, our experimental data were in poor agreement with the well-known $T^{1/2}$ law describing the coercive force of superparamagnetic particles. Coercivities as high as 540 and 850 Oe were obtained for samples with $x=0.3$ at room temperature and at 1.7 K, respectively. From the analysis of the temperature dependence of the saturation magnetization the spin wave stiffness constant was obtained. This quantity evidenced the enhancement of the thermal demagnetization associated with the reduction in size.

I. INTRODUCTION

The high coercivity values (up to 1 kOe) measured for Fe nanoparticles embedded in insulating or conducting matrix have induced a lot of research work on the preparation and characterization of this kind of nanocomposite materials.[1] Most of these materials were prepared by sputtering technique.[1] Although some bulk preparational methods such as high energy ball milling have been successfully used to prepare nanostructured materials, only a few results have been reported regarding the properties of metal nanoparticles prepared by this technique. Recently, using high energy ball milling, Ambrose *et al.*[2] prepared Fe nanoparticles in an Al_2O_3 matrix and obtained coercivities of 600 Oe at 5 K and 230 Oe at room temperature. In this paper we report on the preparation and detailed characterization of the magnetic properties of Fe-SiO_2 nanocomposities prepared by high energy ball milling.

II. PREPARATION OF SAMPLES AND EXPERIMENTAL TECHNIQUES

Samples of the series $Fe_x(SiO_2)_{1-x}$ with Fe volume fraction x in the range $0.1 \leq x \leq 0.65$ were prepared by high energy ball milling. The starting materials consisted of -325 mesh Fe powders and silica gel prepared by the conventional method[3] of hydrolysis and polycondensation of silicon tetraethoxide in water and ethanol solutions under acidic medium. The gel was dried in air at 333 K for 15 days. The amorphous nature of silica gel was confirmed by x-ray diffraction (XRD). Appropriate amounts of Fe and SiO_2 gel were placed in a hardened stainless steel vial with four hardened stainless steel balls so that the ratio of the weight of the balls to that of the powder was 14:1. The vial was sealed in an inert atmosphere to prevent oxidation. These materials were then milled for up to 70 h. The as-milled samples were characterized by XRD and transmission electron microscopy (TEM). Magnetic measurements were carried out in pressed powder samples by means of vibrating sample magnetometer, superconducting quantum interference device, and an ac susceptometer.

III. RESULTS AND DISCUSSIONS

XRD patterns of the samples revealed along with the presence of Fe peaks that the samples were free from the oxides of Fe down to the resolution of the technique. The average Fe grain size was evaluated from the width at half-maximum of the (110) reflection after making the correction due to the instrumental broadening. Figure 1 shows the milling time dependence of the average grain size as measured in the sample with $x=0.3$. From Fig. 1 a rapid decrease of the average grain size down to a saturation value of 9 nm is apparent. In the inset of Fig. 1 we plotted the saturation (70 h milling) average grain size of samples as a function of compositions. Particle size and dispersion were examined by TEM. Figure 2 presents a picture taken in a $x=0.3$ sample (milled for 70 h). From this picture it was possible to evaluate the average particle size as 11 ± 2 nm and to observe the excellent degree of dispersion of the particles. For all the samples comparison of the average grain and particle size showed reasonable agreement and led us to identify both parameters. In Fig. 3 we present, for the different compositions studied, the variation of the magnetization with the milling time corresponding to an applied field of 10 kOe. In all the cases the magnetization decreased down to a composition-dependent saturation value. The milling time dependence of the as-milled room temperature coercive force is presented in Fig. 4. This parameter increased with milling

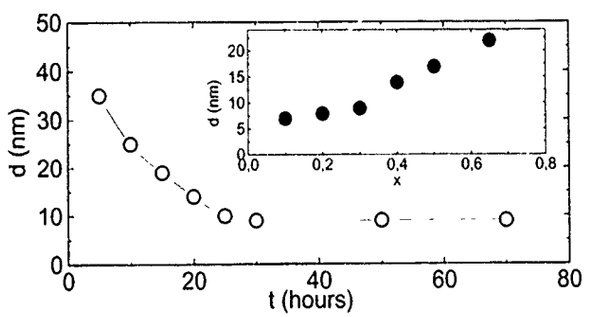

FIG. 1. Typical plot of the average grain size (d) vs the milling time (t) for the $Fe_{0.3}(SiO_2)_{0.7}$ sample. In the inset a plot of d vs Fe volume fraction (x) (samples milled for 70 h) is presented.

time up to a maximum (saturation) value which was achieved after 30 h of milling. The correlation of these results with the milling time evolution of the particle size allowed us to conclude that both the decrease in saturation magnetization and the increase of coercive force were originated by the reduction of particle size. Regarding the first quantity this correlation suggests the presence of superparamagnetic particles in the samples. As for the coercive force the values we obtained are larger than the anisotropy field of Fe which evidences that an interaction different from the bulk magnetocrystalline anisotropy rules magnetization reversal. The inset in Fig. 4 presents the compositional evolution of the coercive force of samples milled for 70 h. Interestingly a maximum is obtained for $x=0.3$ which evidences the occurrence of interparticle interaction since this value is clearly lower than the percolation concentration.

In Fig. 5(a) we present results corresponding to the temperature dependence of the magnetic moment, m, for the sample with $x=0.3$ milled for 70 h. These results represent the behavior of all the samples studied. The magnetic moment was measured after zero field cooling (ZFC) and field cooling (FC) with two different applied fields (20 kOe and 75 Oe). Our data evidence the presence of a fraction of superparamagnetic particles in the samples. Nevertheless, magnetometric measurements did not allow us to distinguish any variation of the blocking temperature either with the composition of the samples or with the milling time (blocking temperatures close to 4 K were observed in all the cases). In order to clarify this point we measured the temperature dependence of the ac (1 kHz) susceptibility [see Fig. 5(b) where results corresponding to $x=0.3$ milled for 70 h are presented]. From these results we obtained the blocking temperature, T_B, plotted in the inset of Fig. 5(b). The values obtained are in quantitative agreement with the magnetometric results, considering the typical measuring time characteristic of both techniques. We can conclude that the average volume of the superparamagnetic fraction of the samples was not influenced very much by the preparation parameters. Considering the evolution with these parameters (and also with the composition) of the average particle size (XRD and TEM) we can conclude that the superparamagnetic particles corresponded to the tails of the size distribution and therefore were only small minority. Going back to thermal evolution of the magnetic moment of the samples [Fig. 5(a)] it is worth

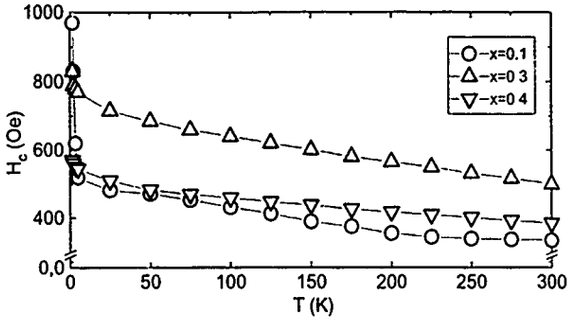

FIG. 7. Plot of coercive force (H_c) vs temperature (T)

pointing out that the increase in magnetic moment with the increase of temperature observed in the low field curves can be understood as corresponding to a decrease of the magnetic anisotropy with the increase of temperature, which originates the alignment with the field of the moments of a larger number of particles. From the high field $m(T)$ curve it was possible to obtain the thermal evolution of the magnetic moment using Bloch's law given by $m(T)=m(0)(1-BT^{3/2})$ where B is spin wave stiffness constant, $m(T)$ and $m(0)$ are the moments at temperatures T and 0 K, respectively. For that purpose we considered a temperature range clearly above the blocking temperature of the superparamagnetic particles. Our results are presented in Fig. 6 where we have plotted the values of B obtained from the fits of the straight line plots of $m(T)/m(0)$ vs $T^{3/2}$ as a function of the composition and average grain size (inset, for the samples milled for 70 h). The occurrence of the enhanced thermal demagnetization in the small particles (compared to the equivalent bulk process) is apparent from Fig. 6. Also it is interesting to note that our B values are of the order of those obtained in samples of similar composites prepared by sputtering.[1] The enhanced demagnetization results from the influence of size in the electronic properties of the materials and has been related to the occurrence of a cutoff frequency in the spin wave spectrum.[1]

The temperature dependence of the coercive force (Fig. 7) also suggested the presence of superparamagnetic particles to which the rapid increase of this parameter with the decrease of temperature could be ascribed. This effect is more clear for the sample with $x=0.1$ where the coercive force increased up to 970 Oe at 1.7 K. The temperature dependence of the coercive force of our samples does not obey the $T^{1/2}$ law[4] which can be ascribed to the occurrence of interparticle dipolar interactions (evidenced by the compositional dependence of the coercive force).

IV. CONCLUSIONS

We have studied the effect of particle size on the magnetization and coercive force of Fe nanoparticles dispersed in silica-gel matrix prepared by ball milling. Reduction in particle size originated a decrease of the saturation magnetization and an increase in both coercivity and spin wave stiffness constant. It is worth remarking that our room temperature coercive force values were of the same order as those obtained in Fe-SiO_2 nanocomposites prepared by sputtering.[1]

^{59}Co spin-echo nuclear magnetic resonance (NMR) experiments have been carried out at 1.3 and 4.2 K, for external magnetic fields up to 9 kOe, in order to study 6–10 Å, single-domain Co clusters isolated inside zeolite NaY supercages. The magnetic behavior is characterized by a superparamagnetic blocking temperature, relaxation time behavior for increasing and decreasing fields, and a dependence on the magnetic history. The observed NMR spectra are broad with structural features characteristic of both fcc- and hcp-like short-range order. Unlike bulk materials, the application of fields up to 9 kOe causes a dramatic increase in the signal intensity. The results are discussed in terms of the particle-size distribution and crystalline anisotropy, and their relationship to the temperature and field dependence of the superparamagnetic/ferromagnetic behavior.

I. INTRODUCTION

In an earlier work, it was demonstrated how information concerning the size and location of Co clusters in zeolite NaY could be obtained by ^{59}Co spin-echo NMR measurements.[1] In particular, the superparamagnetic blocking temperature was used to obtain an estimate for the average Co cluster size in Co/NaY samples which were prepared using different thermal treatments. Also, a selective chemical treatment with triphenylphosphine was used to determine the location of the clusters. It was found that preparation of Co/NaY under "mild" conditions (decomposition and annealing carried out at 200 °C) resulted in the production of Co clusters with an average diameter of 6–10 Å inside the NaY supercages, while preparation of Co/NaY under "extreme" conditions (decomposition and annealing carried out at 500 °C) resulted in larger clusters outside the NaY cages.

This work focused on the interested magnetic behavior which characterizes the 6–10 Å, single-domain Co clusters isolated inside the zeolite NaY supercages.[1] In order to study this behavior, detailed ^{59}Co spin-echo NMR experiments have been carried out at 1.3 and 4.2 K, for magnetic fields up to 9 kOe. The observed spectra are broad with a primary peak and a secondary peak characteristic of fcc- and hcp-like short-range order, respectively. Unlike bulk materials, the application of a magnetic field causes a dramatic increase in the NMR signal intensity which is reversible. As described below, in addition to a superparamagnetic blocking temperature which occurs within this temperature range, the magnetic behavior is characterized by relaxation time effects for increasing and decreasing fields, and a dependence on the magnetic history. [More precisely, the superparamagnetic relaxation is blocked in the time window of the NMR measurement (5 ns).] These results are discussed in terms of the particle-size distribution and crystalline anisotropy, and their relationship to the temperature and field dependence of the superparamagnetic/ferromagnetic behavior.

II. EXPERIMENTAL APPARATUS AND PROCEDURE

Zeolite NaY (Linde LZY-52) was dehydrated at 500 °C for 2 h in Ar, followed by $Co_2(CO)_8$ vapor absorption at room temperature in CO atmosphere. The yellow colored sample was then thermally treated at 200 °C for 1 h in H_2 to remove the carbonyl ligands. The adsorbed hydrogen was subsequently removed by purging with Ar gas at 200 °C for 1 h. The Co/NaY sample was evacuated and then sealed in a Pyrex tube. The final Co loading was approximately 1 wt %.

Spin-echo NMR measurements were carried out on a commercial Matec model 7700 pulse modulator and receiver (mainframe), with matching Matec model 765 rf pulsed oscillator plug in (90–300 MHz and 500 W). The spectrometer system was matched with a Varian model V3400 electromagnet and Fieldial regulated power supply capable of fields up to 9 kOe. Operation at liquid helium temperatures was possible with a conventional glass double-dewar system and pumping system. The measured echo amplitude was normalized and divided by the first power of the frequency in the usual manner. Additional details concerning the sample preparation procedure, pulsed NMR apparatus, data acquisition, and spectral analysis can be found in the previous report.[1]

III. RESULTS AND ANALYSIS

Figure 1 shows the ^{59}Co spin-echo NMR spectrum obtained from the Co/NaY sample described above at 4.2 and 1.3 K, for zero external magnetic field. As illustrated in Fig. 1, no NMR signal was observed at 4.2 K (solid diamonds); however, as the temperature was lowered to 1.3 K, a broad spectrum with a central peak at 212 MHz dramatically appeared (open circles). A secondary peak in the spectrum exists at approximately 222 MHz. As indicated in the earlier work,[1] a consideration of the signal-to-noise ratio indicates that this is indeed the result of a blocking of the superparamagnetic relaxation, and not just an increase in the signal

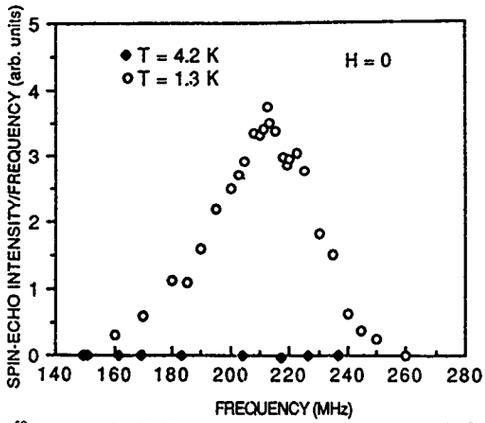

FIG. 1. ^{59}Co spin-echo NMR spectra obtained for zero magnetic field from 6 to 10 Å clusters inside zeolite NaY supercages; solid diamonds, T=4.2 K (no signal observed); open circles, T=1.3 K. The sample was initially cooled from room temperature to 4.2 K and then 1.3 K in zero field.

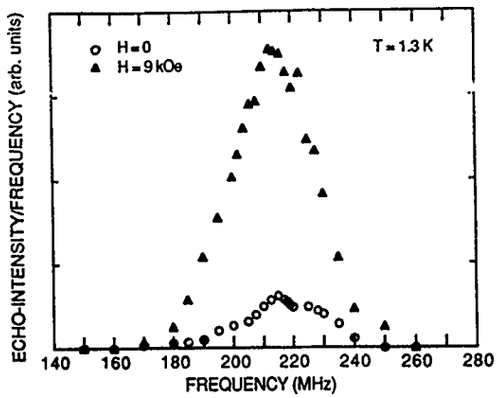

FIG. 2. ^{59}Co spin-echo NMR spectra obtained at 1.3 K from 6 to 10 Å Co clusters inside zeolite NaY supercages; solid triangles, H=9 kOe; open circles, H=0. The sample was initially cooled from room temperature to 1.3 K in zero field.

intensity due to the Boltzmann factor. The existence of a superparamagnetic blocking temperature in this temperature range along with an approximate value for the crystalline anisotropy for small Co particles resulted in an estimate of the average cluster diameter between 6 and 10 Å.[1] This is supported by the fact that a chemical treatment with triphenylphosphine does not change the observed spectrum, indicating that the clusters must be protected by being located inside the NaY supercages. Consequently, an upper limit of 12 Å, which is the diameter of the supercages, is established for the clusters. The principal peak at 212 MHz and secondary peak at 222 MHz are characteristic of fcc- and hcp-like short-range order, respectively. These values are lower than the corresponding bulk cobalt values by about 7 MHz. This tentative assignment seems reasonable in view of a similar spectrum which was obtained from a Co/NaY sample that was prepared under "extreme" conditions (decomposition and annealing carried out at 500 °C), resulting in larger clusters outside of the NaY cages.[1] The larger Co clusters were characterized by a spectrum which was similar in shape to that presented in Fig. 1, although about 25% narrower. The two peak frequencies were quite close to the bulk values.

Figure 2 shows the ^{59}Co spin-echo NMR spectrum obtained from the Co/NaY sample at 1.3 K for external magnetic fields of H=9 kOe (solid triangles) and H=0 (open circles). The spectra illustrated in Fig. 2 were obtained by cooling the sample in zero field from room temperature to 1.3 K, measuring the H=0 spectrum, increasing the field to H=9 kOe, and then remeasuring the spectrum. It is significant to note that, unlike bulk materials, the application of magnetic fields up to 9 kOe causes a dramatic increase in the signal intensity which is reversible. This is illustrated in Fig. 3 which shows the spin-echo intensity (echo height) obtained at 1.3 K and 215 MHz as a function of the external magnetic field. The open circles are for increasing field and the solid triangles represent decreasing field. As discussed below, the variation of the NMR signal intensity with magnetic field is also characterized by (different) relaxation time behavior for both increasing and decreasing fields. The points illustrated in Fig. 3 were measured for times that were long compared to the corresponding relaxation time, and hence, can be considered as equilibrium values. Further, although it is not shown in either Figs. 1 and 2, the application of an external field of 9 kOe causes a reappearance of the NMR signal at 4.2 K. Finally, a careful comparison of the two spectra illustrated in Fig. 2 shows that the application of an external field of 9 kOe causes a downward shift of the spectrum by 2.5 ±0.5 MHz. Based on an analysis carried out by Gossard *et al.*[2] for single-domain Co particles, the shift observed here is about one-third that predicted from bulk behavior.

Figure 4 shows the ^{59}Co spin-echo intensity (echo height) obtained for the Co/NaY sample at 1.3 K and 210 MHz as a function of time for both increasing and decreasing external field. Here, the sample was first cooled in zero field from room temperature to 1.3 K. The field was quickly increased to 9 kOe and the time dependence of the signal intensity was measured (open circles). After coming to equilibrium at 9 kOe, the field was quickly reduced to 0 and the signal intensity was again measured as a function of time (solid triangles). Fitting the data in Fig. 4 to single exponentials resulted in values of 47 and 16 s for the relaxation time

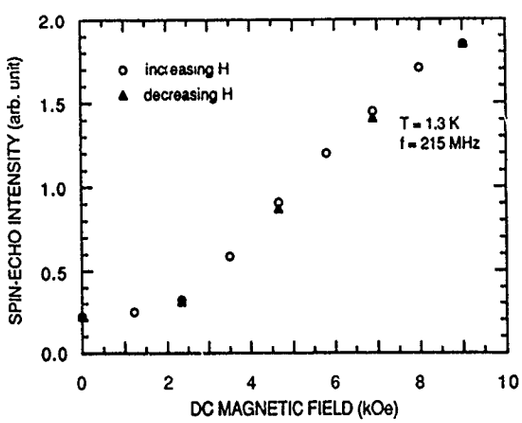

FIG. 3. ^{59}Co spin-echo NMR intensity (echo height) obtained at 1.3 K and 215 MHz from 6 to 10 Å Co clusters inside zeolite NaY supercages vs external magnetic field, H, in kOe; open circles, increasing field; solid triangles, decreasing field. The data points are characteristic of the equilibrium values.

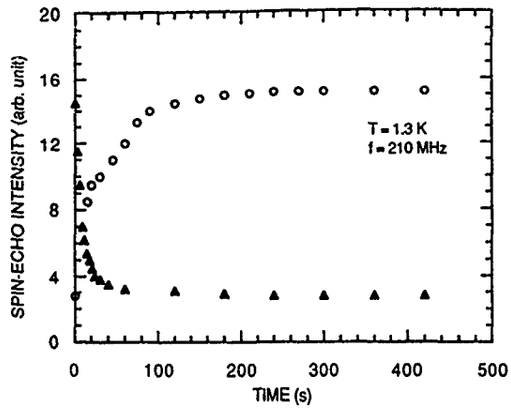

FIG. 4. ^{59}Co spin-echo NMR intensity (echo height) obtained at 1.3 K and 210 MHz from 6 to 10 Å Co clusters inside zeolite NaY supercages versus time, t, in s: open circles, field quickly increased from 0 to 9 kOe; solid triangles, field quickly decreased from 9 kOe to 0. The sample was initially cooled from room temperature to 1.3 K in zero field.

at 1.3 K characteristic of increasing and decreasing field, respectively. The corresponding values at 4.2 K were significantly smaller.

IV. DISCUSSION AND SUMMARY

The magnetic behavior of the small, single-domain Co clusters isolated inside zeolite NaY supercages is characterized by a superparamagnetic blocking temperature which occurs at liquid helium temperatures, relaxation time behavior for increasing and decreasing fields, and a dependence on the magnetic history. The ^{59}Co spin-echo NMR spectra are broad with a central peak at 212 MHz and a secondary peak at 222 MHz, which are attributed to fcc- and hcp-like short-range order, respectively. The application of fields up to 9 kOe results in a downward frequency shift of the spectrum which is approximately one-third that expected for bulk, single-domain Co. For bulk multidomain ferromagnetic materials, the application of an external magnetic field causes a decrease in the NMR signal intensity due to the disappearance of the domain walls. The dramatic increase in NMR signal intensity with applied field that is observed here for the small Co clusters is worthy of special mention.

For zero applied field, a single-domain ferromagnetic particle is magnetized along some easy crystallographic direction (for fcc cobalt, this is the [111] direction). The energy required to reverse the direction of the magnetization relative to the easy direction may be written as K_0V, where K_c is the crystalline anisotropy constant and V is the volume of the particle. (It is assumed that the particles are spherical and not stressed by external forces, so the shape and strain anisotropy can be neglected.) The single-domain particles will have thermal fluctuations in the magnetization direction and, at a given temperature T, there exists a finite probability that the magnetization vector will reverse its direction and the time that describes how rapidly this occurs may be written

$$\tau=(a\nu)^{-1}\exp(K_cV/k_BT), \tag{1}$$

where a is a geometrical factor and k_B is the Boltzmann constant.[3] The frequency factor ν is the Larmor frequency of the magnetization vector M_s in an effective field $H_{\text{eff}}=K_c/M_s$. The behavior of a magnetic particle depends on the experimental observation time τ_{obs}. For $\tau_{\text{obs}}\gg\tau$, the particle will appear to be superparamagnetic, while for $\tau_{\text{obs}}\ll\tau$, the superparamagnetic relaxation will be blocked and the particle will show ferromagnetic behavior. For the present NMR observations, $\tau_{\text{obs}}=1/\nu_L\approx5\times10^{-9}$ s, where ν_L is the resonance frequency (or Larmor frequency of the nuclear moment about the magnetic field at the nuclear site). Thus, if $1/\nu_L\ll\tau$ (i.e., ferromagnetic behavior), the nuclear Zeeman splitting caused by the hyperfine field at the nuclear site will be observed. Conversely, for $1/\nu_L\gg\tau$ (i.e., superparamagnetic behavior), the Zeeman splitting and, consequently, the NMR signal will disappear. A superparamagnetic blocking temperature can be defined as $T_B=K_cV/k_B$. Kündig *et al.*[4] have used the Mössbauer effect to study small particles of α-Fe_2O_3 and β-Co. They find that as the particles transform from ferromagnetic to superparamagnetic behavior (by varying the particle size or the temperature), the Mössbauer spectra shows a decrease in the Zeeman structure with a corresponding increase in the quadrupole structure. The relaxation time described above by Eq. (1) can also be influenced by the application of an external magnetic field, H. In this case, there will be a magnetic energy M_sHV in addition to the anisotropy energy K_cV which will contribute to the superparamagnetic blocking. This will cause more of the (smaller) particles to exhibit ferromagnetic behavior and, hence, contribute to the NMR signal intensity. Further, the application of an external magnetic field will cause the cluster moments to reorient such that the internal fields at the Co nuclei become more aligned perpendicular to the rf excitation field of the NMR spectrometer. Consequently, more nuclei undergo the appropriate transitions and the signal intensity is increased. It is even likely that the clusters are free to reorient such that the easy axes are aligned with the magnetic field in equilibrium. The change in magnetic field behavior shown in Fig. 3 provides an estimate for the anisotropy field of 2 kOe. For external magnetic fields in excess of the 9 kOe used here, the NMR signal intensity may eventually start to decrease due to a decrease in the domain enhancement factor. Work is currently in progress in an attempt to extract a quantitative description of the cluster size distribution from the field dependence of the NMR signal intensity.

Perfluorocyclobutane aromatic ether polymers (PFCB) are being researched as planarization materials for alternative magnetic media substrates allowing smoother surfaces for lower head flying recording. The results of current work reported herein have shown that PFCB can be used to affect surfaces on canasite with R_A's less than 2 nm. In addition, magnetic media can be produced of a quality comparative to that obtained on standard NiP-coated Al as well as that produced on regular canasite with equivalent coercivities at about 1500–1600 Oe and squarenesses of 0.8 or better. In addition to the above magnetic properties the recording performance was excellent with signal-to-noise ratios of planarized media 3.5 dB higher than that on regular canasite.

I. INTRODUCTION

Alternative or nonaluminum magnetic media substrates have been the topic of numerous discussions as well as seminar series as presented by IDEMA[1] and the subject of a recent presentation by one of these authors at the Head and Media Technology Conference (1992) during Comdisk.[2] In addition to these presentations two recent publications by Perettie *et al.*[3,4] have focused on the use of benzocyclobutene (BCB) as a planarization resin for aluminum substrates with conceptually the same idea; the difference being that the BCB work required the coated substrates be cured in an inert atmosphere. A continuation of this effort is presented here with the resin being PFCB.

Perfluorocyclobutane aromatic ether polymers (PFCB) are being researched as planarization materials for alternative magnetic media substrates allowing smoother surfaces for lower head flying recording. Canasite is a glass ceramic material, and is being used as an alternative substrate for advanced magnetic thin film media. Even though the height of the automatically textured surface peaks of polished canasite are uniform, the large peak-to-valley heights are not. However, PFCB-coated canasite substrates have small and uniform peak-to-valley heights which should improve durability and recording performance. The properties of the materials and the surface roughness of the PFCB-coated canasite substrates are being reported here. The magnetic and recording performance of the thin film media deposited on PFCB-planarized substrates are compared with that on regular canasite.

II. EXPERIMENT

A. Substrates

The surface morphology of the substrates was characterized with an atomic force microscope (AFM).

B. Magnetic media

The deposition conditions of the C/CoCr (12 at. %) Ta (2 at. %)/Cr films are shown with Table I. The magnetic properties of the thin film media were measured using a digital vibrating sample magnetometer (VSM). The recording performance of the thin film media were tested using thin film heads with 0.4 μm gap width and 16.5 μm track width. The head wrote and read back an all ones pattern at a relative linear velocity of 10 m/s. The flying height was approximately 0.2 μm. The average signal output amplitude was determined by averaging digitized wave forms. The medium noise was obtained by subtracting the integrated noise power of the recording system from the total integrated noise power over a 20 MHz bandwidth.

TABLE I. Deposition conditions of C/CoCrTa/Cr thin film media.

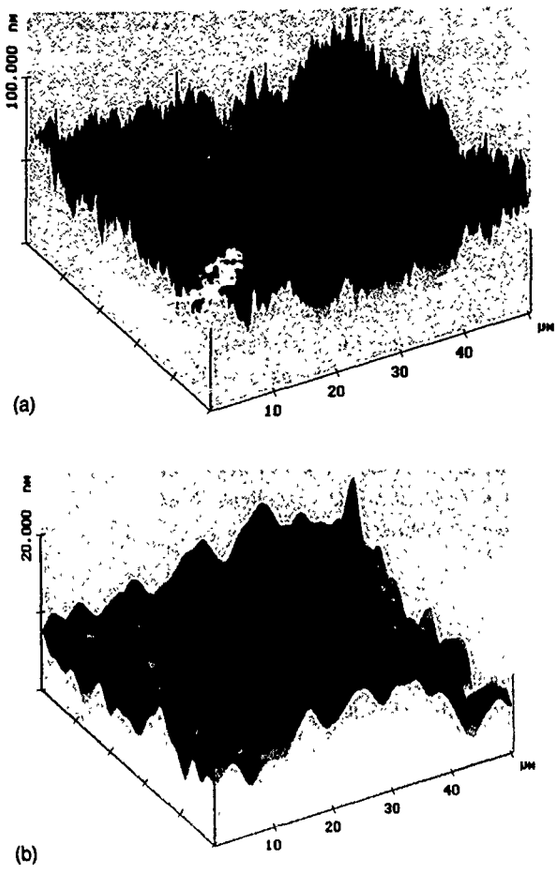

FIG. 1. Surface profile of regular canasite and PFCB-planarized canasite substrates measured with AFM.

III. RESULTS

Figure 1 shows the comparison of the surface topography of regular canasite and PFCB-planarized canasite substrates measured with AFM. Table II shows the calculated roughness of the two types of substrates using the data from AFM with R_A showing mean roughness and R_{max} indicating maximum height which is the difference in height between the highest and lowest points on the profile relative to the mean line over the length of the profile. It is obvious that the surface of PFCB-planarized canasite substrates is much smoother than that of regular canasite substrates.

The effect of sputtering parameters on magnetic properties of CoCrTa/Cr films deposited on NiP/Al substrates has been intensively investigated. For example, it was reported that in-plane coercivity increases and in-planes decrease as substrate temperature increases.[5] The same relative result is true for the CoCrTa/Cr films deposited on PFCB-planarized substrates. In addition, C/CoCrTa/Cr films were deposited on

pure canasite and PFCB-coated canasite substrates under identical deposition conditions but at different experimental runs. The magnetic properties of the films deposited on canasite substrates are not subject to the effect of the possible outgassing from PFCB polymer. The magnetic properties of the CoCrTa/Cr films are shown below in Table III.

The coercivity of the magnetic files deposited on PFCB-coated substrates is higher than those of films deposited on canasite substrates as shown above. Figure 2 also shows the comparison of signal-to-media noise ratio of C/CoCrTa/Cr films deposited at identical conditions on canasite and PFCB-coated canasite substrates, respectively.

The deposition conditions of these samples are shown in Table I. The preheat temperature was 200 °C with the magnetic properties of the samples shown in Table III. The media deposited on PFCB-coated canasite substrates exhibit about

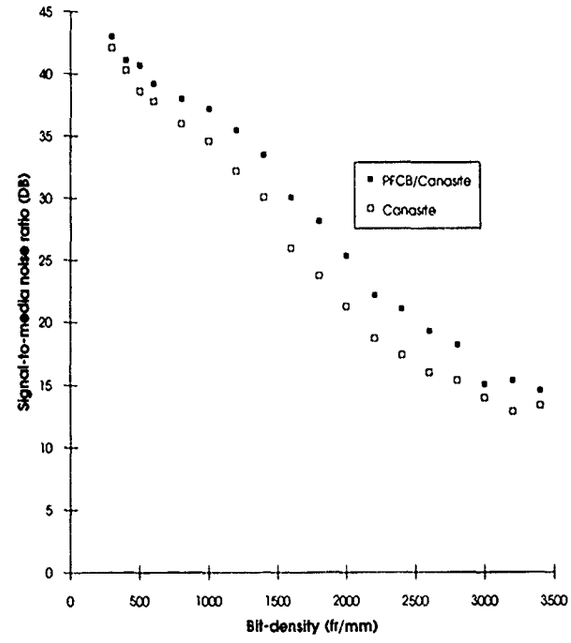

FIG. 2. Comparison of signal-to-media noise ratio of C/CoCrTa/Cr films deposited on canasite and PFCB-coated canasite substrates, respectively. (Preheat temperature is 200 °C.)

3.5 dB higher signal-to-media noise ratio than the films on canasite substrates. The films deposited at 300 °C also show the similar results.

IV. CONCLUSION

PFCB polymer films can be used to affect a surface smooth on canasite with R_A's less than 2 nm in 50 μm scan size. CoCrTa/Cr thin film media deposited on PFCB-coated canasite exhibited higher coercivity and a 3.5 dB higher signal-to-noise ratio over a wide range of recording densities in comparison to media deposited on regular canasite substrates.

Anomalous perpendicular magnetoanisotropy in Mn_4N films on Si(100)

K. M. Ching, W. D. Chang, T. S. Chin, and J. G. Duh

H. C. Ku
Department of Physics, Tsing Hua University, Hsinchu, Taiwan 30043, Republic of China

Ferrimagnetic Mn_4N films were deposited on Si (100) substrate by dc reactive magnetron sputtering from sintered Mn target. Highly (002) textured Mn_4N ordered phase is formed *in situ* at studied substrate temperatures of 150–250 °C without further annealing. Anomalous perpendicular magnetoanisotropy exists in these face-centered cubic films with larger coercivity measured perpendicular to the film (2000–3000 Oe) than that parallel (1100–1300 Oe), as is the remanence. Coercivity in either direction decreases, while the saturation flux density (from 240 to 610 G) increases with increasing substrate temperature. The anomalous perpendicular magnetoanisotropy is attributed to (1) the stress-induced anisotropy due to in-plane tensile stress coupled with a reverse magnetostriction, and (2) the shape anisotropy due to columnar grain structure.

I. INTRODUCTION

In 1932 Ochsenfeld observed that manganese takes up nitrogen at about 1100 °C and gives it off again at 1300–1320 °C, and that the nitrided product has a Curie point of about 500 °C, a coercive force, Hc, of 200 Oe, an intrinsic induction of 200 G under an applied field of 600 Oe, and a remanence, Br, of 110 G.[1]

Although there was an argument that Mn_4N is ferromagnetic,[1,2] according to the result of neutron diffraction in 1962, the Mn_4N compound was identified to be a ferrimagnetic material,[3] which can be formulated as $Mn(I)NMn(II)_3$. It crystallizes in a perovskite-derived structure ABX_3: A is Mn(I) at the corner position, B is N at the body center, and X is Mn(II) at face centers of the cubic cell. Mn(I) has a large moment (3.53 μ_B at 300 K) with antiparallel spin alignment with respect to Mn(II) (−0.89 μ_B at 300 K), leading to a ferrimagnetic order of the lattice with a total magnetization at 300 K of 0.86 μ_B per formula unit.[3]

It is arduous to synthesize Mn_4N powder by traditional ceramic processes, because it requires high temperature (>925 K), long reaction time (>200 h), and precise atmosphere control.[4] However, through the assistance of technology like sputtering, it is possible to obtain such films much more easily, because high temperature phases could be successfully deposited at low substrate temperatures. On the other hand, Mn_4N films were rarely studied. One report studied Mn_4N films prepared by facing target reactive sputtering and obtained a film with saturation flux density of 510 G and coercivity of less than 900 Oe.[5] It is interesting to investigate again other synthesis methods and magnetic properties of such films. In this study, Mn_4N films have been prepared by dc reactive magnetron sputtering at low substrate temperatures on Si (100) substrate. Structure and magnetic properties of the films were studied.

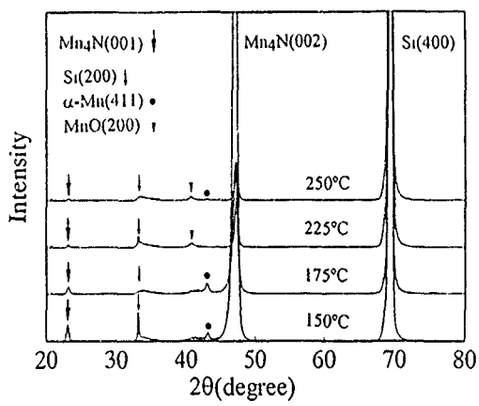

FIG. 1. X-ray diffraction patterns of as-deposited Mn_4N films at various substrate temperatures shown.

II. EXPERIMENT

The Mn_4N films were prepared by dc reactive magnetron sputtering from sintered Mn (99.9%) target. The substrates used were Si (100). The vacuum system was pumped to the base pressure of 5×10^{-5} Torr. Ultrahigh purity Ar and N_2 gases were first mixed at a ratio of 80:40 sccm, and the total pressure during deposition was set at 3 mTorr, controlled by a needle valve. The substrate temperature was varied from 150 to 250 °C. Distance between the target and the substrate was 3.5 cm.

The resultant films were examined by x-ray diffractometry (XRD) using Cu-$K\alpha$ radiation at a scanning speed of 1°/min for phase identification. Hysteresis loop both perpendicular and parallel to the film plane were measured at room temperature by using a vibrating sample magnetometer with a maximum applied field of 20 kOe. The sign of magnetostriction coefficient was measured by a strain gauge. Microstructure of the films was observed by means of a scanning electron microscope (SEM). Stress of the films was mea-

sured by a film stress measurement apparatus (FSM). Thickness of the films was measured by means of a stylus method.

III. RESULTS AND DISCUSSION

Films of fixed 1.2 μm thickness, as monitored by *ex situ* thickness measurements, were deposited on Si (100) at substrate temperature (T_s) of 150, 175, 225, and 250 °C, respectively, with a controlled deposition rate of 27 nm/min. Figure 1 shows the XRD patterns of films deposited on Si(100) substrates. The films exhibit a strong Mn_4N (002) texture with distinguishable (001) superlattice reflection. The degree of ordering, estimated from the peak height ratio between (001) and (002) diffractions, is practically the same for all T_s. There are contaminative phases, MnO and α-Mn. The amount of MnO increases with T_s due to higher oxidation tendency for α-Mn on the substrate with residual oxygen. While the amount of α-Mn decreases with increasing T_s due to oxidation.

Magnetic properties of the films are shown in Table I. For an fcc structure, large magnetic anisotropy is not usually anticipated. However, it is not true for the deposited Mn_4N films. Comparing the hysteresis loops of the films measured parallel (∥) to the film plane with those perpendicular (⊥) (see Fig. 2) the perpendicular coercivity ($Hc_\perp$) and remanence ($Br_\perp$), hence the perpendicular squareness ($S_\perp$) are always much larger than $Hc_\parallel$, $Br_\parallel$, and $S_\parallel$, for all substrate temperatures (T_s). Specifically, $Hc_\perp$ can be 1.8–2.3 times higher than $Hc_\parallel$. Due to much higher Hc values and larger squareness ratio in the perpendicular direction, the films deposited on Si(100) show apparently perpendicular magnetic anisotropy. Also it is found that saturation flux density (Bs) increases with increasing T_s. The film deposited at 250 °C has a Bs of 610 G, which is 34% of the theoretical value (1770 G). This discrepancy should arise from impurity phases (e.g., Mn and MnO) embedded in the films.

By FSM measurement, it was found that films show in-plane tensile stress, which increases with increasing substrate temperature, as shown in Table II. Further, by measuring with a strain gauge bonded on the film, it was confirmed that films deposited on Si(100) at various substrate temperatures have negative magnetostriction coefficient λ in the film plane, as shown in Fig. 3. However, precise magnetostriction was not possible by this method. Magnetoelastic anisotropy constant Ku can be calculated by the following formula:[6]

$$Ku = -(3/2)\lambda\sigma \tag{1}$$

since σ of the films is positive, the reverse magnetostriction makes a positive Ku, that is the perpendicular magnetoanisotropy.

Besides, microstructure observation of the films by SEM, as shown in Fig. 4, reveals that films are in fact composed of columnar grain structure which gives rise to the shape anisotropy that is proportional to the square of saturation magnetization. For the grain shown in Fig. 4, the aspect ratio is estimated to be 5.6, giving rise to a shape anisotropy constant Ks of, assuming the grain structure is perfect having a theoretical saturation magnetization,

$$Ks = (Na - Nc)Ms^2 = 1.1 \times 10^5 \text{ ergs/cm}^3. \tag{2}$$

TABLE II. The in-plane stress of the films vs substrate temperature (T_s, in °C).

Sample	T_s	Stress (MPa)
A1	150	622
A2	175	648
A3	225	667
A4	250	730

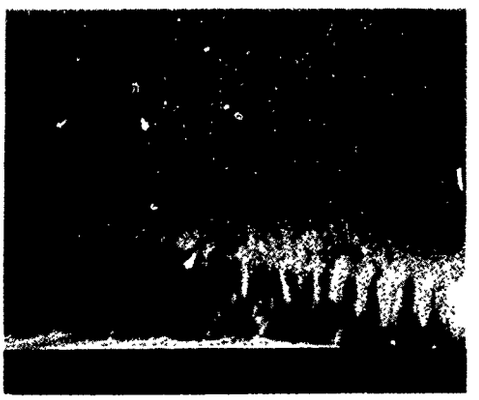

FIG. 4. A typical SEM micrograph of a Mn_4N film showing cross-sectional view of the film structure.

The contribution of the shape anisotropy to coercivity would be as high as 760 Oe, which is within the reasonable increment range as comparing the perpendicular coercivity to that parallel.

IV. CONCLUDING REMARKS

(1) Ferrimagnetic Mn_4N films with ordered structure and (002) texture can be successfully deposited at low substrate temperatures from 150 to 250 °C by using dc magnetron reactive sputtering from sintered Mn target onto Si(100) substrate without any further annealing.

(2) Anomalous perpendicular anisotropy exists in these films. The coercivity measured perpendicular to the film plane (2000 to 3000 Oe) is 1.8–2.3 times that measured parallel. The perpendicular magnetoanisotropy is attributed to the combined effects of (a) the stress-induced anisotropy caused by in-plane tensile stress coupled with a reverse magnetostriction, and (b) the shape anisotropy caused by columnar grain structure.

Polycrystalline samples of $Eu_{2-x}Ce_xCuO_{4-y}$ ($0.0 \leq x \leq 0.18$) were prepared from a sol-gel precursor and sintered in air at different temperatures. From the x-ray diffraction results, the beginning of $Eu_{2-x}Ce_xCuO_{4-y}$ phase formation is observed by increasing the sintering temperature up to 500 °C, as indicated by the presence of very broad Bragg reflections belonging to the desired phase. At 700 °C, $Eu_{2-x}Ce_xCuO_{4-y}$ coexists with Eu_2O_3, CeO_2, and CuO. Additional sintering at 950 °C in air for 20 h results in single phase materials. The effectiveness of Eu replacement by Ce in the Eu_2CuO_4 pristine phase has been confirmed by a decrease in the lattice parameter c with increasing x. Also, the solubility limit of Ce in these series was found to be higher than $x=0.15$. The results of thermal analysis reveal that the eutectic temperature $T_e \approx 1020$ °C is Ce independent. On the other hand, the peritectic temperature T_p increases significantly with increasing Ce concentration. It is close to $T_p \approx 1180$ °C for Eu_2CuO_4 and $T_p \approx 1195$ °C for $Eu_{1.82}Ce_{0.18}CuO_{4-y}$. Thermogravimetric analysis performed during the heating process in all samples studied revealed a weight loss of $\approx 1.5\%$ at the peritectic temperature. This weight loss has been attributed to an oxygen removal which is partially recovered during the cooling process.

I. INTRODUCTION

Since the discovery of electron-doped superconductors by Tokura, Uchida, and Takagi[1] many investigations towards the new class of $Ln_{2-x}Ce_xCuO_{4-y}$ (Ln=Pr, Nd, Sm, Eu; $0.0 \leq x \leq 0.20$) based materials have been carried out in order to better understand the relationship between their crystallographic structure and physical properties.[2,3] Compounds of $Ln_{2-x}Ce_xCuO_{4-y}$ crystallize in the so-called T' (Nd_2CuO_4) structure, but their physical properties strongly depend on the host Ln and the substituent Ce or Th.[2,3] In fact, this is mirrored in the observed superconducting critical temperature T_c: it is almost constant ≈ 23 K for Ln=Pr, Nd, and Sm, and it decreases significantly for Eu ($T_c \approx 13$ K). In addition, when Ln is replaced by heavier Gd, although the T' structure is preserved, the material does not reveal superconducting properties for x up ≈ 0.15.[3,4] Some authors have proposed that $Gd_{2-x}Ce_xCuO_{4-y}$ should show superconductivity for x higher than the Ce solubility limit, which is close to 0.15. This upper limit should be related to the structural instability originated by the growth of the intraplanar stresses.[5] Compounds of $Eu_{2-x}Ce_xCuO_{4-y}$ are on the frontier of this problem involving crystallographic properties and the appearance of superconducting properties. Up to now, few studies have been carried out on the crystallographic and physical properties of $Eu_{2-x}Ce_xCuO_{4-y}$ compounds.[2,3,6]

The conventional procedure used to obtain polycrystalline samples of $Ln_{2-x}Ce_xCuO_{4-y}$ compounds utilizes simple oxides as starting materials and subsequent heat treatments to promote Ce diffusion into the T' structure. Usually, these heat treatments are carried out at temperatures above the eutectic temperature T_e, which involves the presence of a liquid phase.[7,8] On the other hand, it is desirable that sintered materials should be as homogeneous as possible. This implies samples sintered without the presence of a liquid phase, provided that an appropriate Ce diffusion also occurs. Among several processes available in the literature, the sol-gel route allows homogeneous samples and complete Ce diffusion at sintering temperatures well below the eutectic temperature.[9]

In this work we focus on the preparation of polycrystalline $Eu_{2-x}Ce_xCuO_{4-y}$; $0.0 \leq x \leq 0.18$, starting from a sol-gel precursor. All samples were heat treated in air and at different temperatures up to 950 °C. The formation of the desired phases were accompanied by x-ray diffraction measurements and thermal analysis. We have also determined either the eutectic temperature T_e or the peritectic temperature T_p in all samples studied.

II. EXPERIMENTAL DETAILS

Powders of $Eu_{2-x}Ce_xCuO_{4-y}$; $x=0.0$, 0.05, 0.10, 0.15, and 0.18, were prepared as described below. Initially, appropriate amounts of high purity Eu_2O_3 were dissolved in 75 ml of water and 10 ml of 65% HNO_3 in a beaker to form ≈ 3.5 g of the desired phase. The solution was heated on a hot plate at ~50 °C under magnetic stirring. After the complete dissolution of the Eu_2O_3, stoichiometric amounts of $(NH_4)_2Ce(NO_3)_6$ and $Cu(NO_3)_2$ were slowly added to the solution. Ethylene glycol (~40 ml) and 7.6 g of citric acid were also dissolved in the mixture. The resultant blue solution was heated at $T \sim 100$ °C and magnetically stirred to evaporate water in order to form a homogeneous mixture. A brown NO_2 gas evolution during the heating process was frequently observed. Then, the solution was heated until it initiates a process of polymerization through a transformation into a green gel. The product was then transferred to an alumina crucible, and subjected to a continuous heating up to 150 °C. When the product dried, it reacted by spontaneous

ignition, transforming into a fine brown powder. This powder was heat treated in air in a muffle furnace at temperatures of 300, 500, 700, and 950 °C for 22 h.

In order to characterize these powders, x-ray diffraction measurements (XRD) and thermal analysis were performed. The XRD measurements were taken in a Jena–Zeiss URD-6 diffractometer with Ni filtered Cu$K\alpha$ radiation. All samples were measured between $10° \leq 2\Theta \leq 70°$ with angular scanning of 0.05°. All measurements were made at ambient temperature. Lattice parameters were obtained through the refinement of the corrected peak positions utilizing a least-square program.

The XRD reflections belonging to polycrystalline samples of $Eu_{2-x}Ce_xCuO_{4-y}$, $0.0 \leq x \leq 0.18$, were indexed according to the symmetry of the tetragonal T' phase, namely the $I4/mmm$ space group.[10,11] A computer simulated pattern was generated by using the experimentally calculated lattice parameters and by replacement of Ln by Eu and Ce on the atomic coordinates of the T' structure.[10,11] The simulated and the experimental patterns were in good agreement, with typical deviation $\leq 3\%$ for the intensity of the Bragg reflections.

Differential thermal analysis and thermogravimetric analysis (TG) were performed in air by using Al_2O_3 as the reference. The temperature T ranged between 20 °C $\leq T \leq$ 1400 °C. Heating and cooling rates of 10 °C/min have been employed in these measurements.

III. RESULTS AND DISCUSSIONS

While the as-dried precursors revealed low crystallinity, Fig. 1 displays XRD patterns measured on polycrystalline samples of $Eu_{1.85}Ce_{0.15}CuO_{4-y}$ heat treated at several higher temperatures: 500 °C (a), 700 °C (b), and 950 °C (c). In Fig. 1(a), the XRD pattern of the heat-treated powder at 500 °C shows very broad reflections which are strong evidence for low crystallinity. Some of these broad peaks have been identified as belonging to CuO and Eu_2O_3. All the reflections belonging to CeO_2 are probably overlapped with those of Eu_2O_3. A few reflections attributed to $Eu_{2-x}Ce_xCuO_{4-y}$ phases are also identified. Additional sintering at 700 °C [Fig. 1(b)] promoted the crystallization process of the desired phase. However, vestiges of reflections belonging to Eu_2O_3, CuO, and CeO_2 were still present. The lattice parameters obtained for sintered samples at 700 °C showed that they have intermediate values between Eu_2CuO_4 and $Eu_{1.85}Ce_{0.15}CuO_{4-y}$, suggesting a partial Ce diffusion at this temperature.

Finally, sintering at $T = 950$ °C for 20 h [Fig. 1(c)] resulted in almost single phase material for $Eu_{1.85}Ce_{0.15}CuO_{4-y}$. A very small unidentified peak at ~29.0° has been detected in all samples studied and it is the object of future work. Similar XRD patterns as those shown in Fig. 1 were obtained for other x values, except for $x = 0.0$. For this particular concentration and sintered samples at 500 °C, the XRD patterns showed additional peaks (not shown), which were attributed to Ce-free complexes formed during the ignition of the mixture.

By comparing the diffractograms obtained in heat-treated samples at 950 °C with different Ce concentrations,

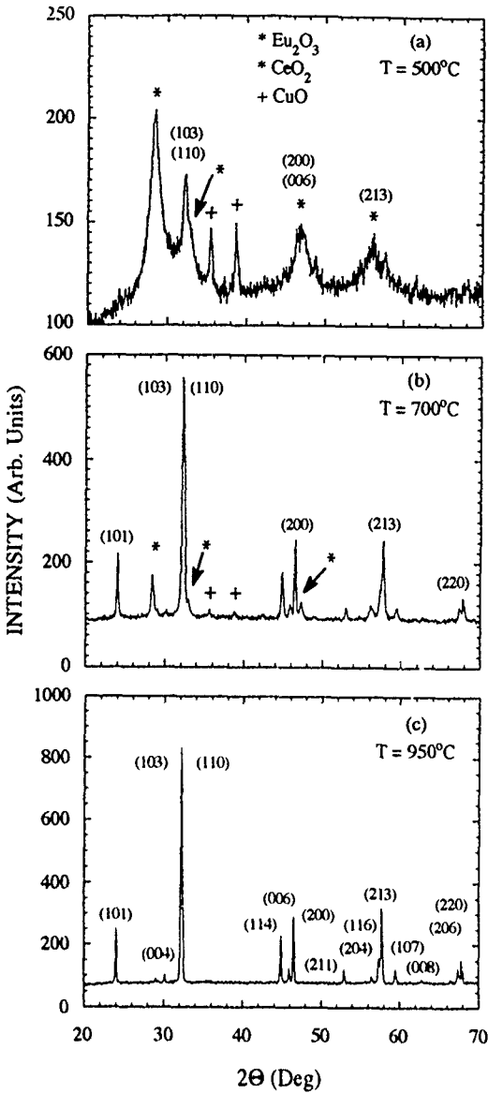

FIG. 1. XRD patterns of heat-treated polycrystalline samples of $Eu_{1.85}Ce_{0.15}CuO_{4-y}$ at different temperatures: 500 °C (a), 700 °C (b), and 950 °C (c). The desired phase is marked with Miller's indexes.

the lattice parameter evolution has been followed. This can be made by monitoring the observed shift in the (006) peak in samples with different x. It shifts to higher 2Θ angles with increasing x, while the (200) peaks are almost constant since the lattice parameter a shows small changes with increasing Ce concentration. Another perceptible evidence of Eu replacement by Ce is the observed enlargement of the (103)–(110) peak separation with increasing Ce concentration. Following this analysis, the lattice parameters a and c have been calculated from several reflections and the relevant data are shown in Fig. 2. The lattice parameter c decreases with increasing Ce concentration, while the lattice parameter a is almost constant for all the range studied. The decrease in the lattice parameter c with increasing Ce concentration strongly suggests that Ce^{+4} ions, with an effective ionic radius 0.97 Å, replaces Eu^{+3}, with an effective ionic radius 1.066 Å, in these series. The calculated lattice parameters were $c = 11.902(2)$ Å for Eu_2CuO_4 and $c = 11.834(3)$ Å for $Eu_{1.82}Ce_{0.18}CuO_{4-y}$.

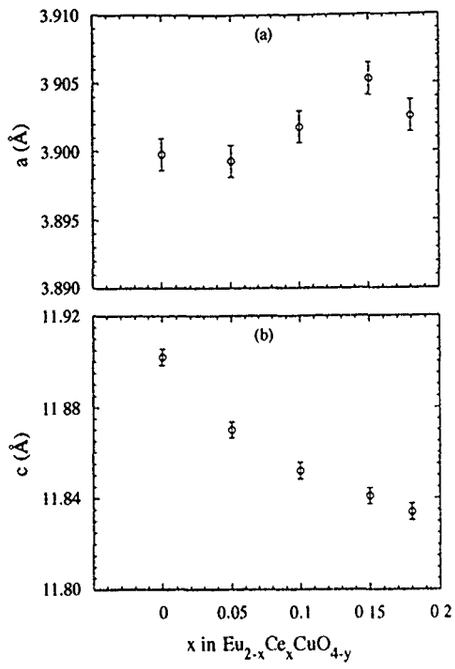

FIG. 2. Lattice parameters a and c as a function of Ce concentration of polycrystalline samples of $Eu_{2-x}Ce_xCuO_{4-y}$.

The results of differential thermal analysis performed on the as-grown powders (not shown) revealed a broad endothermic peak in the range of temperatures between 260 and 530 °C with a prominent maximum at ~400 °C. Such a peak has been associated with the desired phase formation. At higher temperatures, we also have observed two endothermic peaks: one of them close to the temperature $T_e \approx 1020$ °C and the other one close to temperature $T_p \approx 1190$ °C. The first one has been attributed to a eutectic temperature T_e and the other one to the peritectic temperature T_p. We have obtained these temperatures for all the samples studied and the relevant data are shown in Table I. It is worthwhile to mention that a small variation $\Delta T < 5$ °C has been found in the determination of the eutectic temperature for all samples studied. Similar behavior has been not observed at the peritectic temperature which increases with increasing Ce concentration. For example, it is close to 1178 °C for Eu_2CuO_4 and it is close to 1195 °C for $Eu_{1.82}Ce_{0.18}CuO_{4-y}$. Similar behavior in the peritectic temperature as a function of Ce content has also been observed by Oka and Unoki[12] in isomorphic series of $Nd_{2-x}Ce_xCuO_{4-y}$, $0.0 \leq x \leq 0.3$.

TABLE I. Eutectic temperature (T_e) and peritectic temperature (T_p) measured in polycrystalline samples of $Eu_{2-x}Ce_xCuO_{4-y}$, $0.0 \leq x \leq 0.18$. These temperatures were obtained from differential thermal analysis measurements performed in air.

x	T_e (°C)	T_p (°C)
0.0	...	1178(5)
0.05	1021(3)	1188(3)
0.10	1018(3)	1190(3)
0.15	1023(3)	1191(3)
0.18	1025(3)	1195(3)

The results of TG (not shown) revealed a large weight loss, about 25% of the total mass, during the reaction of the formation of the phases. This weight loss, which occurs at temperatures between 250 °C $\leq T \leq$ 550 °C, is believed to be related to the decomposition of the complexes into simple oxides as Eu_2O_3, CeO_2, and CuO. Another weight loss, which is of the order of 1.2%, near the peritectic temperature $T_p \approx 1190$ °C, has been also observed, during the heating process. However, this weight loss was found to be reversible during the cooling process. Such a weight loss was then attributed to the oxygen removal from the T' structure. This point is now being explored.

From these results and the preliminary discussion made above, one can surmise that, in samples prepared through the sol-gel process, the Ce diffusion into the T' structure occurs even at low temperatures ($T \leq 950$ °C). Such a complete diffusion can be explained by invoking features of the precursor material as a higher contact surface that improves the diffusion at low sintering temperatures, etc.

In summary, the formation of polycrystalline $Eu_{2-x}Ce_xCuO_{4-y}$, $0.0 \leq x \leq 0.18$, prepared from a sol-gel precursor, has been investigated. The desired phase has been obtained at sintering temperatures up to 700 °C, but the complete Ce diffusion only occurs at ≈950 °C. This temperature is well below the eutectic temperature of ≈1020 °C. The Ce solubility limit was found to be higher than $x = 0.15$ in these series. Thermogravimetric analysis showed a small weight loss near the peritectic temperature. This weight loss was found to be reversible and it was attributed to an oxygen removal from the T' structure.

Thermal decay of N coupled particles

Ivo Klik and Ching-Ray Chang
Department of Physics, National Taiwan University, Taipei, Taiwan, China

Jyh-Shinn Yang
Division of General Education, National Taiwan Ocean University, Keelung, Taiwan, China

A periodic chain of N magnetostatically coupled uniaxial particles is considered within the nearest-neighbor approximation of weak coupling. The time-dependent magnetization of the ensemble, which relaxes thermally in constant reversing field, is calculated using a master equation approach. It is found that at very small applied fields the net magnetization relaxes via simple exponential decay while at large reversing fields its relaxation becomes multiexponential. It is conjectured that at large N this effect gives rise to field induced logarithmic decay.

In a recent work[1] we analyzed the evolution of an array of N identical interacting uniaxial particles whose magnetization reverses by thermally activated coherent rotation. Such an array has up to $\mathcal{N}=2^N$ distinct metastable configurations and its evolution may then be given by the master equation

$$dn_i/dt=-\sum_{k=1}^{\mathcal{N}} K_{ik}n_k, \tag{1}$$

where n_i is the probability that the system finds itself in the ith configuration and K_{ik} is the matrix of transition probabilities between these configurations. By conservation of probability $\Sigma_i n_i=1$ and hence $\Sigma_i K_{ik}=0$ for every k. Zero is thus an eigenvalue of K to which there corresponds the stationary state of thermal equilibrium. We shall address first the formal properties of Eq. (1): If K is independent of time (constant applied field H and temperature T) and if it has no degenerate eigenvalues then the solution of Eq. (1) assumes the simple form $n_i(t) = \Sigma_k c_k u_i^{(k)} e^{-r_k t}$ where $\mathbf{u}^{(k)}$ is the eigenvector corresponding to the eigenvalue r_k ($r_1=0$ and $u^{(1)}$ is the thermal equilibrium probability distribution) while the integration constants c_k are to be determined from initial conditions. Let further $M_i=m_i M_s$, M_s is saturation magnetization, be the magnetization of the ith configuration whose reduced magnetization is m_i. The nonequilibrium magnetization then becomes

$$M(t)=M_s\sum_{k=1}^{\mathcal{N}} w_k e^{-r_k t}, \tag{2}$$

where the weights w_k are defined as $w_k = N^{-1}c_k\Sigma_{i=1}^{\mathcal{N}} m_i u_i^{(k)}$. Equation (2) may be viewed as an average, $M(t)=M_s\langle e^{-rt}\rangle_w$, over a discrete distribution w normalized by initial conditions, $M(0)/M_s=\Sigma_k w_k$, equilibrium magnetization, $M_{eq}=M_s w_1$. The time dependence of $M(t)$ is determined by the index function w_k and one may encounter simple exponential, multiexponential, or logarithmic decay. In either case one may write

$$S(t)=-dM(t)/d\ \ln(t/t_a)=M_s\sum_{k=1}^{\mathcal{N}} w_k r_k t e^{-r_k t} \tag{3}$$

(t_a is an arbitrary time scale). Logarithmic decay is observed[2] if the the sum $S(t)$ maintains its peak value over long periods of time. The distribution of relaxation rates within the sample is usually attributed to a distribution of activation volumes or nucleation fields[2,3] but Eq. (1) shows that a similar effects may occur also due to the presence of interparticle coupling. This conclusion has been reached previously, within a mean field theory, by Lottis *et al.*[4]

The determination of the matrix K poses a major problem. We have analyzed[1,5] the case of two magnetostatically coupled particles described recently by Chen *et al.*[6] The easy axes of the two particles are aligned with applied field and their bond angle $\beta=0$ or $\pi/2$. To the first order of small coupling strength ρ (defined below) the magnetization reversal of the particle pair takes place[1,6] by single particle switching events during which one particle remains frozen at the metastable minimum while the other particle reverses in magnetostatic field. At larger ρ both particles deviate initially from the metastable minimum, but only one of them overcomes the energy barrier while the other returns back[6] and at even larger ρ both particles reverse simultaneously.[6]

We consider here a chain of N identical uniaxial particles with individual energies $E_i=KV(\sin^2\theta_i-2h\cos\theta_i)$ where K is the anisotropy constant, V is the activation volume, and θ_i is the angle spanned by the applied field $\mathbf{H}=H\mathbf{k}$ and the magnetization of the ith particle. The reduced field $h=H/H_n$, $H_n=2K/M_s$. Following Chen *et al.*[6] we write $E_{int}=2KV\rho[\boldsymbol{\alpha}_i\cdot\boldsymbol{\alpha}_j-3(\mathbf{r}\cdot\boldsymbol{\alpha}_i)(\mathbf{r}\cdot\boldsymbol{\alpha}_j)]$ for the interaction energy of two particles at a distance R from each other, $\rho=M_s^2V/(2KR^3)$ is the coupling constant, $\boldsymbol{\alpha}_i$ is a unit vector in the direction of the magnetization of the ith particle, and $\mathbf{r}=\sin\beta\mathbf{i}+\cos\beta\mathbf{j}$, $\beta=0$ or $\pi/2$. We assume here the weak

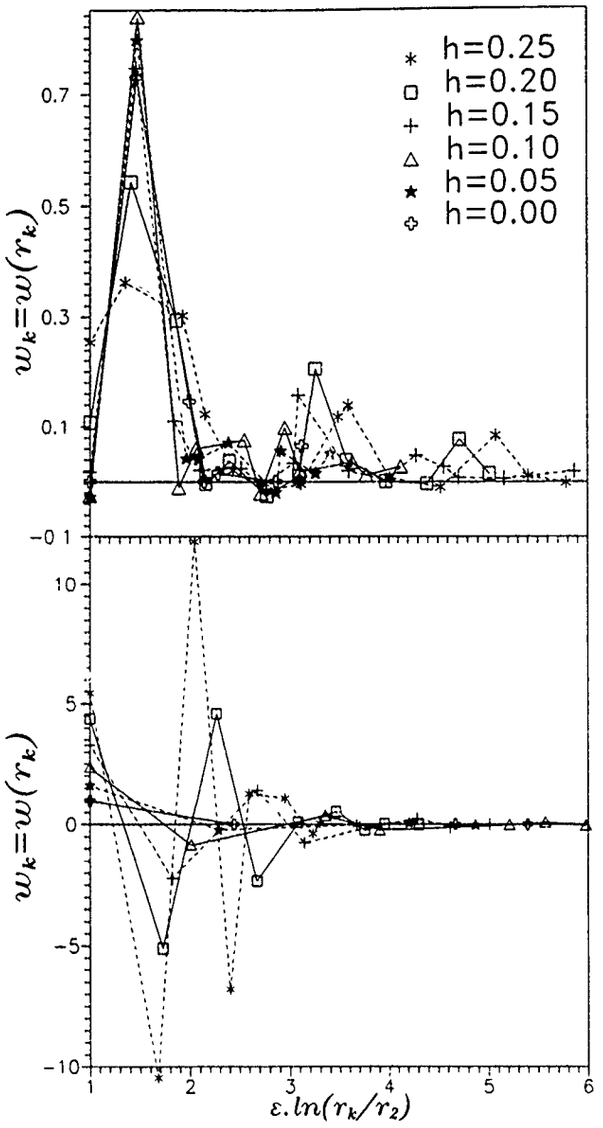

FIG. 2. The weights w_k for $N=8$ at selected values of reversing applied field h. The system was initially saturated and $\Sigma_k w_k=1$. Coupling strength $\rho=0.03$ for $\beta=\pi/2$ and $\rho=0.05$ for $\beta=0$. The scaling factor $\epsilon|_{\beta=0}=1.5$ and $\epsilon|_{\beta=\pi/2}=1$. $r_2=r_2(\rho,h)$ is the smallest nonzero eigenvalue of K.

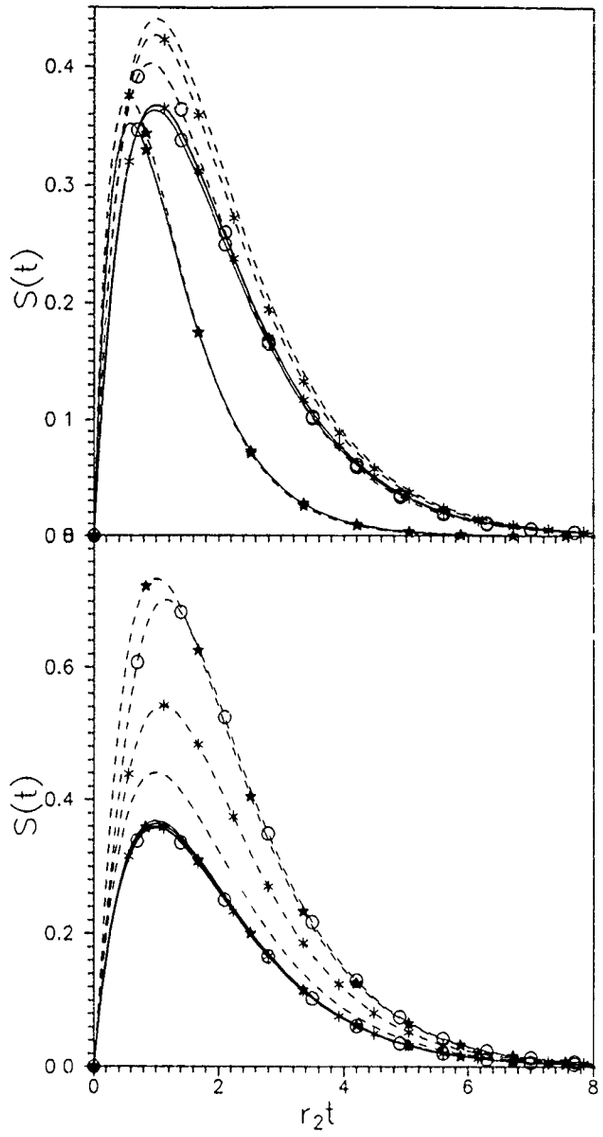

FIG. 3. The derivative $S(t)$ plotted vs the scaled time tr_2, $r_2=r_2(\rho,h)$ $N=8$, $\beta=\pi/2$ (top), and $\beta=0$ (bottom). Applied field $h=0$ (solid lines) and $h=0.05$ (dashed lines). Coupling strength $\rho=0$ (no marks), $\rho=0.01$ (*), $\rho=0.03$ (○), and $\rho=0.06$ (*) if $\beta=\pi/2$; $\rho=0.05$ (*), $\rho=0.1$ (○), and $\rho=0.15$ (*) if $\beta=0$.

coupling limit of single particle reversals, periodic boundary conditions, and nearest-neighbor interactions. There exist[1] then only six independent relaxation rates

$$\uparrow\uparrow\uparrow \xrightarrow{\kappa_1} \uparrow\downarrow\uparrow \xrightarrow{\kappa_2} \uparrow\uparrow\uparrow, \tag{4}$$

$$\downarrow\uparrow\uparrow \xrightarrow{\kappa_3} \downarrow\downarrow\uparrow \xrightarrow{\kappa_4} \downarrow\uparrow\uparrow, \tag{5}$$

$$\downarrow\uparrow\downarrow \xrightarrow{\kappa_5} \downarrow\downarrow\downarrow \xrightarrow{\kappa_6} \downarrow\uparrow\downarrow, \tag{6}$$

where $\kappa_{2i+1} = f_0 \exp[-q(1+h_{\rm eff}^{(i)})^2]$ and $\kappa_{2i+2} = f_0 \exp[-q(1-h_{\rm eff}^{(i)})^2]$, $h_{\rm eff}^{(0)}=h+\epsilon(\beta)$, $h_{\rm eff}^{(1)}=h$, and $h_{\rm eff}^{(2)}=h-\epsilon(\beta)$, with $\epsilon(0)=4\rho$ and $\epsilon(\pi/2)=-2\rho$. For the prefactor we take the value[7] $f_0=e^{25}$ Hz and we set $q=KV/k_BT=25$ throughout. All possible metastable configurations of four particles ($N=6$) are schematically shown in Fig. 1. Here $K_{11}=4\kappa_1$, $K_{12}=-\kappa_4$, $K_{21}=-4\kappa_1$, $K_{22}=\kappa_2+2\kappa_3+\kappa_1$, etc. For large N we use a separate program which classifies all configurations and writes down the FORTRAN code for $K=K(\kappa_i)$ which is sparse and the initial value problem (1) is fairly easily solved[8] even for large N.

The associated eigenvalue problem is numerically much more demanding since K is not symmetric and its eigenvalues are not necessarily real though Re $r_k \geq 0$ by construction. In order to gain some insight into the problem we shall restrict ourselves here to a small number of particles, $N \leq 8$, $\mathcal{N} \leq 27$, where the eigenvalue problem is easily solvable. In all cases $M(0)=M_s$ and $n_1(0)=1$ (see Fig. 1). Then all eigenvalues are real[9] and for $N=8$ we show the weights w_k in Fig. 2 and the corresponding functions $S(t)$ in Fig. 3. The

two bond angles share a common feature: At very small h only a single eigenstate is excited and one observes simple exponential decay regardless of the coupling strength and the $h=0$ curves are thus almost identical. The exception is the $\beta=\pi/2$, $\rho=0.06$ curve and we ascribe its irregular behavior to a breakdown of the weak coupling limit. With growing h ever higher eigenstates are excited so that the system, which at zero field exhibited simple exponential decay, relaxes multiexponentially. The two graphs of Fig. 2 are unlike in their character: At zero bond angle the weights are highly oscillatory (also note the scale) while at $\beta=\pi/2$ they resemble, in particular at higher fields, a smooth distribution. This leads us to conjecture that at very large N and sufficiently large reversing fields the weights w_k may assume the aspect of a real distribution function and give rise to a field-induced magnetic viscosity which vanishes if the applied field is removed.

The finding that the number of open relaxation channels depends, in interacting systems, on the magnitude of applied field is the main result of this work which was sponsored by the National Science Council of ROC under Grant No. NSC-82-0208-M002-35.

Influence of size and magnetocrystalline anisotropy on spin canting anomaly in fine ferrimagnetic particles

D. H. Han, J. P. Wang, Y. B. Feng, and H. L. Luo
State Laboratory for Magnetism, Institute of Physics, Chinese Academy of Sciences, Beijing 100080, China

Fine equiaxed γ-$Co_xFe_{2-x}O_3$ (x=0, 0.06) particles with a diameter ranging from 200 to 1000 Å were prepared by chemical precipitation. The average crystallite sizes were determined from x-ray line broadening measurements. The saturation magnetization and magnetocrystalline anisotropy of the particles were determined by using the approach to saturation. An empirical linear dependence of the specific saturation magnetization σ_s on the specific surface area S_a of the fine crystallites was obtained in the form of $\sigma_s(S)=\sigma_s(\infty)(1-AS_a)$. The slope A which reflects the surface spin canting anomaly is different for γ-Fe_2O_3 and γ-$Co_{0.06}Fe_{1.94}O_3$ particles. Under the supposition of the fine crystallite consisting of two parts, i.e., the surface layer, whose magnetic moment cannot be turned entirely along the direction of the applied field, but makes an average canting angle with the field, and the inner part, whose magnetic moment can be aligned along the direction of the applied field, the above formula can be interpreted well. The different slope A for γ-Fe_2O_3 and γ-$Co_{0.06}Fe_{1.94}O_3$ particles may be caused by the different anisotropies of the two series particles.

I. INTRODUCTION

More recently the spin canting anomaly and its origin in fine ferrimagnetic particles have experienced a renaissance of fresh research activities.[1,2] The surface spin canting anomaly in fine ferrimagnetic particles was demonstrated more than two decades ago,[3] and it was found that the smaller the particles, the larger the reduction of the saturation magnetization.[4] However, the results of the specific saturation magnetization decreasing with the reduction of the particles or crystallites size have not been explained yet. The origin of this phenomenon is still a matter of dispute.[2,5] As Co-γ-Fe_2O_3 particles or crystallites have become the fundamental structural units of very high density magnetic recording media, it is necessary to study the dependence of the specific saturation magnetization (σ_s) on the specific surface area (S_a) of the fine crystallites in detail.

In this article, the relationship between σ_s and S_a of the crystallites of equiaxed γ-$Co_xFe_{2-x}O_3$ (x=0,0.06) particles with various sizes are studied. An empirical formula of $\sigma_s(S)=\sigma_s(\infty)(1-AS_a)$ was obtained. The results are well explained with the assumption of the surface spin canting. The different slope A may be caused by the different anisotropies of the two series particles.

II. EXPERIMENT

The equiaxed γ-$Co_xFe_{2-x}O_3$ (x=0,0.06) particles with the diameter from 200 to 1000 Å were prepared by chemical precipitation. The samples with x=0 are denoted, in the following, as series F, and the ones with x=0.06 as series C, respectively. The crystal structure of the particles was determined by using a SRA M18XHF x-ray diffractometer. The average crystallite sizes were determined from x-ray diffraction line broadening measurements by using the Scherrer formula.[6] The morphology of the particles was determined by using a Hitachi H-700 transmission electron microscope. The magnetic properties and magnetocrystalline anisotropy of the particles were measured at 295 and 79 K by using a LDJ vibrating sample magnetometer with a maximum field of 20 kOe. The saturation magnetization of the particles was obtained by a $1/H$ extrapolation to infinite field.

III. RESULTS AND DISCUSSION

All the particles were determined with the structure of γ-Fe_2O_3 with a crystalline lattice parameter a_0=8.35 Å, and no other phase was found.[7] The particles are equiaxed with a small size distribution. The dependence of σ on $1/H$ for series C, measured at 295 and 79 K are shown in Figs. 1(a) and 1(b), from which σ_s can be obtained by extrapolation to infinite field. As the result, the average crystallite size D, S_a under the assumption of cubic crystallites, as well as σ_s are listed in Table I. The dependence of σ_s on S_a of series C and F at 295 and 79 K are shown in Figs. 2(a) and 2(b), respectively. It can be seen clearly that for the two series σ_s decreases linearly with the increasing S_a at both 295 and 79 K. These results are very similar to that of Mollard *et al.*[4] and

$C-D_2$	91	134.3	65.2	49.2

also to that of the estimated data from Berkowitz *et al.*[9] These dependencies can be expressed as the following empirical linear formula:

$$\sigma_s(S_a)=\sigma_s(\infty)(1-AS_a), \tag{1}$$

where $\sigma_s(S_a)$ is the specific saturation magnetization of the particles composed of the crystallites with an average diameter D, $\sigma_s(\infty)$ the specific saturation magnetization when S_a approaches zero, and A the slope of the straight line. The values of $\sigma_s(\infty)$ and $[\sigma_s(\infty)A]$ by linear regression of $\sigma_s(S_a)$ vs S_a for series F and C are listed in Table II.

Various assumptions have been proposed to explain the decrease of the saturation magnetization with the decrease of particles and/or crystallites size. Some of them are, (1) the magnetization is actually reduced by adsorbed water and a noncollinear spin arrangement;[3] (2) the nonmagnetic grain boundary may instead be a magnetic boundary in which the spin suffers considerable canting, and at 4.2 K the random-angle assumption is equivalent to an average canting angle of

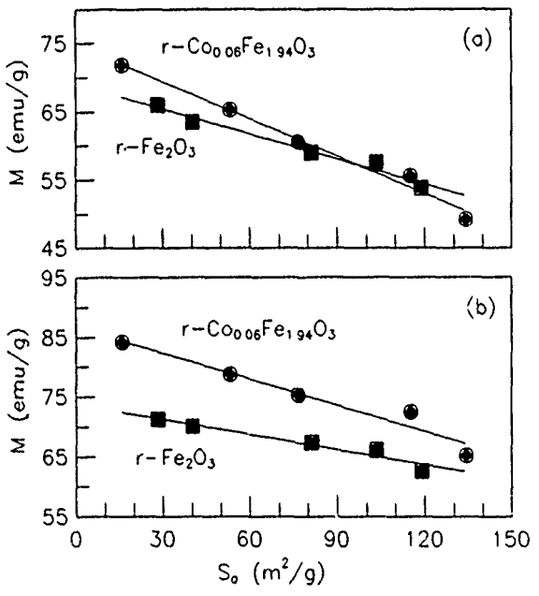

FIG. 2. The dependencies of σ_s on S_a of series F and C measured at (a) 295 and (b) 79 K.

TABLE II. The values of $\sigma_s(\infty)$ and $[\sigma_s(\infty)A]$ by linear regression of $\sigma_s(S_a)$ vs S_a for series F and C at 295 and 79 K.

Sample	$\sigma_s(\infty)$ (emu/g) 295 K	$\sigma_s(\infty)$ (emu/g) 79 K	$[\sigma_s(\infty)A]$ (emu/m^2) 295 K	$[\sigma_s(\infty)A]$ (emu/m^2) 79 K
F	69.1	73.8	−0.12	−0.08
C	73.9	86.1	−0 17	−0.14

54.5°,[8] which is consistent with the results of Coey *et al.*;[3] (3) the crystallites in acicular γ-Fe_2O_3 particles are separated by a nonmagnetic grain boundary on the order of 6 Å wide;[9] (4) in small particles below the superparamagnetic blocking temperature, the magnetization direction fluctuates around an average minimum corresponding to an easy direction of magnetization with average angle $\langle\cos\theta\rangle_T$.[10]

In order to analyze the effects of the fluctuation on the magnetization reduction of the particles, the coercivities, measured at 79 K, of samples F–D (242 Oe) and C–D_2 (2737 Oe) were first taken into Eq. (2)[10]

$$H_c=\frac{2K}{M_s}\left[1-\left(\frac{25k_BT}{KV}\right)^{1/2}\right], \tag{2}$$

to calculate the effective anisotropy constant K, and then estimate $\langle\cos\theta\rangle_T$, respectively. The results are listed in Table III. From the large differences between the calculated $\langle\cos\theta\rangle_{T,C}$ values and the measured ones $\langle\cos\theta\rangle_{T,M}$ [measured from the curves of 79 K for samples F–D and C–D_2 in Fig. 2(b) and Table II, respectively], one knows that the magnetization reduction with the increasing S_a cannot be explained by the magnetization thermal fluctuation.

We assume that the fine crystallite consists of two parts. The first part is the noncollinear surface layer with a thickness t, whose magnetic moment cannot be turned entirely along the direction of the applied magnetic field, but makes an average canting angle α with respect to the field direction. The second one is the inner part, whose magnetic moment can be aligned along the direction of the applied magnetic field. Under this circumstance the measured σ_s of the samples is actually contributed by the effective magnetic volume V_{eff}, not by the geometric volume V_0, i.e.,

$$\frac{V_{\text{eff}}M_s}{V_0\rho}=\sigma_s(S_a), \quad \frac{V_0M_s}{V_0\rho}=\sigma_s(\infty), \tag{3}$$

where ρ is the density of the corresponding materials and in this article it is taken as 4.9 g/cm^3 for both γ-Fe_2O_3 and γ-$Co_{0.06}Fe_{1.94}O_3$ particles.

According to this model and neglecting the small values of higher powers of t, the relationship between σ_s and S_a can be deduced as

TABLE III. The measured H_c, V, $\langle\cos\theta\rangle_{T,M}$, and the calculated K, $\langle\cos\theta\rangle_{T,C}$ of samples F-D and C-D_2 at 79 K.

Sample	H_c(Oe)	V(cm^3)	K(erg/cm^3)	$\langle\cos\theta\rangle_{T,C}$	$\langle\cos\theta\rangle_{T,M}$
F-D	242	8.8×10^{-19}	3.1×10^5	0.98	0.85

[e]Reference 9.

$$\frac{\sigma_s(S_a)}{\sigma_s(\infty)}=\frac{V_{\text{eff}}}{V_0}=1-(1-\cos\alpha)\rho t S_a. \tag{4}$$

Comparing Eq. (4) to Eq. (1), one knows that the measured linear dependence of $\sigma_s(S_a)$ on S_a has the same form to that of the deduced one with an equation of

$$A=(1-\cos\alpha)\rho t. \tag{5}$$

Therefore according to the measured A in Eq. (1) and the assumed α in Eq. (5) one can calculate the thickness t of the noncollinear surface layer.

It is worthy to point out that in Figs. 2(a) and 2(b) there are obvious differences in slope A between series F and C at the same temperature and between 295 and 79 K for one series. At a certain temperature, as shown in Figs. 2(a) and 2(b), γ-$Co_{0.06}Fe_{1.94}O_3$ particles show a larger slope than that of γ-Fe_2O_3 particles. And for a certain series the slope is larger at 79 K than that at 295 K. According to Eq. (5) the slope of the straight line is affected by two independent factors α and t. If one factor is measured or assumed, then the other one can be calculated from Eq. (5). Morrish *et al.*[8] have assumed that for γ-Fe_2O_3 particles α is 54.5°. If assuming α for both γ-Fe_2O_3 and γ-$Co_{0.06}Fe_{1.94}O_3$ particles and at both 79 and 295 K to be 54.7°, then we can obtain the thickness t of the noncollinear surface layer.

The measured A, assumed α and calculated t for series F and C are listed in Table IV. As a reference, the results of Morrish *et al.*,[8] Mollard *et al.*,[4] as well as Berkowitz *et al.*[9] are also listed in Table IV. From this table one knows that the measured relationship between $\sigma_s(S_a)$ and S_a can be explained with the simple model of the fine crystallite being consisted of the spin collinear core and the spin canted surface layer. Under the assumption of the same σ, γ-$Co_{0.06}Fe_{1.94}O_3$ crystallites show a larger t, 8 and 11 Å at 295 and 79 K, respectively, than those of γ-Fe_2O_3 crystallites, 6 and 8 Å at the above two temperatures. The different slopes of the different straight lines for series F and C may be caused by the different effective anisotropies of the two series particles. The magnetocrystalline anisotropy constants K_1 were determined by using the approach to saturation at 295 K to be 2.2×10^5 ergs/cm^3 for series C and 4.4×10^4 ergs/cm^3 for series F, respectively. The larger thickness t of the surface spin canting layer for series C, comparing to that of series F, may be caused by the larger effective magnetocrystalline anisotropy of the particles.

IV. CONCLUSION

The specific saturation magnetizations of both γ-Fe_2O_3 and γ-$Co_{0.06}Fe_{1.94}O_3$ particles decrease linearly with the increasing specific surface area of the fine crystallites. The results can be explained with the model of the spin canted surface layer. The fine crystallites consist of two parts, i.e., the surface layer, whose magnetic moment cannot be turned entirely along the direction of the applied field, but make an average canting angle with the field, and the inner part, whose magnetic moment can be aligned along the direction of the applied field. With this assumption, the empirical linear formula of σ_s and S_a can be interpreted. The different thickness t of the surface spin canting layer between series F and C may be caused by the different effective anisotropies of the two series particles.

Magnetic properties of nanometer-sized Fe_4N compound (abstract)

Y. B. Feng
State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, P.O. Box 603, Beijing 100 080, China

Nanometer-sized magnetic materials have attracted a lot of attention because of their potential applications in the fields of ferrofluids, high density magnetic recording, and magnetic refrigeration. The sol-gel method[1] has been considered to be effective for creating dispersions of small metal particles in nonmetallic materials. In this work, nanometer-sized Fe-N compound particles were prepared by nitrogenating the iron-boron oxide glass powders, which were synthesized by the sol-gel method from ethylene glycol gel. The magnetic properties of nanometer-sized iron nitride were measured by a vibrating sample magnetometer (VSM). The specific magnetic moment σ is equal to 132 emu/g and the coercivity H_c is 150 Oe. The phase composition was determined by using an x-ray diffractometer (XRD). The diffraction pattern shows that the sample consisted of a main phase of Fe_4N and a small α-Fe phase. The crystallite size d of the Fe_4N particles was estimated by Scherrer's formula, and is about 12 nm. The nanometer-sized Fe-N compound was also studied by using Mossbauer spectroscopy. The Mossbauer absorption pattern consisted of a ferromagnetic component superimposed on a superparamagnetic doublet. The ratio of superparamagnetic fraction to ferromagnetic is about 13%. It is shown that the sol-gel technique could be used to prepare ultrafine particles of Fe-N compound.

Theory of the negative magnetoresistance of ferromagnetic-normal metallic multilayers (invited)

L. M. Falicov and Randolph Q. Hood
Department of Physics, University of California, Berkeley, California 94720-7300 and Materials Sciences Division, Lawrence Berkeley Laboratory, Berkeley, California 94720

Transport properties for a system consisting of a ferromagnetic-normal metallic multilayer are theoretically examined. The in-plane conductance of the film is calculated for two configurations; the ferromagnetic layers aligned (i) parallel and (ii) antiparallel to each other. The results explain the giant negative magnetoresistance encountered in these systems when an initial antiparallel arrangement is changed into a parallel configuration by application of an external magnetic field. The calculation depends on (a) geometric parameters (the thicknesses of the layers); (b) intrinsic metal parameters (number of conduction electrons, magnetization and effective masses in the layers); (c) bulk sample properties (conductivity relaxation times); and (d) interface scattering properties (diffuse scattering versus potential scattering at the interfaces). It is found that a large negative magnetoresistance requires, in general, considerable asymmetry in the interface scattering for the two spin orientations. All qualitative features of the experiments are reproduced. Quantitative agreement can be achieved with sensible values of the parameters. The effect can be conceptually explained based on considerations of phase-space availability for an electron of a given spin orientation as it travels through the multilayer sample in the various configurations.

I. INTRODUCTION

Ferromagnetic-normal metallic superlattices and sandwiches[1,2] display several interesting properties, such as a varying interlayer magnetic coupling[3] and a negative, sometimes very large magnetoresistance (MR) effect.[4–15] A few examples include $(Co/Cu)_n$, $(Fe/Cr)_n$, $(Fe/Cu)_n$, $(Co/Ru)_n$, (NiFe/Cu/NiFe), and (NiFe/Ag/NiFe). In these systems the magnetic moment of each ferromagnetic layer is arranged with respect to that of the neighboring ferromagnetic layers either in a parallel or an antiparallel fashion, depending on the thickness of the metal spacers and on the quality of the interfaces.

When the consecutive moments are arranged antiparallel to each other, the application of an external magnetic field to the sample rearranges the moments into a completely parallel arrangement for fields of the order of 1 T. Also, the resistance of the sample decreases—negative MR—in all directions (in-plane in particular). The MR can vary from a few percent to as large as 55% (for Co/Cu at liquid-helium temperatures).[13] A decrease by more than 20% is generally known as the *giant magnetoresistance effect* (GMR).

Spin-dependent interfacial scattering plays an important role in the MR in many different ferromagnetic-normal metallic multilayers. Experiments by Fullerton *et al.*[16] indicate that increased interfacial roughness enhances the GMR in $(Fe/Cr)_n$. Parkin[17] found that the addition of thin Co layers at the interfaces of $(NiFe/Cu)_n$ enhanced the MR. The MR increased monotonically as the Co layer increased to 4 Å, then become insensitive to the thickness of the Co layer with a MR similar to that of $(Co/Cu)_n$ despite the presence of the NiFe layers sandwiched between thin Co layers. Baumgart *et al.*[18] have found that ultrathin layers of elements (V, Mn, Ge, Ir, or Al) deposited at the Fe/Cr interface lead to changes in the MR which correlate with the ratio of spin-up and spin-down resistivities arising from spin-dependent impurity scattering of these elements when alloyed with Fe. This result is in agreement with the suggestion of Baibich *et al.*[4] that the spin dependence of impurity scattering at the interfaces is related to that observed[19] in alloyed ferromagnetic metals such as Fe, Co, and Ni.

Further confirmation of the importance of the interface in the MR effect was provided by Barthélémy *et al.*[20] who point out that the experimental data they obtained for epitaxially grown Fe(001)/Cr(001) multilayers seem to be in agreement with a variation of the MR of the form

$$\exp(-t_{Cr}/\lambda^*),$$

where t_{Cr} is the thickness of Cr layer and λ^* is a length of the order of the mean-free path. Such a variation of the MR with layer thickness is expected from spin-dependent interface scattering.

It is important to distinguish clearly between the concepts of spin-flip scattering and spin-dependent scattering. The first refers to an event in which, during scattering, an electron reverses its spin orientation; such a phenomenon is normally caused by spin-orbit effects and/or by scattering from impurities with a localized magnetic moment. Spin-flip scattering is neglected in this contribution. The second one refers to the fact that electrons with different spin orientations experience different potentials and have different phase-space distributions. Consequently, they have very different scattering cross sections both in the bulk and at the interfaces. The latter is extremely relevant for the purposes of this study.

 0021-8979/94/76(10)/6595/6/$6.00 © 1994 American Institute of Physics

The aim of this contribution is to present a model that incorporates spin-dependent interfacial scattering in a more realistic way. While the model presented here is similar in many respects to that of Camley and Barnaś[21,22] it does not suffer from the shortcomings encountered there in the description of interfacial scattering. Utilization of a more accurate description of the interface permits a study and separation of the various scattering mechanisms and their relevance in the MR effect.

The present model, an extension of the Fuchs–Sondheimer theory,[23,24] uses a Stoner description[25] of the itinerant ferromagnetic layers; it introduces different potentials for majority and minority spins. Band-structure and electron-density effects are included only by means of a constant, metal- and spin-dependent potential, and an isotropic effective mass for each spin in each layer. The different potentials in neighboring layers result in coherent potential scattering (i.e., refraction) of electrons as they traverse the interface. The angular-dependent effects are treated by a quantum-mechanical matching of the electron wave functions at the interfaces. Scattering at the interfaces from impurities and interfacial roughness are also a source of spin-dependent scattering, and they contribute to the present model through a spin-dependent function, in a way similar to that used by Camley and Barnaś.

The model predicts the dependence of the MR on the quality of the samples (mean-free path), on the quality (roughness) of the interfaces, and on the thickness of the layers.

II. THE MODEL

The in-plane conductivity was calculated for a multilayer consisting of alternating layers of a ferromagnet (F) of thickness d_F, and a spacer layer of thickness d_s. The coordinate system is chosen with the z axis perpendicular to the layers. There is complete isotropy in the (x,y) plane.

For each structure the conductivity was calculated for both an antiparallel alignment, denoted $\sigma\uparrow\downarrow$, and for a parallel alignment, denoted $\sigma\uparrow\uparrow$, of the moments of successive F layers. The structure repeats itself after four layers ($\cdots/F\uparrow/s/F\downarrow/s/\cdots$) in the antiparallel arrangement. In the parallel arrangement the period consists of two layers ($.../F\uparrow/s/...$). Application of a sufficiently large magnetic field to a sample in the antiparallel arrangement results in a parallel alignment of the magnetic moments. The magnetoresistance ($\Delta\rho/\rho$), is defined by

$$\frac{\Delta\rho}{\rho}\equiv\frac{\rho\uparrow\downarrow-\rho\uparrow\uparrow}{\rho\uparrow\downarrow}=\frac{\sigma\uparrow\uparrow-\sigma\uparrow\downarrow}{\sigma\uparrow\uparrow}, \tag{1}$$

where $\rho_{\mu,\nu}=(\sigma_{\mu,\nu})^{-1}$. Note that this quantity varies between zero and one (or 0% and 100%) whenever the resistance decreases upon the application of an external magnetic field.

For both alignments the conductivity is obtained by adding the contributions of the spin-up and the spin-down electrons, calculated separately. This is the two-current model,[19] which provides a good description of electron transport in magnetic $3d$ metals. As mentioned above spin-flip processes, which mix the two currents, are neglected. Their effect is know to be small at low temperatures.

The electrons involved in transport are considered as free-electron-like with spherical Fermi surfaces. Within each layer the electrons move in a constant potential $V_{i\sigma}$ which depends on the particular layer i and the spin σ of the electron.

The electron distribution function is written in the form

$$f_{i\sigma}(\mathbf{v},z)=f^0_{i\sigma}(\mathbf{v})+g_{i\sigma}(\mathbf{v},z), \tag{2}$$

for each layer i and for each spin σ, which is independent of x and y by symmetry. The first term $f^0_{i\sigma}(\mathbf{v})$ is the equilibrium distribution in the absence of an electric field and $g_{i\sigma}(\mathbf{v},z)$ is the deviation from that equilibrium in the presence of the electric field. For an electric field of magnitude E in the $\hat{x}$ direction, the Boltzmann equation in the relaxation-time approximation reduces to

$$\frac{\partial g_{i\sigma}}{\partial z}+\frac{g_{i\sigma}}{\tau_{i\sigma}v_z}=\frac{|e|E}{m_{i\sigma}v_z}\frac{\partial f^0_{i\sigma}}{\partial v_x}, \tag{3}$$

where $\tau_{i\sigma}$ is the relaxation time in layer i for spin σ, and e is the charge of the electron. The second-order term, proportional to the product $(E\cdot g_{i\sigma})$, has been discarded since nonlinear effects (deviations from Ohm's law) are neglected. The Lorentz-force term, proportional to $(\mathbf{v}\times\mathbf{H}/c)$, has also been dropped from the Boltzmann equation since it gives an effect which is orders of magnitude smaller than those considered here.[21]

Because of the nature of the boundary conditions it is useful to divide $g_{i\sigma}$ into two parts: $g^+_{i\sigma}(\mathbf{v},z)$ if $v_z\geq 0$ and $g^-_{i\sigma}(\mathbf{v},z)$ if $v_z<0$. The boundary conditions for the potential (nondiffusive) scattering at the (i,j) interface then take the form

$$\begin{aligned} g^-_{i\sigma}&=S_{ij;i;\sigma}R_{ij,\sigma}g^+_{i\sigma}+S_{ji;i;\sigma}T_{ji;\sigma}g^-_{j\sigma},\\ g^+_{j\sigma}&=S_{ji,j;\sigma}R_{ji;\sigma}g^-_{j\sigma}+S_{ij;j;\sigma}T_{ij;\sigma}g^+_{i\sigma}. \end{aligned} \tag{4}$$

Here $S_{ij;k;\sigma}$, which varies between zero and one, is a factor that indicates the degree of potential scattering at the interface (i,j) for an electron of spin σ arriving at the interface from the layer i and being scattered into the layer k. The scattering is completely diffusive when $S=0$ and follows the reflection–refraction laws when all $S=1$. The notation used for the transmission T and the reflection R coefficients is the following: $T_{ij;\sigma}\equiv$ probability for an electron of spin σ in layer i to be transmitted (refracted) into layer j; $R_{ij,\sigma}\equiv$ probability for an electron of spin σ in layer i with a velocity directed towards layer j to be reflected back into layer i. The equations and boundary conditions, as written, satisfy all necessary conservation laws.

The functional dependence of the transmission and reflection coefficients was determined[26] by matching the free-electron-like (plane-wave) functions and their derivatives at each interface. The solution to this problem, which is identical to that encountered in optics for an interface between two media with different index of refraction, is illustrated in Fig. 1.

The current density along the electric field in each layer i for electrons with spin σ is given by

$$J_{xi\sigma}(z)=-|e|\left(\frac{m_{i\sigma}}{h}\right)^3\int v_x g_{i\sigma}(\mathbf{v},z)d^3\mathbf{v}, \tag{5}$$

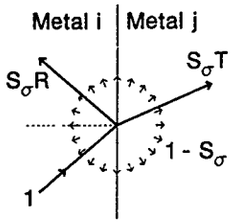

FIG. 1. Schematic diagram of the scattering process at the metal–metal interface. The parameter S_σ defines the fraction controlled by the potentials; $S_\sigma R$ is the probability of specular scattering; $S_\sigma T$ is the probability of transmission (refraction) into the other metal.

where h is Planck's constant. The conductivity of the multilayer is obtained by averaging over the whole film

$$\sigma = \frac{1}{E d_{\text{film}}} \sum_{i} \sum_{\sigma=\uparrow,\downarrow} \int J_{xi\sigma}(z) dz.$$

The MR, $(\Delta\rho/\rho)$, is found by calculating independently the conductivities $\sigma\uparrow\downarrow$ and $\sigma\uparrow\uparrow$. Many parameters are necessary to characterize a structure. Associated with the electrons in the F layers are the minority (denoted using a small subscript m) and the majority (denoted using a capital subscript M) spins with effective masses m_m and m_M, relaxation times τ_m and τ_M, and potentials V_m and V_M. In the spacer layer s the spin-up and spin-down electrons move in a potential V_s with an effective mass m_s and relaxation time τ_s. At the interfaces, the functions $S_{ij;k;\sigma}$, which vary with angle of incidence, describe the interfacial scattering of the majority and the minority spins.

The values of the potentials are determined by treating all of the valence s and d electrons as being in a single free-electron-like band with an isotropic effective mass. In general the effective mass is taken to be larger than the electron mass, since the d electrons, which contribute to the density of electrons, are in narrower bands than the free-electron-like s electrons. Within the F layers the bands for the minority and the majority spins are shifted by a k-independent exchange potential, yielding two different spin-dependent, constant potentials, V_m and V_M. The value of the exchange splitting is chosen so that the difference in the density of the majority and the minority electrons yields the net magnetic moment of the bulk ferromagnetic material.

III. RESULTS

As developed thus far, the theory includes 11 parameters and eight angular functions:

three effective masses m_M, m_m, and m_s;
three constant potentials V_M, V_m, and V_s;
three relaxation times τ_M, τ_m, and τ_s;
two thicknesses d_F, and d_s;

and

eight interface scattering functions $S_{F,s,F;M}$, $S_{F,s,F,m}$, $S_{F,s,s,M}$, $S_{F,s,s,m}$, $S_{s,F;s,M}$, $S_{s,F;s,m}$, $S_{s,F;F,M}$, and $S_{s,F,F,m}$.

The results presented here include only the cases for which the *relaxation times* are identical $\tau \equiv \tau_m = \tau_M = \tau_s$. (Note that the *mean-free paths* of the minority and the majority spins within the F layers and for the spacer metal are different, since the Fermi velocities are different.) The interfaces are treated in two different ways. In the first approach the angular dependence of the functions $S_{ij;k;\sigma}$ is neglected and the eight functions are replaced by two constants

$$S_{F,s,F,M} = S_{F,s,s;M} = S_{s,F;s;M} = S_{s,F;F,M} = S_M,$$

$$S_{F,s;F;m} = S_{F,s;s;m} = S_{s,F;s,m} = S_{s,F;F;m} = S_m.$$

In this approach the system is defined by 11 constants.

In the second approach the different angular dependences in various $S_{ij;k;\sigma}$ are explicitly included.

Results are presented for two different multilayer systems, $(\text{Fe/Cr})_n$ and $(\text{Fe/Cu})_n$. In these three metals the isotropic effective mass is assumed to be independent of the material and spin orientation with a value $m_M = m_m = m_s = 4.0\times$ free-electron mass. With this effective mass the potentials, with respect to the Fermi energy E_F chosen to be at $E_F = 0$, are

$$V_M = -8.23 \text{ eV}, \quad V_m = -5.73 \text{ eV for Fe};$$

$$V_s = -5.77 \text{ eV for Cr};$$

$$V_s = -8.54 \text{ eV for Cu}.$$

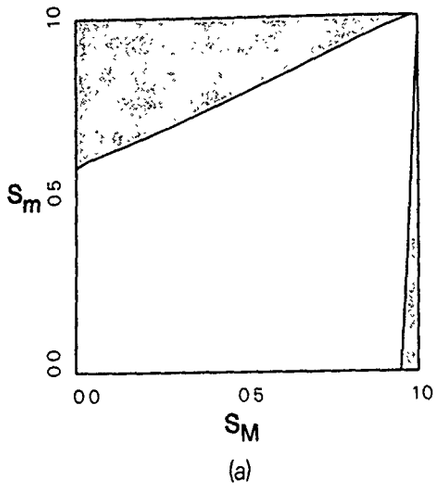
The parameters that remain to be specified for each case—$(\text{Fe/Cr})_n$ and $(\text{Fe/Cu})_n$—in the constant-S approximation are altogether five: (a) one relaxation time τ, which depends on bulk sample properties; (b) two geometric parameters d_F and d_s; and (c) two interface scattering parameters S_M, S_m (diffuse scattering versus potential scattering at the interfaces for the majority and the minority spins, respectively).

Even with these simplifications, the phenomena under consideration are complicated functions of the five variables, and the task of describing these dependencies is not simple. In general terms, and with exceptions, it is found that $(\Delta\rho/\rho)$ is a strong function of the interface parameters S_M and S_m, and a relatively weak function of the thicknesses and the mean-free path. For example, as S_M and S_m independently vary between 0 and 1, the calculated $(\Delta\rho/\rho)$ varies between 0% and 92.7% for $(\text{Fe/Cr})_n$ and 0% and 94.4% for $(\text{Fe/Cu})_n$, when values of $d_F = 20.0$ Å; $d_s = 10.0$ Å and $\tau = 5.0\times10^{-13}$ s are chosen. Figure 2 shows the regions in the two-dimensional parameter space $(S_M - S_m)$, where $(\Delta\rho/\rho)$ is greater than 20% for these values of d_F, d_s, and τ. With this choice of τ, the mean-free paths are (i) 4250 Å for the majority-spin electrons and 3540 Å for the minority-spin electrons in Fe; (ii) 3560 Å for electrons in Cr; and (iii) 4330 Å for electrons in Cu. These values correspond to all mean-free paths which are orders of magnitude larger than the film thicknesses, i.e., the clean-film limit, where interface effects are supposed to be paramount.

Some of the interesting results of the calculations are illustrated in Figs. 2–6. It was found in general that:

(a) $(\Delta\rho/\rho)$ is only a few percent when $S_M = S_m$, except[27] when both parameters are close to 1 (see Figs. 2 and 3).

(b) $(\Delta\rho/\rho)$, as a function of d_F, exhibits a variety of behaviors that include (i) a monotonic decrease with increas-



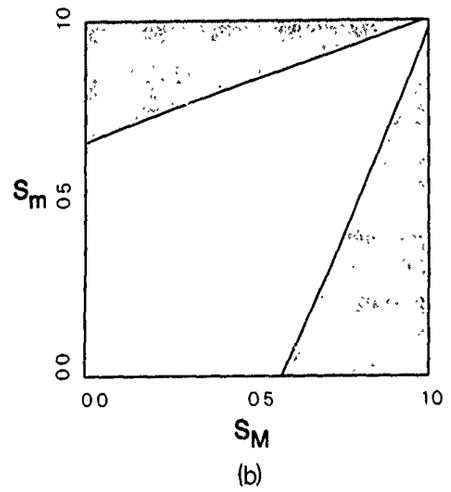


FIG. 2. The region in the two-dimensional parameter space (S_M, S_m), where $(\Delta\rho/\rho)>0.2$ for $d_F=20$ Å, $d_s=10$ Å, and $\tau=5.0\times10^{-13}$ s. (a) Potential parameters corresponding to $(Fe/Cr)_n$. (b) Potential parameters corresponding to $(Fe/Cu)_n$.

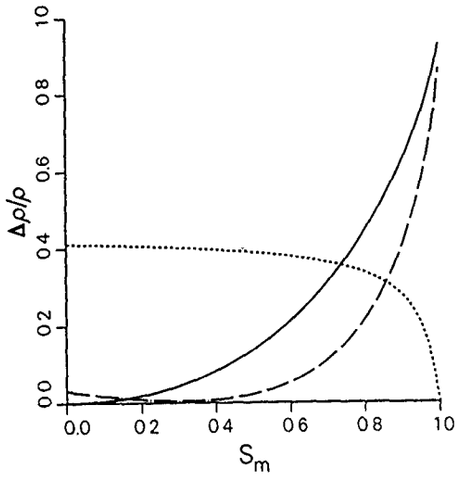

FIG. 3. Variation of $(\Delta\rho/\rho)$ as a function of S_m for the parameters of $(Fe/Cr)_n$, $\tau=5.0\times10^{-13}$ s, $d_F=d_s=10$ Å and three values of S_M: (1) dashed curve $S_M=1$; (2) chain-dotted curve $S_M=0.5$; and (3) solid curve $S_M=0$.

ing d_F; and (ii) an initial increase followed by a decrease (a single maximum); in all cases the asymptotic value as $d_F\to\infty$ is zero (see Fig. 4).

(c) $(\Delta\rho/\rho)$, as a function of increasing d_s, exhibits either (i) a continuous monotonic decrease, or, more commonly, (ii) a single maximum at a value of d_s of the order of d_F; the asymptotic value as $d_s\to\infty$ is also zero (see Fig. 5).

(d) $(\Delta\rho/\rho)$, as a function of the relaxation time τ, either (i) increases monotonically and saturates at a maximum value, or, more commonly, (ii) increases to a maximum, and then *very gradually* decreases (see Fig. 6).

Figure 2 contains information on how the quality of the interfaces influences the MR, for specific values of d_F, d_s, and τ. From the figure it is evident that the region of large MR is close either to the line $S_M=1$, or to the line $S_m=1$, and away from the line $S_M=S_m$. There is a very large asymmetry between S_M and S_m in $(Fe/Cr)_n$, but considerably less so in $(Fe/Cu)_n$.

A more realistic approach to the diffuse-versus-potential scattering at the interface requires the full angular dependence of the eight functions $S_{ij;k;\sigma}$. In general[28–31] the diffuse scattering is considerably larger for electrons impinging upon the interface in directions close to the normal. Grazing-angle electrons are less effectively scattered, and they tend to be almost completely internally reflected. A common (first-order) approximation to these functions[28–31] is

$$S_{ij;i;\sigma}=S_\sigma \exp[-4\eta^2(k_{i\sigma}\cos\Theta_i)^2], \tag{6}$$

$$S_{ij;j;\sigma}=S_\sigma \exp[-\eta^2(k_{i\sigma}\cos\Theta_i-k_{j\sigma}\cos\Theta_j)]. \tag{7}$$

Here, η is a parameter which depends on the roughness of the interface as well as the strength and physical distribution of the scattering centers at the interface, $k_{i\sigma}$ is the magnitude of the k vector at the Fermi sphere of the spin-σ electrons in layer i, and Θ_i is the angle between the electron velocity and

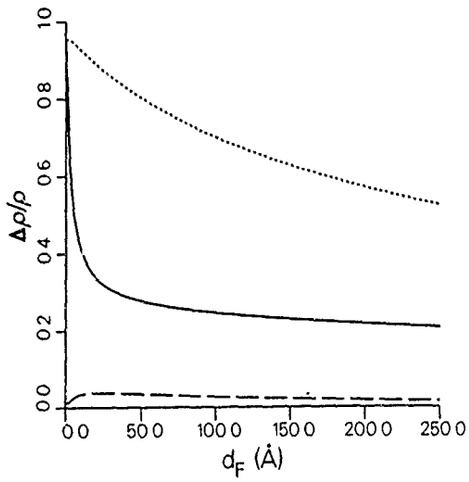

FIG. 4. Variation of $(\Delta\rho/\rho)$ as a function of d_F for the parameters of $(Fe/Cr)_n$, $d_s=10$ Å, $\tau=5.0\times10^{-13}$ s and three different values of S_M and S_m: (1) chain-dotted curve $S_M=S_m=0.8$; (2) dashed curve $S_M=0$, $S_m=1$; and (3) solid curve $S_M=1$, $S_m=0$.

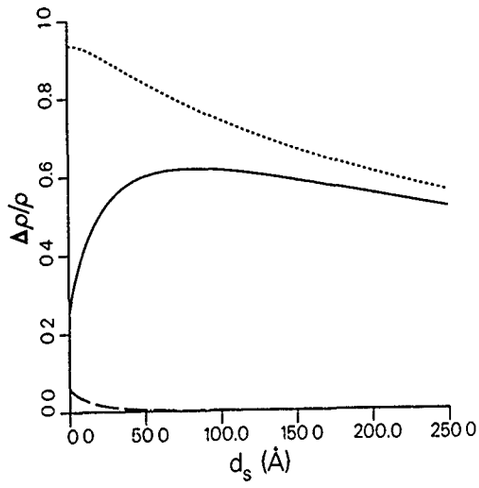

FIG. 5. Variation of $(\Delta\rho/\rho)$ as a function of d_s for the parameters of $(Fe/Cr)_n$, $d_F=20$ Å, $\tau=5.0\times10^{-13}$ s and different values of S_M and S_m: (1) solid curve $S_M=1$, $S_m=0$; (2) dashed curve $S_M=0$, $S_m=1$; and (3) chain-dotted curve $S_M=S_m=0.9$.

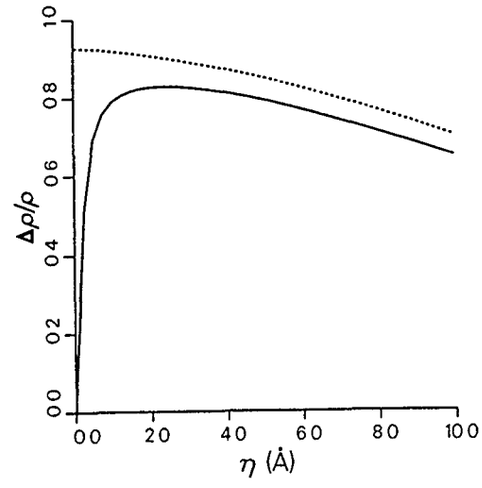

FIG. 7. Variation of $(\Delta\rho/\rho)$ as a function of η for the parameters of $(Fe/Cr)_n$, $d_s=10$ Å, $d_F=20$ Å and two different values of S_σ in Eqs. (6) and (7): (1) solid curve $S_M=S_m=1$; and (2) dashed curve $S_M=0$, $S_m=1$.

the normal to the interface; S_σ is the overall diffuse scattering strength at grazing angle $\Theta=\pi/2$. It should be noted that the limit $\eta=0$ reduces the approximation to the one previously discussed.

The influence of this angular dependence on the MR is shown in Fig. 7. As η increases, the MR in general decreases, except for the case in which S_M and S_m are very close in value; in the latter, the difference in k vector between the two spins, and the nonvanishing η produce an asymmetry in the diffuse interface scattering between the spins in the F layers, and thus increases the MR.

IV. DISCUSSION AND CONCLUSIONS

Figure 2(a) shows a marked asymmetry in the dependence of $(\Delta\rho/\rho)$ for $(Fe/Cr)_n$ on S_M and S_m, i.e., the majority- and minority-spin interface scattering have a very different effect on the MR. For this system

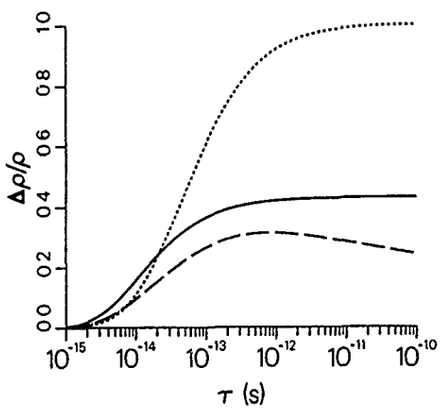

FIG. 6. Variation of $(\Delta\rho/\rho)$ as a function of τ for the parameters of $(Fe/Cr)_n$, $d_s=10$ Å, $d_F=20$ Å, and three different values of S_M and S_m: (1) chain-dotted curve $S_M=0$ and $S_m=0.7$; (2) dashed curve $S_M=0.5$ and $S_m=1$; and (3) solid curve $S_M=1$ and $S_m=0$.

$$|V_M|<|V_s|\approx|V_m|.$$

By contrast, a large asymmetry is not present in $(Fe/Cu)_n$, Fig. 2(b). Here,

$$|V_s|\approx|V_M|<|V_m|.$$

This difference in V_s has a large effect on the MR, as can be seen in plots of the in-plane current distribution across the layers.[26] Often when $(\Delta\rho/\rho)$ is very large, the current distribution responsible for the large value of $\sigma\uparrow\uparrow$ is such that it is highly concentrated in one type of layer, either in the ferromagnet or in the spacer. This effect, which can be called *channeling*, appears frequently when there is a GMR. When the channeling is in the spacer layer it occurs *only when there is parallel alignment*. Channeling in the FM layers, on the other hand, occurs (in one type of F layer for each electron spin orientation) for both the parallel and the antiparallel configurations. From these considerations the channeling in the spacer layer should be more intimately connected with a GMR. It should emphasized that channeling is present when the potentials are different; GMR requires, in addition, asymmetric values of S_σ. Channeling and GMR are strongly correlated.[32]

The experimentally observed values of MR in $(Fe/Cr)_n$ and $(Fe/Cu)_n$ multilayers can be obtained by the calculation with a proper choice of the parameters. However, the model in its present form, which considers all of the valence s and d electrons as comprising a single band with a single isotropic effective mass, yields effective resistivities $\rho\uparrow\uparrow$ and $\rho\uparrow\downarrow$ which are about an order of magnitude smaller than those measured in multilayer structures. The effective resistivities are too small because the model has too many free-electron-like conduction electrons: 8 in Fe, 6 in Cr, and 11 in Cu. Proper consideration must be taken of the fact that, in these metals, s and d electrons contribute very differently to the transport properties. The narrow character of the d bands has been accounted for in the single-band approach by a single, large, isotropic effective mass, four times larger than the

free-electron mass. A better approach to the problem would be to include a realistic band structure with its 12 bands, wide and narrow, as well as the hybridization and spin polarization. Such a treatment would make the calculations much more difficult.

Within the confines of a single-band model a simple, natural way to decrease the number of conduction electrons is by reducing the density of the electrons in each layer by a constant scaling factor, γ, independent of the material and the spin of the electron. It should be stressed that the introduction of such a scaling factor does not change the form of the results found above. The number of electrons and the magnetization decreases by a factor of γ. The resistivities $\rho\uparrow\uparrow$ and $\rho\uparrow\downarrow$ increase by a factor of about γ, and $(\Delta\rho/\rho)$ decreases by a factor of about $\gamma^{1/3}$. A value of $\gamma=8$ was chosen for making comparisons with experimental data. With this value the number of effective free-electron-like conduction electrons are 1.00 in Fe, 0.5 in Cr, and 1.38 in Cu. Calculations were able to yield values of the MR and the resistivities, $\rho\uparrow\uparrow$ and $\rho\uparrow\downarrow$, similar to those measured experimentally.

Baibich *et al.*[4] found that a multilayer of (Fe 30 Å/Cr 9 Å)$_{60}$, prepared by molecular beam epitaxy, had $(\Delta\rho/\rho)\approx 0.46$ and a absolute resistivity change of about 23 $\mu\Omega$ cm. With $S_M=0.23$, $S_m=0.98$, $d_F=30$ Å, $d_s=9$ Å, and $\tau=1\times10^{-13}$ s values of $\rho\uparrow\uparrow=30.6$ $\mu\Omega$ cm and $\rho\uparrow\downarrow=56.6$ $\mu\Omega$ cm were calculated, which corresponds to $(\Delta\rho/\rho)=0.46$ for the MR. Experimental values of ρ are between 20 and 80 $\mu\Omega$ cm. With this choice of γ, τ, and effective mass (i.e., an effective mass of four times the electron mass), the bulk mean-free paths are 425 Å for the majority-spin electrons and 354 Å for the minority-spin electrons in Fe; and 356 Å for the electrons in Cr.

Pétroff *et al.*[14] report that a multilayer (Fe 15 Å/Cu 15 Å)$_{60}$ made by sputtering, had the following characteristics: $\rho\uparrow\uparrow=24.8$ $\mu\Omega$ cm, $\rho\uparrow\downarrow=27.8$ $\mu\Omega$ cm, and $(\Delta\rho/\rho)=0.108$. With $S_m=0.71$, $S_M=0.92$, $d_F=d_s=15$ Å and $\tau=1\times10^{-13}$ s values of $\rho\uparrow\uparrow=25.2$ $\mu\Omega$ cm and $\rho\uparrow\downarrow=28.3$ $\mu\Omega$ cm were calculated, which correspond to $(\Delta\rho/\rho)=0.11$. Here, the bulk mean-free paths are 425 Å for the majority-spin electrons and 354 Å for the minority-spin electrons in Fe; and 433 Å for the electrons in Cu.

As seen above, a large MR requires, in general, a large difference in interface scattering for the different spins. When $S_M=S_m$ the MR is found to be not more than a few percent. Therefore, a large MR cannot be explained as being caused solely by different densities of electrons with different spins, which vary from layer-to-layer. What is required is a spin imbalance *and* a spin-dependent scattering mechanism at the interface, i.e., $S_M\neq S_m$. When such a spin-dependent scattering mechanism exists, for example when magnetic impurities are present at the interfaces, the MR is profoundly influenced by spatial variations in the density of electron spins. This is the main cause of the GMR effect in ferromagnetic multilayers.

[32] It should be noted that the channeling effect, *per se*, does not necessarily lead to a GMR, as can be seen from the case shown in Fig. 3 [$(\Delta\rho/\rho)=0$ for $S_M=S_m=1$; the current distribution is nevertheless concentrated in the ferromagnetic layers]. The GMR appears when, in the parallel arrangement, there is channeling for *only one spin* and diffuse interface scattering for the other one. In that case, in the antiparallel arrangement, both spins partake in the diffuse scattering, and the long electron trajectories (and the channeling) are lost.

Giant magnetoresistance in Co/Cu multilayers after annealing

T. R. McGuire, J. M. Harper, C. Cabral, Jr., and T. S. Plaskett[a)]
IBM Research Division, Thomas J. Watson Research Center, P.O. Box 218, Yorktown Heights, New York 10598

Multilayer films of [Co 10 Å/Cu(t)]$_{64}$ with copper thicknesses from $t=10$ to 29 Å annealed for 1 h at temperatures about 350 °C showed a decrease in sample resistivity at 4.2 K. The giant magnetoresistance (GMR) maximums for as-deposited films at $t=10$ Å and $t=23$ Å shifted with annealing. The GMR decreased for $t=10$ Å and $t=23$ Å but increased for $t=19$ Å and $t=29$ Å indicating a complex behavior with annealing. Similarities with granular films are discussed.

I. INTRODUCTION

It is known that both granular Cu-Co films[1–3] and multilayer films[4,5] undergo large changes in giant magnetoresistance (GMR) with annealing. Hylton *et al.*[4] found that sputtered multilayers of $Ni_{80}Fe_{20}$/Ag have no significant magnetoresistance in the as-prepared state but after annealing at just above 300 °C a GMR of over 5% at room temperature is observed. This GMR is attributed to the breakup of NiFe layers because of diffusion of the Ag layer into grain boundaries and cracks in the NiFe layers. A discontinuous magnetic layer is created with a distribution of magnetization directions which increases the spin-dependent electron scattering causing GMR.

For the Cu-Co system consider first the granular films where annealing precipitates Co particles from the Cu matrix. These particles cause large GMR from conduction electron spin-dependent scattering attributed mainly at the interface of the Co particle with the Cu matrix. In addition resistivity (ρ) decreases in annealed granular Cu-Co films because of the increased purity of the Cu matrix as the Co precipitates out.

Annealed multilayers of Cu/Co have been studied by Zhang *et al.*[5] They find for a series of films with varying Cu thickness that there is a decrease in resistivity with increasing annealing temperature (T) up to 300 °C. There is also a decrease in GMR at 300 °C but in some cases an increase is found at lower T. The GMR results are mainly for room temperature.

It is the objective of the present work to study a similar series of films as reported by Zhang *et al.*[5] with emphasis on low temperature measurements where the GMR is largest. Data are given in units of specific resistivity (ρ) and volume magnetization (M) to help in interpretation and for comparison with previous work.

II. EXPERIMENTAL RESULTS AND DISCUSSION

Our multilayer films are deposited on glass substrates by magnetron sputtering in a 3 m Torr Ar atmosphere. Multilayer structures are made[6,7] using computer control where substrates at ambient temperature are moved sequentially over each gun to deposit the Co or Cu layer. The films have the form Cu 10 Å/[Co 10 Å/Cu(t)]$_{64}$ where the Cu thickness t has values ranging from 10 to 29 Å. We previously reported[6] that Co/Cu multilayer films studied by high angle x-ray and transmission electron microscopy were found to be polycrystalline with a (111) texture and the Co had the fcc structure.

The films are annealed in a vacuum furnace at 350 °C. This temperature was based on that used in other studies[3,4] as well as from a continuous *in situ* measurement of ρ vs T for the multilayer film (Co 10 Å/Cu 23 Å)$_{64}$ which showed a linear rise in ρ up to 235 °C followed by a strong decrease at higher temperatures. Two films for each Cu thickness are annealed; a rectangular one for M and a disc sample for ρ. They were both measured prior to annealing.

Magnetic measurements are made with a "quantum design" superconducting quantum interference device magnetometer with the applied field H parallel to the plane of the film. The film is initially cooled in a -20 kOe field and then measured over the range $H=\pm 20$ kOe. The total volume of Co is determined from the rectangular area (approximately 0.55×1.2 cm^2) and Co thickness which is 640 Å for this series of films. Measured values of saturation volume magnetization M at 4.2 K are listed in the Table I. The saturated value for bulk Co at 4.2 K is $M_0=1430$ emu/cm^3, the listed values are scattered about the bulk value. Because of this variation of M we could not determine if there was any

TABLE I. Data at 4.2 K for as-deposited (d) and annealed (a) [Co 10 Å/Cu(t)]$_{64}$ films.[a]

Films Cu(t)	ρ_{max} ($\mu\Omega$ cm)	ρ_{min} ($\mu\Omega$ cm)	GMR (%)	w (kOe)	M_0 (emu/cm^3)
10 Å d	24.5	18 8	36.3	2.6	1350
a	15.8	14.0	12.9	3.5	1350
19 Å d	14.1	13.1	7.4	0.5	1450
a	9.4	6.9	36.8	0.9	1470
21 Å d	15.9	12.4	28.0	0.3	1360

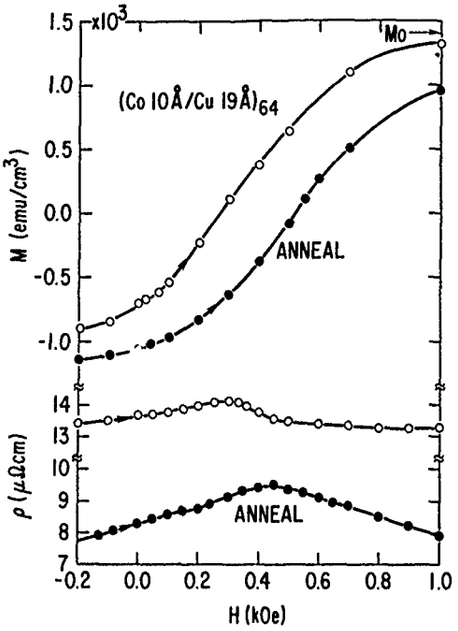

FIG. 1. Magnetization M and resistivity ρ at 4.2 K of as-deposited and annealed multilayer film (Co 10 Å/Cu 19 Å)$_{64}$ as a function of applied field H. The saturation value M_0 for Co is marked by an arrow.

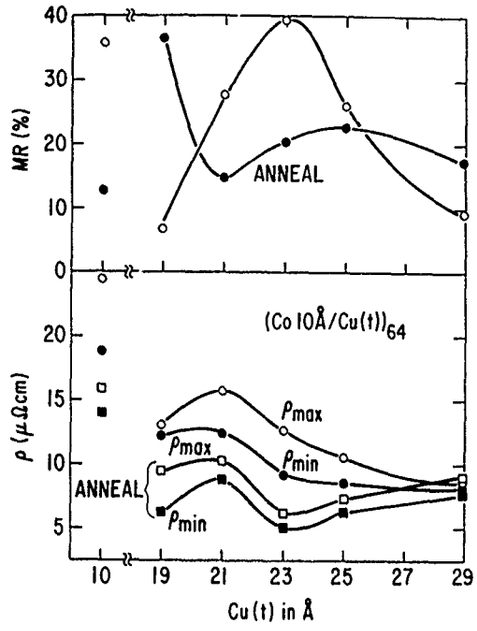

FIG. 3. Resistivity at 4.2 K for various Cu(t) thicknesses. GMR is calculated from $(\rho_{max}-\rho_{min})/\rho_{min}$.

change in saturation M before and after annealing.

Figures 1 and 2 shows M vs H plots at low values of H taken from a complete magnetization curve for as deposited and annealed films with $t=19$ Å and Fig. 2 for $t=23$ Å. These plots illustrate a general feature that the annealed samples all saturate more slowly and have a slightly higher coercive field (H_c) than the as-deposited samples. At

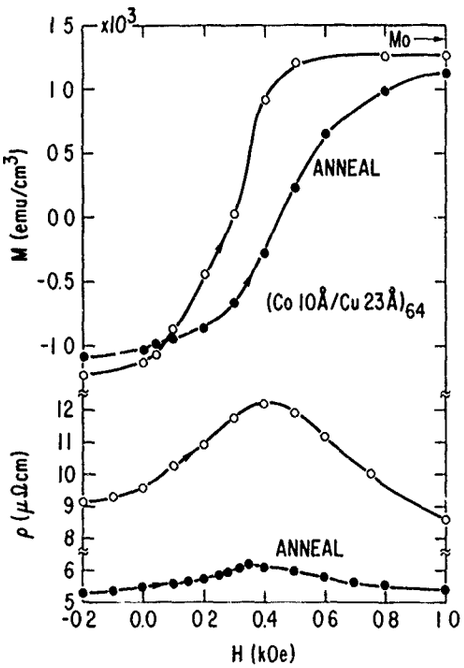

FIG. 2. Magnetization M and resistivity ρ at 4.2 K of as-deposited and annealed multilayer film (Co 10 Å/Cu 23 Å)$_{64}$ as a function of applied field H. The saturation value M_0 for Co is marked by an arrow.

$H=1000$ Oe the as-deposited multilayer film has almost reached saturation while the annealed film is several percent below saturation.

Figures 1 and 2 also show resistivity as a function of field for the respective compositions and annealed state. Resistivity is measured on a disc sample using the van der Pauw method over the range $H=\pm 18$ kOe. In both Figs. 1 and 2 the maximum in resistivity (ρ_{max}) is approximately at H_c. Both ρ_{max} at H_c and ρ_{min} at $H=18$ kOe are listed in the Table I. The ratio $(\rho_{max}-\rho_{min})/\rho_{min}$ gives the GMR and this is tabulated as MR(%). We note that MR(%) increases with annealing for the $t=19$ Å but MR% decreases for $t=23$ Å. The annealed magnetization curves, however, look about the same for both thicknesses. Figure 3 shows ρ_{max}, ρ_{min}, and MR(%) vs Cu(t). Compositions $t=10$ Å and $t=23$ Å correspond to the first two peaks[4,7] in GMR as a function of t for as-deposited films. As seen in Fig. 3 the peaks in GMR are shifting with annealing.

Another change that takes place during annealing is the width of the ρ vs H curve. As shown on Figs. 1 and 2 the width of the maximum region in the annealed films has increased somewhat. We define the half-width (w) of the ρ vs H curve as that width in kOe midway between ρ_{max} and ρ_{min}. We find that w increases at 4.2 K from about 2.6 to 3.5 kOe for $t=10$ Å and 0.7 to 0.8 kOe for $t=23$ Å with annealing as listed in Table I. This increase in w is opposite to that found by Hylton *et al.*[4] in NiFe/Ag multilayers where w narrowed with annealing.

The decrease in ρ in Cu/Co multilayers has been attributed in part to grain growth by Zhang *et al.*[4] We suggest also there is the possibility that any mixing of the Cu and Co at the interface in the as-prepared film is now changed in some way by Co precipitation from annealing as found in granular films. Since the spin-dependent scattering of the conduction

electrons is chiefly involved with the interface[8] this could cause a change in GMR depending on initial conditions of the as-deposited film and the annealing temperature. Zhang *et al.* found that room temperature GMR increased at annealing temperatures of 250 °C in some of their compositions. It appears that the annealing has a complex behavior and that there may exist a sensitive threshold of temperatures which gives the best interface conditions for large GMR.

In addition we had previously pointed out[6] that the shape of the ρ vs H curve for [Co 10 Å/Cu 10 Å]$_{64}$ is within a few percent identical with granular Cu-Co films.[2] This similarity suggests that as-deposited multilayer [Co 10 Å/Cu(t)]$_n$ may have noncontinuous Co layers that act like a granular particulate. After annealing the discontinuities in the Co layer are no longer the same size and GMR is decreased but in some cases an optimum is reached in terms of discontinuities as well as interface conditions and GMR is increased. A series of annealing temperatures for each composition are needed to determine the best T to give maximum GMR.

III. SUMMARY

(a) The peak value of GMR with Cu thickness shifts with annealing at 350 °C.

(b) There is a decrease of film resistivity as much as 50% with annealing at 350 °C.

(c) The half-width of the magnetoresistance vs field curve increases with annealing and this increase correlates with the slower increase in films magnetization with field.

The 2-ML (monolayer) oscillation period has been observed in the magnetization as well as in the magnetoresistance of Fe/Cr/Fe trilayers. Kerr effect measurements were performed in order to verify the periodicity and determine the kind of the coupling between the Fe layers. The magnetoresistance loops show characteristic steps at magnetic field values at which the size of the magnetization changes.

I. INTRODUCTION

Magnetic multilayers have attracted much attention since they display a wide variety of interesting physical properties.[1–11] In the Fe/Cr system, the coupling between adjacent Fe layers was found to switch between ferromagnetic and antiferromagnetic depending on the thickness of the Cr interlayer.[1] This was seen first in a giant magnetoresistance, the amplitude of which oscillated with the thickness of Cr with a period of 18 Å.[2,3] Magneto-optic Kerr effect measurements (MOKE) confirmed this period for the coupling between Fe layers.[5] With improvements in the layering quality, an additional short period oscillation was seen in Fe/Cr/Fe trilayers, probed by scanning electron microscopy with spin polarization analysis (SEMPA).[9] The short period oscillation was found to have a length of two monolayers and be commensurate with the spin density wave found in bulk Cr.[12,13] However, the SEMPA and MOKE studies were performed on trilayers which were grown on Fe whiskers or thick metallic buffer layers, making these samples unsuitable for electrical transport studies.

We report here on electrical transport and magneto-optical studies performed on Fe/Cr/Fe trilayers grown epitaxially on MgO(100) substrates without any buffer layer. Both the magnetoresistance (MR) and the MOKE measurements clearly display the existence of the short period oscillation. At the same time the MOKE measurements are used to identify the nature of the coupling between the Fe layers. This also allows the direct comparison of the Kerr loops with the magnetic field dependence of the MR. The magnetoresistance displays steps at values of the magnetic field at which the absolute value of the magnetization of the sample changes.

II. SAMPLE PREPARATION

The Fe/Cr/Fe trilayers were prepared in a Riber molecular beam epitaxy (MBE) deposition system (base pressure 2×10^{-11} mbar) equipped with two electron-beam guns and four Knudsen cells. Fe and Cr (both starting materials of 99.996% purity) were *e*-beam evaporated at a rate of 1 Å/s on MgO (100) substrates held at 150 °C. A homemade feedback control system using Balzers quadrupole mass spectrometers was utilized to stabilize the rate to within 1%. *In situ* reflection high-energy electron diffraction (RHEED) was used to monitor the quality of the substrate, the epitaxial relationship and the quality of the growth.

The Fe thickness of the top and bottom layers was 50 Å and the Cr thickness varied, respectively, from 4 to 20 Å and from 0 to 40 Å with slopes of 1 and 2 Å of Cr per mm for the two samples. The wedges were prepared using a computer controlled movable shutter. The wedge direction was chosen parallel to the [010] direction of the Fe/Cr layers (the [011] direction of the MgO) in order to facilitate alignment with the magnetic field during the MOKE and MR experiments. The trilayer was then covered with 30 Å of Ag as protection against oxidation of the Fe.

First, MOKE experiments were performed at room temperature, using a Kerr effect configuration which is sensitive for the longitudinal Kerr effect. The field was applied parallel to the easy [010] axis of the Fe layers. A micrometer screw was used to move the wedged sample through the laser beam, with an alignment accuracy of 10 μm. The coupling strength between the Fe layers was estimated from the saturation field of the Kerr rotation.

Subsequently, one sample was patterned using standard photolithographic techniques to produce a stripe pattern. The stripes used for transport measurements were 80 μm wide and about 1 cm long and separated from each other by about 30 μm. Each stripe has a Cr thickness variation of 0.2 Å, due to the wedge itself and any possible misalignment during the lithography procedure. To measure the MR, leads were attached to the sample by ultrasonic wire bonding. Four-probe measurements were performed at 4.2 K in a cryostat equipped with a superconducting magnet. Since the signal was relatively small, a Linear Research bridge was used to measure the resistance versus field data. The sample was aligned in such a way that the Fe [010] direction was parallel to the field.

In the following the magnetoresistance is defined as the ratio $\Delta\rho/\rho_s$, with $\Delta\rho=\rho_0-\rho_s$, where ρ_0 is the resistivity at $H=0$ Oe and ρ_s is the saturation resistivity at $H=3$ kOe. We define the magnetization saturation field as the field, H_s at which the Kerr signal reaches its saturation value.

III. RESULTS AND DISCUSSION

Figure 1 shows a plot of H_s from the MOKE measurements and the MR of the transport measurements versus Cr

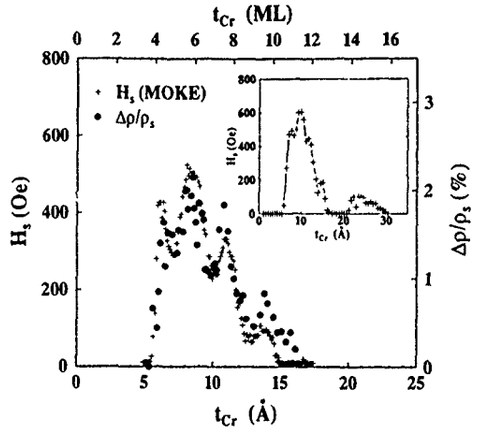

FIG. 1. The saturation field H_s (crosses, scale at left) for the Kerr rotation, and MR (filled circles, scale at right) for the magnetoresistance vs Cr interlayer thickness in angstroms and monolayers. The inset shows a plot of the saturation fields obtained from the MOKE measurements over a wider range of t_{Cr}.

thickness in both angstroms and monolayers. Both sets of data clearly show four peaks in the range 4 to 10 ML (monolayers). This 2-ML oscillation period is in agreement with the value reported from SEMPA measurements.[9] The inset in Fig. 1 shows a plot of the saturation fields over a wider range of t_{Cr} determined from the MOKE measured on a sample with a larger variation in t_{Cr}. The oscillation with the period of 18 Å in t_{Cr} is clearly visible.

Figure 2 shows typical MR and MOKE hysteresis curves for different values of t_{Cr}. With increasing t_{Cr} the nature of the coupling changes from biquadratic coupling [at about t_{Cr}=7 Å, see Fig. 2(a)], over to a combination of bilinear and biquadratic coupling [around t_{Cr}=8.5 Å, see Fig. 2(b)] to again biquadratic coupling [at t_{Cr}=13 Å, see Fig. 2(c)]. The arrows on the figures indicate the orientation of the magnetization of the top and bottom Fe layers.

In the case of biquadratic coupling, there is a remnant field at zero applied field and the magnetization vectors in the layers of Fe are not parallel, but differ by 90°. As the field increases, the magnetization of the layers becomes aligned parallel at the saturation field. The sample with t_{Cr}=8.5 Å is antiferromagnetically coupled at zero field, and switches to 90° coupling at a higher field before being saturated at H_s. The 90° coupling is explained in terms of biquadratic coupling possibly due to a roughness at the interfaces of 1 ML monolayer.[14] In all cases, the total strength of the coupling is well described by the saturation field. The surface energy per unit area as a function of the individual coupling strengths is given by

$$E_s = -J_1 \cos\theta - J_2 \cos^2\theta,$$

where J_1 and J_2 are the bilinear and biquadratic coupling strengths and θ is the angle between the magnetization vectors in the two Fe layers. From the MOKE measurements, J_1 and J_2 can be determined. For example, at t_{Cr}=8.5 Å, J_1 and J_2 were found to be, respectively, -0.46 mJ/m^2 and -0.20 mJ/m^2.

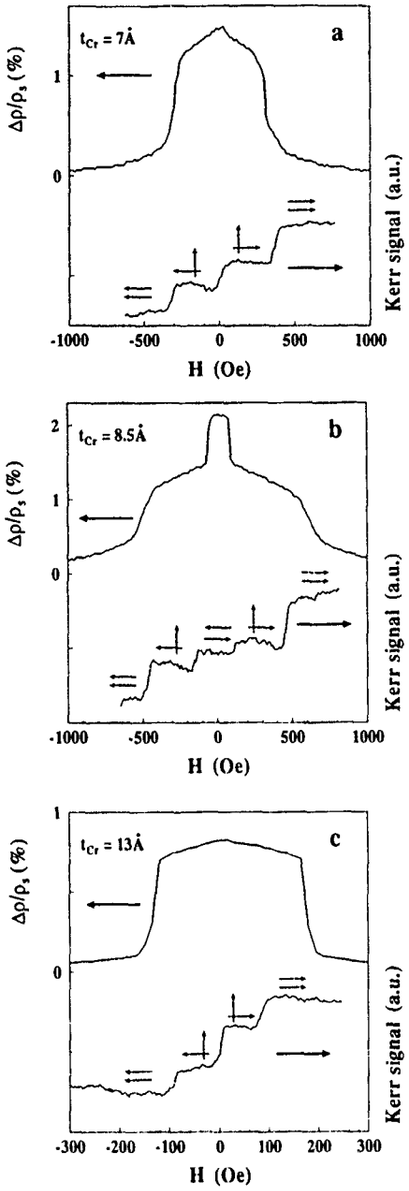

FIG. 2. MR at 4.2 K and Kerr effect at 300 K over applied magnetic field of Fe/Cr/Fe trilayers for three different values of t_{Cr}: (a) t_{Cr}=7 Å, showing biquadratic coupling; (b) t_{Cr}=8.5 Å, showing a combined bilinear and biquadratic coupling; (c) t_{Cr}=13 Å, showing biquadratic coupling. The arrows indicate the direction of magnetization of the two Fe layers. The corresponding MR loops show steps at field values at which the size of the magnetization changes.

Figure 2 also shows the measured MR loops for the different values of t_{Cr}. In the case of biquadratic coupling [Figs. 2(a) and 2(c)] the MR displays steps at values of the magnetic field at which the 90° coupling is saturated. The reversal of the sign of the magnetization at zero field produces only a step in the Kerr loop but not in the MR. This can be easily explained by the fact that the MR is sensitive only to changes in the size of the magnetization but is not sensitive to changes of its orientation.

In Fig. 2(c) the magnetic field values of the steps in the Kerr effect (measured at 300 K) and the MR (measured at 4.2 K) do not match, a fact which is likely due to the tem-

perature dependence of the coupling constants. This temperature dependence is changing with t_{Cr},[15] which is in qualitative agreement with the decrease of H_s with increasing temperature at t_{Cr}=13 Å [Fig. 2(c)].

The MR loop at t_{Cr}=8.5 Å [Fig. 2(b)], corresponding to the maximum of the MR oscillations, reproduces all four steps visible in the magnetization. Each of the steps in the magnetization corresponds to a change in its absolute value and accordingly causes a change in the magnetoresistance. Small differences in the values of the switching fields can be explained by the different coupling strength due to the different measuring temperature.

The MR curves of Fe/Cr superlattices do not display sharp steps but have more bell-shaped or triangular-field dependencies[2,16,17] This may be due to an averaging effect over many layers which have different coupling strengths. A bell-shaped MR curve would correspond to either biquadratic coupling as in Fig. 2(a) or to bilinear coupling which should naturally produce a similar shape. The triangular shape would be a reminiscent of the combined bilinear and biquadratic coupling as in Fig. 2(b).

IV. CONCLUSION

We have observed the 2-ML period in the oscillations of the magnetoresistance in Fe/Cr/Fe trilayers. This periodicity arises from the antiferromagnetism of the Cr interlayer. MOKE measurements indicate that the Fe layers can be aligned parallel, antiparallel, or 90° degrees off. The magnetoresistance displays characteristic steps at values of the applied magnetic field at which the amplitude of the magnetization changes.

Structural and magnetic properties of Co/Ag multilayers

E. A. M. van Alphen, P. A. A. van Heijden, and W. J. M. de Jonge
Department of Physics, Eindhoven University of Technology, P.O. Box 513, 5600 MB Eindhoven, The Netherlands

The structural properties and growth of sputtered Co/Ag multilayers were studied with nuclear magnetic resonance. For samples with a nominal Co thickness of less than 10 Å the Co grows in three-dimensional islands. If the nominal Co thickness is larger than 10-Å continuous Co layers are formed. The relation of the structural properties with magnetization and magnetoresistance is discussed.

Currently Co/Ag multilayers and Co-Ag alloys are widely studied because of their giant magnetoresistance (MR) effects.[1–3] Since the magnetoresistance and the magnetic properties are strongly related to the structure of the magnetic layer and the topology of the interfaces, the present paper focuses on the structural information as can be obtained from ^{59}Co nuclear magnetic resonance (NMR) studies. We also discuss the influence of annealing on the magnetoresistance. The strain in these Co/Ag multilayers has been studied previously.[4]

The Co/Ag multilayers were made by magnetron sputtering on Si [100] at the Michigan State University. The deposition rate was 4 Å/s for Co and 8 Å/s for Ag. The Ag layer thickness was 20 Å for all the samples, the Co thickness varied between 4 and 100 Å. The number of repetitions was 100. X-ray diffractometry confirmed the superlattice modulations and showed [111] texture.

The NMR experiments were performed with a coherent spin echo spectrometer at a temperature of 1.5 K. Magnetic fields, larger than the saturation field, were applied parallel to the film plane. The hyperfine field B_{hf} was obtained from the resonance field B_r and the frequency f using the relation $2\pi f=\gamma(B_{hf}-B_r)$, where γ is the ^{59}Co nuclear gyromagnetic ratio ($\gamma/2\pi=10.054$ MHz/T).[5] The transverse magnetoresistance was measured at room temperature in fields up to 1.3 T using a standard four-probe method.

Figure 1 shows the NMR spectra of the 100·(x Å Co+20 Å Ag) multilayers with $x=4$, 8, 10, 12, and 15 Å Co. The integral of the intensity is normalized to the nominal Co thickness. Apart from the intensity which arises from bulk Co nuclei around 21 T, a clear contribution at lower fields can also be observed. This intensity at lower fields is believed to originate from Co atoms at or near the interfaces (Co atoms with one or more Ag neighbors). The maximum at 17.5 T probably arises from Co atoms at locally flat (111) interfaces. Both the interface and the bulk lines are much broader than the lines found in Co/Ni and Co/Cu multilayers were the structure of the Co is mainly fcc.[5] This is because the Co in Co/Ag multilayers is a mixture of fcc Co, hcp Co, and Co in stacking faults.

Figure 2 gives a survey of the different contributions to the spectrum as a function of the Co thickness. The intensities are obtained by dividing the spectra in two parts and integration of these parts (interface part 15–19.5 T, bulk part 19.5–23 T). Changing the boundary between the bulk and the interface part a little bit, as well as comparing the height of the interface and the bulk line, give similar results.

Remarkable is the presence of the bulk Co signal for the sample with a nominal thickness of 4 Å (2 monolayers) Co (Fig. 1). The presence of this signal demonstrates that the Co did not grow in the layer-by-layer mode but in three-dimensional islands, becuase in the case of layer-by-layer growth every Co atom would have Ag neighbors. If the Co layer thickness is increased from 4 to 8 to 10 Å both the interface and the bulk intensity increases and the relative increase is approximately the same for both. Consequently, this implies that the volume to surface ratio remains constant [see Fig. 2(c)]. This behavior can only be understood if, in the nominal Co thickness range 4–10 Å, the growth mode is such that the number of three-dimensional islands increases or the islands become larger. (This last option is only possible when the influences of the edges of the islands are negligible.) The bulk intensity [Fig. 2(b)] increases from 4 to 10 Å Co with a certain slope. The fact that this line extrapolates approximately to zero also indicates that the growth cannot be layer-by-layer [such a growth would result in a straight line with a positive intersection with the Co thickness axis; 4 Å for perfectly smooth layers and more than 4 Å for layers with a certain roughness (Ref. 5)].

For Co thicknesses increasing from 10 to 15 Å the intensity of the interface remains approximately constant [Fig. 2(a)] while the amount of Co atoms in the bulk increases [Fig. 2(b)]. The constant intensity of the interface shows that for Co thicknesses larger than 10 Å apparently a continuous Co layer is formed and the islands mentioned before have merged and cover the whole layer at a nominal thickness of 10 Å. This implies that the Co layers are build with clusters of Co with a thickness of about 5 ML (monolayers) in the nominal range up to 10 Å Co. As an additional check on this conclusion we can compare the interface to bulk ratio of the spectra of 4, 8, and 10 Å Co. Clusters with a Co thickness of 5 ML would have at least 2-ML Co at the interface and at most 3 ML bulk Co resulting in a bulk to interface intensity ratio of at most 3/2 (if the interfaces are sharp and the islands are relatively large). Roughness as well as a finite lateral size would result in a ratio smaller than 3/2. The measured bulk/interface ratio of about 1 [Fig. 2(c)] fits reasonably in this model. If we assume that the islands are cubes or cylinders with a thickness of 10 Å and implement the experimental bulk to interface ratio of 1, we can estimate the lateral dimensions of the islands. This approximation results in typical lateral length scales of about 50 Å. Roughness would decrease this number.

In this same (simple) growth model we can also predict

 0021-8979/94/76(10)/6607/3/$6.00 © 1994 American Institute of Physics

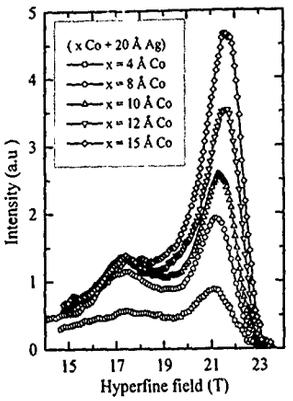

FIG. 1. NMR spectra measured at 1.5 K of 100·(x Å Co+20 Å Ag) multilayers. The integral (between 15 and 23 T) of the spectra are normalized to the nominal Co thickness. The spectra are corrected for enhancement.

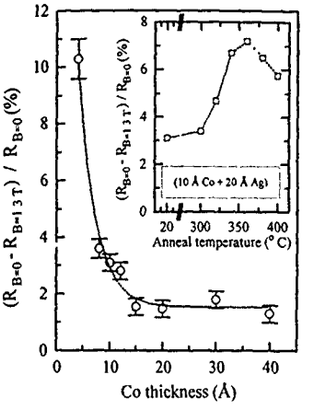

FIG. 3. Magnetoresistance as a function of the nominal Co thickness. The inset shows the MR of (10 Å Co+20 Å Ag) as a function of the anneal temperature. All MR measurements were performed at room temperature with the applied field parallel to the film plane.

the increase of the bulk to interface ratio above the nominal thickness of 10 Å since in our model all Co above this thickness contributes to the bulk intensity. The resulting prediction is shown by the solid line in Fig. 2(c) and fits remarkably well with the data for Co thicknesses just above 10 Å. If the Co thickness is further increased (t_{Co}>15 Å) the increase of the interface intensity [Fig. 2(a), interfaces become rougher] brings about a deviation of the data with this theoretical line.

The growth mode of the Co/Ag multilayers observed in the present experiments is in accordance with the expectations based on a comparison of the surface energies of Co and Ag.[6] Because the surface energy of Co is much larger than the surface energy of Ag and because the atomic interaction between the Co and the Ag atoms is weak,[7] Co is expected to grow in three-dimensional islands on Ag (Volmer–Weber mode) and Ag is expected to grow in the layer-by-layer mode on Co. Earlier reflection high-energy electron diffraction (RHEED) studies on molecular beam epitaxy (MBE) grown Co/Ag multilayers[8] yielded, for some growth temperatures, similar results, although in this paper no information is given about the size of the clusters.

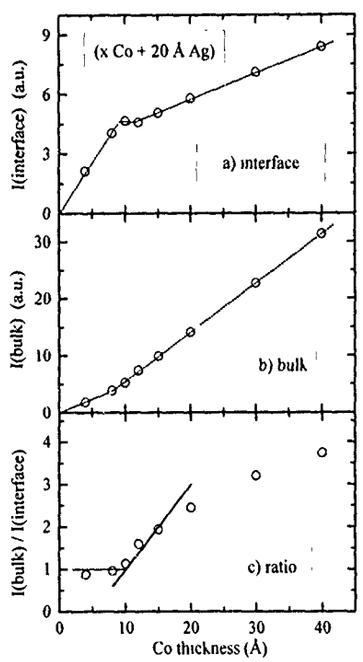

FIG. 2. Intensity of the interface part (a), the bulk part (b), and the ratio between the bulk and the interface part (c), as a function of the nominal Co thickness. The dotted lines are guides to the eye, the solid line in Fig. 2(c) is in accordance with the model discussed in the text.

The magnetoresistance as well as the magnetization of the present series of samples has been investigated.[9] We will restrict ourselves here to a few general comments specifically in relation to the structural data observed by NMR.

The magnetoresistance of these Co/Ag multilayers, defined as $(R_{B=0} - R_{B=1.3\ T})/R_{B=0}$, is shown in Fig. 3. The MR increases strongly for nominal Co thicknesses smaller than 10 Å. As we have seen this is the regime in which the Co layers are discontinuous. For nominal Co thicknesses larger than 10 Å (continuous Co layers) the MR is small and almost independent of the Co thickness. The larger MR for the discontinuous Co layers might be caused by mechanisms similar as reported by Hylton *et al.*[10] for the NiFe/Ag system; isolation of pinholes or interlayer magnetostatic coupling. One difference between the present Co/Ag system and the NiFe/Ag system is that now the transition from continuous to discontinuous layers is not achieved by annealing but is already present in the as deposited state (for t_{Co}<10 Å).

The restoration of interlayer (AF) coupling as deduced from the decrease of the remanent magnetization (M_r) in NiFe/Ag does not seem valid for Co/Ag. Although we observed in (Co/20 Å Ag) a strong decrease of M_r in the nominal t_{Co} range below 10 Å (when discontinuous layers are formed), we also found an identical decrease in a (6 Å Co+40 Å Ag) multilayer, where the interlayer coupling (if any) is weak. In our analysis the behavior of M_r is brought about by the change of anisotropy (magnetostatic as well as surface) when the continuous layer breaks up in (noninteracting) clusters. This ultimately results in almost isotropic

magnetization for the 4-Å Co system and an increase in MR due to the transition from a ferromagnetic layer system to an assembly of decoupled clusters. This effect is enhanced upon annealing as is corroborated by NMR.

A similar dependence of the MR on the Co thickness for Co/Ag multilayers is reported by Araki.[2] As a reason for the strong increase of the MR properties below 10 Å of Co an increase of the fcc phase of Co for thin Co layers is suggested. In Fig. 1, however, we can see that the line shape of the bulk part does not change when the Co layers become thinner. From this we can conclude that, for the present Co/Ag multilayers, the changes in the MR cannot be explained by change in the structure of the Co.

The inset of Fig. 3 shows the magnetoresistance of the Co/Ag multilayer with 10 Å Co and 20 Å Ag as a function of the anneal temperature. When the multilayer is annealed the MR first increases (from 3% to 7%), while for anneal temperatures higher than about 360 °C the MR decreases upon annealing. This behavior agrees with earlier results of Tosin *et al.*.[11]

In summary, we have shown with NMR that the growth of sputtered Co/Ag multilayers starts with a three-dimensional island growth of Co. For nominal Co thicknesses larger than 10-Å continuous Co layers are formed. The strong increase in the magnetoresistance for nominal Co thicknesses smaller than 10 Å is related to the transition from continuous to discontinuous Co layers in this thickness range. A more detailed paper on the MR of Co/Ag multilayers with discontinuous Co layers is planned.[9]

The authors gratefully acknowledge the Michigan State University, where the Co/Ag multilayers were produced in the sputtering system funded by the U.S. National Science Foundation under Grant No. DMR-9122614, and the MSU Center for Fundamental Materials Research.

Magnetic states of magnetic multilayers at different fields

P. A. Schroeder, S.-F. Lee, P. Holody, R. Loloee, Q. Yang, W. P. Pratt, Jr., and J. Bass

The resistance of an as-sputtered magnetic multilayer in zero applied magnetic field can be considerably different from the maximum resistance measured after the multilayer has been cycled to above its saturation field. We examine the relation between these two resistances in some Ag/Co, Cu/Co, and Cu/NiFe multilayers, and its implications for interpreting giant magnetoresistance.

The magnetoresistance (MR) of a magnetic multilayer composed of alternating thin layers of a ferromagnetic (F) and a nonmagnetic (N) metal is defined as $\mathrm{MR}(H)=[R(H)-R(H_s)]/R(H_s)$, where H_s is the in-plane magnetic field at which the resistance $R(H)$ saturates at its lowest value. This quantity can be measured with the current parallel (CIP-MR) or perpendicular (CPP-MR) to the layer planes. Figure 1 shows the resistance in CIP and CPP geometries, along with the total magnetization M parallel to the layer planes, for a Cu(6 nm)/Co(6 nm) multilayer as a function of H. We see that there are two different states of locally maximal MRs: one, labeled H_0, the as-grown state at $H=0$, which might be associated with the demagnetized state of the multilayer; and one at H_p, the state of maximum resistance after cycling to above H_s. H_p is close to the coercive field, H_c, where $M=0$. In this article, we provide some new experimental information about $\mathrm{MR}(H_0)$ and $\mathrm{MR}(H_p)$, to stimulate more thought about the significance of both quantities.

The largest MRs in magnetic multilayers occur when the N-metal layer thickness, t_N, is such that the magnetizations of neighboring F layers are aligned antiparallel (AP) to each other in zero field—antiferromagnetic (af) coupling. In this case, H_p is essentially zero, and $\mathrm{MR}(H_0)\approx\mathrm{MR}(H_p)$. This is the situation that is standardly modeled, because the magnetic states of the system are known at both limits of the MR. Unfortunately, af coupling gives large values of H_s, which make such multilayers unsuitable for most applications. There is thus interest in understanding the MR when there is only weak coupling between F layers, such as that illustrated in Fig. 1. From studies of oscillatory behavior in magnetic multilayers, we take this regime as $t_N \geq 6$ nm.[1,2]

The most direct attack upon the "weak coupling" regime was made by Zhang and Levy,[3] who proposed modeling the $H=H_c$, $M=0$ state as a superposition of statistically uncorrelated (SU) magnetic configurations that satisfy the condition $\Sigma M_i=0$. (M_i is the magnetization of individual layers.) They noted that the CPP-MR should be the same for the SU and AP states, but that the CIP-MR should be smaller for the SU than the AP state.

In the weak coupling regime, the CIP-MR has usually been evaluated at H_p, both because this state is reproducible after cycling to above H_s and because it occurs near H_c—i.e., near $M=0$. Zhang and Levy[3] have analyzed such data in terms of a SU state, and argued that such a state is needed to explain why the CPP-MR is usually so much larger than the CIP-MR. [We note that our experiments suggest that H_p is not identical to H_c, and $M(H_p)$ may be an appreciable fraction of $M(H_s)$.]

For the CPP-MR, in contrast, we have focused upon H_0[4,5] as the $M=0$, SU state, for two reasons: (1) $\mathrm{MR}(H_0)$ is usually larger than $\mathrm{MR}(H_p)$—and one expects the AP and SU states to have the highest possible MRs. (2) It fits better a data analysis[6] involving extrapolation from the af regime to the completely uncoupled regime, that we now describe. We and others have shown[5,7,8] that a two-current model, in which spin up and spin down electrons carry current independently through the multilayer, gives a good description of a wide range of CPP-MR data on Ag/Co,[5,6,9] Cu/Co,[6,9] and Cu/NiFe.[10] For multilayers in the AP or SU configurations, with fixed F metal thickness t_F and fixed total thicknesses t_T, this model predicts that the plot of the total resistance R_T versus number of bilayers N, should be a straight line with an intercept on the ordinate axis that can be independently determined. This straight line should pass through the data for AP states and for uncoupled SU states, but not those for which significant ferromagnetic coupling is present. Experimentally we find that such a line fits the data for H_0 much better than the data for H_p in Cu/Co,[6] where the differences between the two sets of data are large. The H_0 data for Cu/NiFe also fits this pattern but the distinction between the H_0 and H_p data is small.[11]

With this background we now turn to a more detailed examination of the ratio $\mathrm{MR}(H_0)/\mathrm{MR}(H_p)$ in our sputtered multilayers than has hitherto been presented. We first examine the ratio under different conditions in different multilayer systems, and then describe some preliminary tests we have made to see whether the H_0 states can be restored by demagnetizing a sample.

In Figs. 2(a), 2(b) we plot the ratio $\mathrm{MR}(H_0)/\mathrm{MR}(H_p)$ for a series of Ag/Co, Cu/Co, and Cu/NiFe samples with fixed $t_F=6$ nm, and with $t_F=t_N$, respectively.

For "uncoupled" samples, $t_N \geq 6$ nm, we see that most of the Ag/Co and Cu/Co data lie in a band around a ratio of 1.5 in Fig. 2(a) and around 2 in Fig. 2(b). Importantly, most of the CIP-MR data for Ag/Co behave very similarly to the CPP-MR data for both Ag/Co and Cu/Co. For these "uncoupled" samples, H_0 and H_p thus seem to have similar significance for the CPP- and CIP-MRs. This similarity rules out the possibility that the H_0 and H_p states are AP and SU states, respectively. For while in CIP this would result in $R(H_0)/R(H_p)>1$, in CPP the ratio would be 1. The situation for Cu/NiFe is more complex, with some data falling close to the data for Ag/Co and Cu/Co, and other data falling around

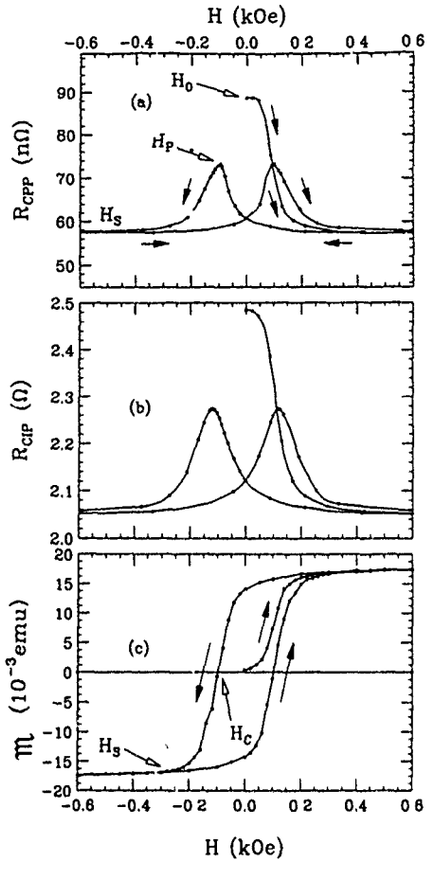

FIG. 1. (a) and (b) give the resistances of a [Cu(6 nm)/Co(6 nm)]×60 multilayer in the CPP and CIP geometries, respectively. (c) shows the magnetization of the same sample.

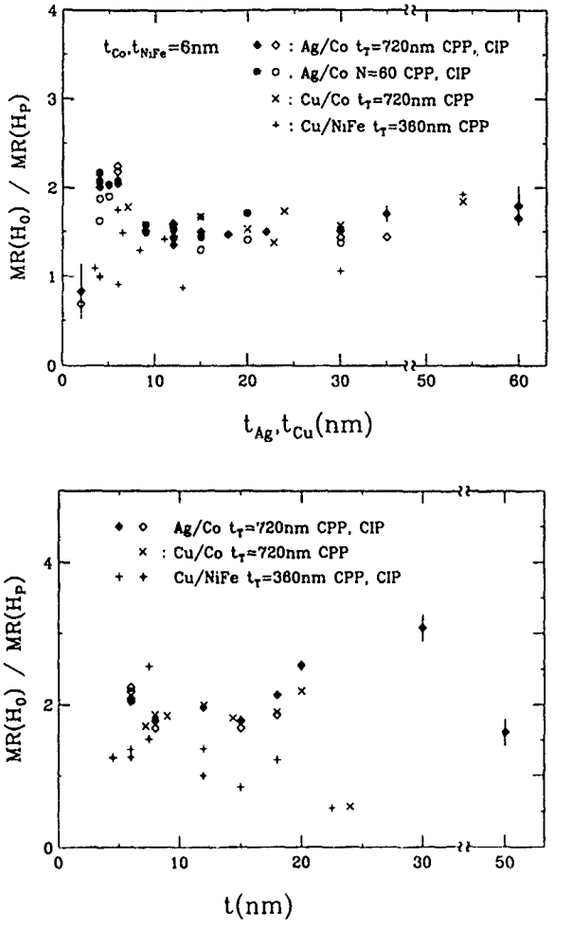

FIG. 2. (a) MR(H_0)/MR(H_p) plotted against thicknesses of Ag and Cu for a variety of multilayers with constant t_F=6 nm (b) MR(H_0)/MR(H_p) plotted against t, the thickness of both the F and N layers, for samples with $t=t_F=t_N$.

1. The reasons for these variations are not yet understood, but it should be noted that the uncertainties in the Cu/NiFe ratios are large partly because the MRs themselves are smaller than those for equivalent Ag/Co and Cu/Co samples.

For the samples with the thinnest Ag layers in Figs. 2(a) and 2(b), we find MR(H_0)/MR(H_p)<1. Values of this ratio below 1 have been found rather generally in Ag/Co samples with t_{Ag}<3 nm, as we will show elsewhere.[12] This may indicate ferromagnetic bridging between the Co layers. Apparently the values ~1.5–2 shown in Figs. 2(a) and 2(b) are representative only of weakly coupled samples.

If, as suggested at the beginning, we wish to associate the H_0 state with a demagnetized state, then we could hope to restore this state by demagnetizing the sample by cycling it through steadily decreasing fields. In Table I we give MRs evaluated for H for the states H_0, H_p, and H_0'' which is the zero field state after demagnetization. The first sample is strongly af coupled, and the second is f coupled. Here, exchange forces dominate coercive effects and the MRs are not dramatically different. The third sample is weakly af coupled and the remaining samples are uncoupled, and now there are significant differences. For Cu(9 nm)/Co(6 nm), MR(H_0'') is appreciably greater than MR(H_p) but much less than MR(H_0). This result supports our assumption that the H_0 state is the best candidate to date for the AP state. For Cu/NiFe, on the other hand, for t_{Cu}<10 nm, MR(H_0)<MR(H_p), and MR(H_0'') is larger than both. Here, MR(H_0'') is probably the best available experimental estimate for the AP state.

For the Cu/Co and Ag/Co systems, both H_0 and H_p seem to be rather well-defined states, in the sense that their properties vary systematically with other parameters in the system. In the uncoupled region, the H_0 state seems to correspond better with the AP state. Once a sample has passed

TABLE I. MR(H_0), and MR(H_0'') are the MRs (in percent) of the multilayers in zero field as prepared, and after demagnetization, respectively. MR(H_p) is the peak MR after cycling to H_s. Layer dimensions are given in nm.

System		MR(H_0)	MR(H_p)	MR(H_0'')
[Cu(0.8)/NiFe(6)]×53	CIP	35	34	34
[Cu(3)/NiFe(6)]×40	CPP	1 3	1.3	1.3
[Cu(2.0)/Co(1.5)]×143	CPP	68	58	64
	CIP	12	8.2	9 3
[Cu(9.0)/Co(6.0)]×49	CPP	61	37	44
[Cu(5.7)/NiFe(1.5)]×50	CPP	17	26	33
[Cu(3.3)/NiFe(1.5)]×75	CPP	23.6	35	39
	CIP	7.6	8.0	10.5

through a complete hysteresis cycle, we have not succeeded in restoring the original H_0 state by demagnetization at 4.2 K. For our "uncoupled" sputtered multilayers of Ag/Co and Cu/Co, the ratio $MR(H_0)/MR(H_p)$ is rather stable at ≈ 1.6 or 2 for multilayers with fixed t_F or $t_F = t_N$, respectively. For "uncoupled" Cu/NiFe with $t_{Cu} < 10$ nm, on the other hand, larger resistances at zero field can generally be obtained by demagnetizing at 4.2 K; here, the H_0 state cannot be the AP state.

We conclude that H_p is unlikely to closely represent the SU state. Further study is needed to establish how close H_0 comes to the AP state in different systems. In hopes of clarifying this issue, we are making CPP-MR measurements on spin-valve multilayers, in which alternating layers of F_A and F_B have values of H_c different enough that they should give an AP state for $H_{cA} < H < H_{cB}$.

Investigation of the magnetic structures in giant magnetoresistive multilayer films by electron microscopy

L. J. Heyderman and J. N. Chapman

The magnetic structures which occur in $(Co/Ni_{81}Fe_{19}/Co)/Cu$ multilayer films showing giant magnetoresistance have been investigated using electron microscopy. Rather similar fine domains, with sub-μm dimensions, were found in films comprising 14 and 6 magnetic layers. Whilst the observed structure depended greatly on the magnetic history of the sample, a combination of differential phase contrast imaging and low angle diffraction allowed an estimate to be made of the extent to which neighboring magnetic layers were aligned antiparallel to each other. For both samples typically two layers were found to have parallel alignment leading to the possibility that departures from the expected antiferromagnetic behavior are more prevalent at the surfaces rather than in the bulk of the multilayer.

I. INTRODUCTION

In a recent paper the magnetic structures present in giant magnetoresistive $(Co/Ni_{81}Fe_{19}/Co)/Cu$ multilayer films with 14 magnetic layers were investigated using various Lorentz modes of transmission electron microscopy.[1] The films, which gave magnetoresistance ratios of up to 18% at room temperature, displayed distinct and rather complex small-scale magnetic structures at zero field that were incompatible with complete antiparallel alignment of the magnetization in adjacent layers. Whilst Lorentz microscopy is one of the few techniques with the ability to image submicron domain structures, a detailed interpretation of the images is made difficult in this instance because information is provided only on the projection of the in-plane component of magnetic induction averaged through the multilayer stack. In the present work we have gained further insight into the magnetic structures by comparing observations in the 14-layer sample with those in a sample of identical composition but which comprised only six magnetic layers. Furthermore, low angle electron diffraction (LAD) has been introduced to provide quantitative data on the degree of magnetic alignment throughout the multilayer stack.

The multilayer material was chosen to ensure that films were soft whilst retaining high magnetoresistance (MR) values,[2] its composition being substrate |30ÅRu|5ÅCo|11ÅNiFe|5ÅCo|$n\times${19.5Cu|5ÅCo|11ÅNiFe|5ÅCo|}|50ÅRu|. $n+1$ is the number of magnetic layers in the multilayer stack. The magnetic structures were observed by Fresnel imaging and differential phase contrast (DPC) microscopy. The former is an out-of-focus technique suitable for domain observations during magnetization reversal. Large *in situ* perpendicular fields were available using the objective lens field[3] and, on tilting the sample, an in-plane field component of up to 1000's Oe could be applied. DPC imaging was used to look in more detail at structures of particular interest and processed DPC image pairs yielded vector maps of the magnetic induction averaged through the magnetic layers.[4] LAD was employed to quantify the total Lorentz deflection suffered by the electrons as they passed through the magnetic layers of the multilayer films and, as such, gave a direct measure of the net magnetization alignment in the multilayer stack. The LAD patterns were recorded from sample areas $\approx$20 μm in diameter and the patterns were calibrated by reference to a standard diffraction grating specimen.

II. RESULTS

A Fresnel image of a typical fine domain structure in the 14-layer sample at near-zero field is given in Fig. 1 (the applied field orientation is given by the double headed arrow). This is the highest magnetic contrast state during magnetization reversal. For comparison, some features of interest during magnetization reversal in the six-layer sample are shown in Fig. 2. As the field was reduced from saturation, fine striations which are similar to magnetization ripple were observed [Fig. 2(a)]. Reduction of the applied field to zero followed by a small increase in the reverse sense [Figs. 2(b) and 2(c)] led to an increase in the magnetic contrast and the formation of an irregular submicron domain structure similar to that observed in the original 14-layer film (Fig. 1). Thus the generic form of the domain structure formed during magnetization reversal from a saturated state did not change when the number of magnetic layers was reduced to six.

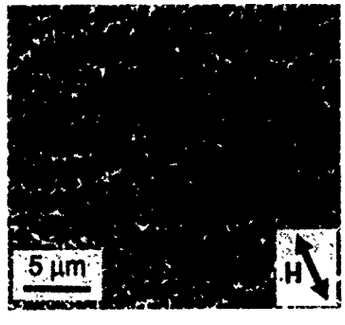

FIG. 1. Fresnel image of the near-zero field domain structure ($H=4$ Oe) in the 14-layer sample.

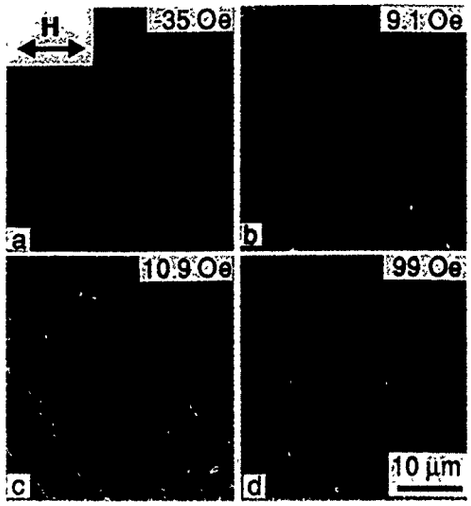

FIG. 2. Fresnel images of magnetization reversal in the six-layer sample.

Application of higher fields to the six-layer sample, however, introduced further complexities. In the presence of a greater reverse field, a high density of 360° wall structures formed as the irregular domain structure collapsed [Fig. 2(d)]. Annihilation of these 360° wall structures required field values in excess of 350 Oe. These observations should be contrasted with what happened when the sample was demagnetized along a minor hysteresis loop for maximum field values between 20 and 30 Oe. Under these circumstances much larger domains were nucleated [Fig. 3(a)]. Whilst increasing the field from this state once again led to the formation of 360° loops, these spanned much larger areas than those in Fig. 1(d) as a consequence of their originating from the larger domains. Figure 3(b) shows such 360° wall structures after the field was removed. Thus substantially different magnetic structures could be induced in the sample dependent on its magnetic history.

We have investigated the small and large domain structures discussed above [Figs. 2(c) and 3(a)] using DPC microscopy. One of a pair of DPC images for each of the small and large domain structures at zero field are given in Figs. 4(a) and 4(b). While the large domains [Fig. 4(b)] are ≈ 1 μm across, the dimensions of the small domains [Fig. 4(a)] are $\ll 1$ μm. Using pairs of DPC images sensitive to orthogonal induction components, the vector maps corresponding to

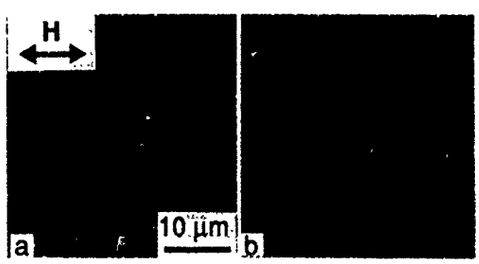

FIG. 3. (a) Large domains induced in the six-layer sample and (b) resulting 360° wall structures.

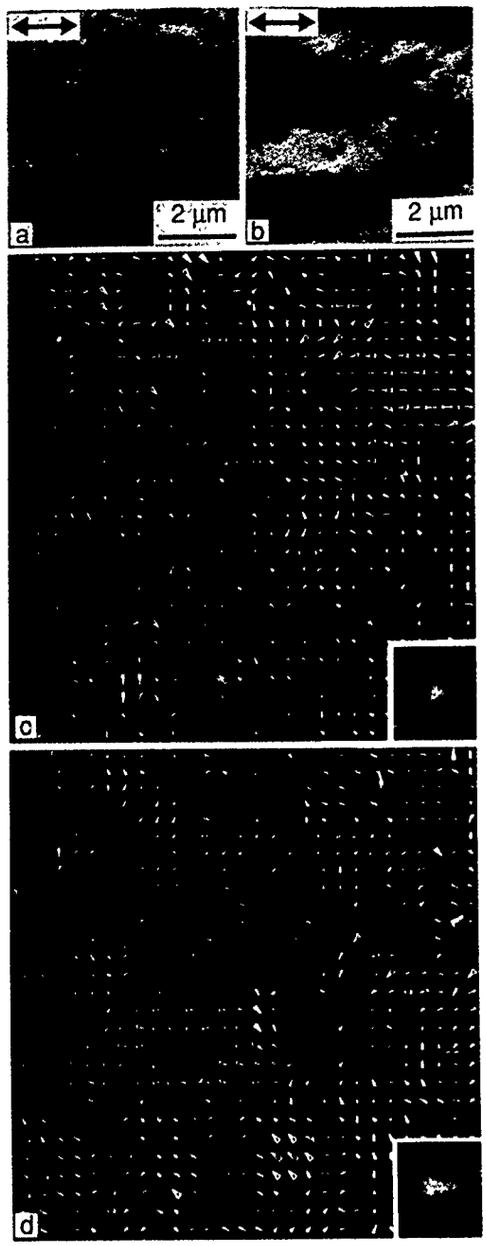

FIG. 4. DPC images of (a) small and (b) large domain structures in the six-layer sample mapped along directions given by the double headed arrow. (c) and (d) are vector maps for the regions in (a) and (b), each with a scattergram inset.

the regions shown in Figs. 4(a) and 4(b) were formed. These are given in Figs. 4(c) and 4(d) and clearly show spatial variations in magnetization orientation and magnitude on a sub-μm scale. The inset in each vector map is a scattergram which can be thought of as a two-dimensional histogram of the in-plane induction components within each area mapped.[4] The scattergram in Fig. 4(c) indicates that all orientations of the projected induction and magnitudes below a certain limit (defined by the width of the scattergram) are present. The elongation of the scattergram in Fig. 4(d) is consistent with the horizontal directionality of Fig. 4(b) but it is clear that, as before, all magnitudes for the projected in-

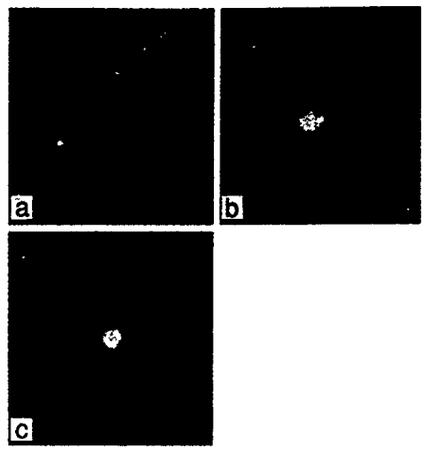

FIG. 5. LAD patterns for (a) a 14-layer ferromagnetically coupled sample at a region of near-180° domain walls; the fine domain states of (b) the 14-layer sample and (c) the 6-layer sample.

duction from the maximum observed value down to zero are present. Similar observations were made on the 14-layer sample.[1]

Quantitative information on the magnitude of the projected induction were obtained using LAD. For comparison purposes, an LAD pattern for a 14-layer sample containing magnetic layers of the same thickness but with intervening Cu interlayers of reduced thickness, thereby favoring parallel alignment of the magnetic layers,[1] is given in Fig. 5(a). This pattern is typical of one from a simple ferromagnetic film supporting in-plane magnetization and containing domains separated by ≈180° walls. The two lobes in the LAD pattern correspond to the two almost anitparallel domain magnetization orientations and the circumferential spread in the lobes is an indication of the magnetization dispersion in the sample. The expected Lorentz deflection, β_L, for a multilayer supporting parallel magnetization alignment is given by $\beta_L=(e\lambda/h)\int B_0\,dt$, where B_0 is the magnetic induction of the material, λ is the electron wavelength, and the integral is evaluated over the thickness of the magnetic layers. Assuming saturation magnetization values appropriate to bulk Co and permalloy, the expected value of β_L was calculated to be 26 μrad. This compares reasonably with the experimental value of 23 μrad.

The LAD patterns seen in Figs. 5(b) and 5(c) are very different to that in Fig. 5(a). They were taken from the fine domain structures seen in the 14- and 6-layer samples and closely resemble the scattergram of Fig. 4(c). Furthermore, despite the fact that the number of layers in the two samples differs markedly, the extent of the LADs are remarkably similar and substantially less than that of Fig. 5(a). Indeed most of the intensity in the diffraction patterns is within an angular radius of 6 μrad. This corresponds to ≈25% of the maximum deflection angle that would be obtained for the 14-layer sample if the magnetization in adjacent layers was always parallel and ≈60% of the corresponding quantity for the 6-layer sample. More significantly the observed distributions resemble what would be observed if, in different areas of the multilayer film, zero, two, and occasionally up to four layers were aligned parallel rather than antiparallel to each other.

III. DISCUSSION AND CONCLUSIONS

We have shown that complex domain structures, dependent on the magnetic history of the sample, exist in multilayer films with a composition that ensures a high value of MR and relatively low switching fields. In general, the magnetic contrast is rather low but neither it, nor the geometry of the structures, differs substantially in films comprising both 14 and 6 magnetic layers. A combination of DPC imaging and LAD has shown that whilst local areas exist within the films where the net magnetic deflection is zero, in most regions, the electrons suffer a small deflection as they pass through. This is consistent with an incomplete antiparallel alignment of magnetization in adjacent layers throughout the multilayer stack. Furthermore, using LAD we have made a quantitative estimate of the extent to which parallel alignment is present and have shown that the parallel alignment is usually between two layers, and rarely exceeds four magnetic layers. As similar results are found for both 14- and 6-layer samples, rather than there being a scaling with the number of layers, it is possible that parallel alignment is most frequently found near one or both film surfaces. Further investigations involving smaller numbers of layers should help to clarify this. We conclude that a contribution of electron imaging and diffraction techniques provides information on magnetization processes in complex multilayer structures that would not be accessible by other experimental techniques.

Distribution of current in spin valves (abstract)

Bruce A. Gurney, Virgil S. Speriosu, Harry Lefakis, and Dennis R. Wilhoit
IBM Research Division, Almaden Research Center, 650 Harry Road, San Jose, California 95120-6099

We present a model describing the distribution of spin up and spin down currents within the layers of spin valve structures. With this model and experimentally determined bulk mean free paths we successfully describe a variety of experimental results, including the variation of resistance and magnetoresistance with both ferromagnetic and nonferromagnetic layer thicknesses, and the current-induced field acting on the ferromagnetic layers versus overall current. Our model is based on an approximate path integral solution of the Boltzmann equation for in-plane transport in a multiply layered structure. For a given orientation of the magnetizations it calculates the current density $j^{\sigma}(\mathbf{r})$ at each point $\mathbf{r}$ for each spin σ throughout the structure. From $j^{\sigma}(\mathbf{r})$ it is straightforward to obtain the current in each layer for parallel versus antiparallel magnetizations, or of the current density near interfaces relevant to electromigration. Included in our model are both spin dependent bulk scattering as well as scattering at interfaces, which are treated as thin layers. For example, in order to obtain quantitative agreement with experiments with permalloy based structures it is essential to include spin independent scattering arising from Fe and Ni atoms rendered nonferromagnetic next to the spacer due to interfacial intermixing. Our results bear directly on the fundamentals of GMR by successfully describing transport in spin valves using the measured bulk spin dependent mean free paths of the individual layers. Our results are also of technological interest because they predict how current affects the MR response to an external field.

A comparison of the giant magnetoresistance and anisotropic magnetoresistance in Co/Cu sandwich films (abstract)

B. H. Miller, E. Youjun Chen,[a] Mark Tondra, and E. Dan Dahlberg
School of Physics and Astronomy, University of Minnesota, 116 Church Street SE, Minneapolis, Minnesota 55455

By a systematic variation of structures, recent measurements conclude the scattering associated with the high resistance giant magnetoresistance (GMR) state occurs within 0.25 nm of the magnetic interface.[1] We have accomplished a similar measurement that does not require such stringent control of the sample structure. Instead, the present work uses measurements of the anisotropic magnetoresistance (AMR) in both the high resistance and low resistance GMR states. The samples are sandwiches of Co/Cu/Co/CoO with Co thicknesses ranging from 1 to 10 nm and Cu thickness of approximately 2.5 nm. The AMR is measured with the Co magnetizations aligned parallel to one another (the low resistance GMR state) and with the Co magnetizations aligned antiparallel to one another (the high resistance GMR state). The data show that the AMR in the antiparallel configuration is less than that in the parallel configuration. An analysis that relates the reduced AMR to the magnetic interfacial region giving rise to the high resistance GMR state indicates the scattering occurs within approximately 0.5 nm of the interface.

Enhanced magnetoresistance in chromium doped Fe/Cr multilayers (abstract)

Noa M. Rensing and Bruce M. Clemens
Department of Applied Physics and Department of Materials Science and Engineering, Stanford University, Stanford, California 94305-2205

We report enhanced room temperature magnetoresistance of up to 11.4% in sputter deposited Fe/Cr multilayers when the iron layers are doped with additional chromium. To our knowledge, this is the largest room temperature magnetoresistance in polycrystalline Fe/Cr multilayers reported to date. In comparison, the magnetoresistance was 7.5% in a similar, undoped sample made at the same time. The magnetoresistance of antiferromagnetically coupled Fe/Cr multilayers has been the subject of considerable study in the past five years. We have investigated the possibility of doping the Fe layers with additional chromium, in order to increase the magnetoresistance by enhancing the spin dependent scattering. In one series of samples, the chromium dopant was concentrated into thin layers within the Fe layer. A 1 Å layer of chromium ($\frac{1}{2}$ monolayer) was deposited at a depth of 4, 8, or 15 Å into the 30-Å-thick iron layers of the multilayers. The magnetoresistance was enhanced in all of the samples, to 8% when the doping layer was at 4 Å and to 10.5% in the others. In the second series of samples the iron layers were alloyed with between 1.5% and 50% chromium. The maximum magnetoresistance was 11.4%, observed in the sample with 20% chromium in the Fe layers. This is larger than the magnetoresistance in any of the samples where the Cr was concentrated in a thin layer within the Fe layer, but a given amount of chromium appears to be more effective in increasing magnetoresistance when it is concentrated in a layer rather than distributed as an alloy. A 1 Å layer of Cr is roughly equivalent to a 3% alloy, but the alloyed sample only showed 8% magnetoresistance, in comparison to up to 10.5% in the samples with layered doping.

Low field giant magnetoresistance and oscillatory interlayer exchange coupling in polycrystalline and (111)-oriented permalloy/Au multilayers (abstract)

S. S. P. Parkin, T. A. Rabedeau, R. F. C. Farrow, and R. Marks
IBM Research Division, Almaden Research Center, San Jose, California 95120-6099

The existence of oscillatory interlayer exchange coupling of ferromagnetic layers via (111)-oriented noble metal spacer layers is controversial. We present evidence from magnetic and giant magnetoresistance studies for well-defined antiferromagnetic interlayer coupling in single crystalline (111) permalloy/Au multilayers. Four oscillations in the coupling are observed as the Au spacer layer thickness is increased. The oscillation period is $\simeq$10 Å which is significantly shorter than the period of $\simeq$11.5 Å predicted in Ruderman–Kittel–Kasuya–Yosida based models. Similar oscillatory interlayer coupling is found in polycrystalline permalloy/Au multilayers prepared by dc magnetron sputtering. The interlayer coupling strength is significantly weaker in the polycrystalline as compared to the (111)-oriented crystalline samples. In both cases the coupling strength is weaker than in comparable structures containing Ag, for which the coupling is weaker than in similar structures containing Cu. The weakness of the antiferromagnetic interlayer coupling via Au leads to very low saturation fields, lower than for all other noble and transition metals. Indeed, the saturation fields are as low as just a few Oersted for sufficiently thick Au layers. Consequently, we find giant magnetoresistance values of $\simeq$1%/Oe or greater at room temperature in polycrystalline permalloy/Au multilayers. These values are the highest values yet reported in multilayer structures and are comparable to or greater than those recently reported in discontinuous permalloy/Ag multilayers.

The structural changes that accompany the development of GMR (giant magnetoresistance) at low ($\lesssim$10 Oe) fields in annealed magnetic multilayers[1] are of current interest because of potential applications of such structures in sensors. In this paper we report a study of the development of GMR in [111]-oriented multilayers comprising ferromagnetic films of a mixture of Ag and permalloy (Ni_xFe_{1-x}, $x\sim0.8$) alternating with Ag spacer films. The multilayers were grown by molecular beam epitaxy (MBE) on Pt(111) seed films on sapphire (0001) substrates at temperatures in the range 20 to 200 °C. The structure of the multilayers was investigated using x-ray diffraction and electron microscopy. For a series of multilayers grown with nominally identical ferromagnetic and spacer layer thicknesses, the magnetoresistance is found to be strongly dependent on both growth temperature and subsequent annealing temperature. The multilayers exhibited a negative magnetoresistance in the as-grown state which more than doubled when the growth temperature was increased from 20 to 100 °C. However, the highest magnetoresistance (peak 5.6%; maximum slope 0.4% per Oe) was obtained by annealing (at 400 °C) multilayers grown at 100 °C. Transmission electron microscopy studies of such multilayers showed no evidence for discontinuities or penetration of the ferromagnetic films by Ag along grain boundaries. Thus, we conclude that discontinuous or granular multilayers with complete phase separation are not necessary for GMR with low saturation fields.

The full article appeared in the 15 September 1994 issue of Journal of Applied Physics on p. 3688.

Effects of domains on magnetoresistance (abstract)

Shufeng Zhang and Peter M. Levy
Department of Physics, New York University, New York, New York 10003

Our present understanding of the giant magnetoresistance observed in magnetic multilayered structures is based on the premise that the layers are either monodomains or that the sizes of the domains are much larger than all other length scales (mean free path, spin-diffusion length, and layer thickness) relevant to the magnetoresistance. We extend our theory of magnetoresistance to include multilayers with small in-plane domains where there is the possibility that their size may be limited by columnar growth.[1] We study magnetoresistance in the presence of in-plane domains both for the current parallel and perpendicular to the plane of layers. The domain boundaries introduce additional scattering and the direction of the internal current will be different from that of the driven current. In the presence of spin-dependent scattering, a transverse spin current develops so that the current in each of the spin channels is "mixed" even without spin-flip processes. Analytical expressions will be given for limiting cases where the mean free path is either much larger or much smaller than the layer thickness and the domain size. We find that the domain size is a relevant length scale and contributes to the spin diffusion length λ_{sdl} in the equations that govern the spin diffusion attendant to charge transport in magnetic multilayers. If one does not know the domain structure, nor the amount of spin-flip scattering, both mechanisms are equally plausible for producing spin diffusion which suppresses the magnetoresistance for the current perpendicular to the plane of the layers.

The synthesis, structure, and characterization of α''-$Fe_{16}N_2$ (invited)

K. H. Jack
University of Newcastle upon Tyne and the Cookson Group plc., United Kingdom

Controversy about the magnetic properties of α''-$Fe_{16}N_2$ thin films makes it desirable to examine bulk material. In the original preparation and crystal structure determination of α'' in 1951, N-austenite (γ) prepared by nitriding α-iron powder at 700–750 °C was quenched to give N-martensite (α') which then gave $\alpha+\alpha''$ on long tempering at 120 °C. The final product was a mixture of either $\alpha+\alpha''$ or $\alpha+\alpha''+\gamma$ with less than 50%α''. Recent repetitions of this preparative method in three different laboratories have given mixtures with varying amounts of α'', again never greater than 50%, and with magnetic moments of α''—assessed from measurements made on the mixtures—that show considerable variation. Studies of α' tempering by XRD, and of α'' precipitation from supersaturated N ferrite (α) by high-resolution TEM, both show that slow ordering of N atoms to produce α'' occurs only after localized regions of α' and α reach the Fe_8N composition by a clustering process. Thus α'-Fe_8N can be obtained with a tetragonality c/a equal to that of α'', but without the complete N ordering that is characteristic of $Fe_{16}N_2$. This might explain some of the variability in magnetic properties. The inhibiting effect of oxygen and other impurities on the nitriding of iron is emphasized, the existence of the α''-carbonitride $Fe_{16}(C,N)_2$ is noted, and possible methods for 100% production of bulk α'' are suggested.

I. INTRODUCTION

α''-$Fe_{16}N_2$ was discovered and its crystal structure determined in 1951,[1] but its magnetic properties remained unexplored until 1972 when Kim and Takahashi[2] reported an abnormally high magnetization in films obtained by evaporating iron onto a glass substrate in low-pressure nitrogen. The major phase was α'', and from the experimentally determined volume fraction its polarization was calculated as 2.76 T, corresponding to an average moment of 2.9 μ_B per Fe atom. This discovery, neglected for nearly two decades, has inspired much recent activity. Various techniques have been used to produce films on a variety of substrates with very variable results;[3–6] see Table I. Most remarkably, Sugita and co-workers[4,5] claim single-crystal α'' films, prepared by MBE on $Ga_{0.8}In_{0.2}As$ substrates, with a moment per Fe atom of 3.2 μ_B at room temperature. At the other extreme, Takahashi and his colleagues more recently report[6] that films produced both by plasma evaporation and by sputtering show no abnormally large magnetization. A "giant magnetic moment" seems incompatible with band theory; three independent calculations[7–9] based on the structure of α''-$Fe_{16}N_2$ give an average moment of 2.4 μ_B per Fe atom, i.e., only about 10% higher than that of α-iron.

Because of the controversy engendered by these widely different observations, it seems essential to measure the properties of pure, bulk samples of α''-$Fe_{16}N_2$. So-far, this has been attempted in three different laboratories,[10–12] but again with different results. Reasons for the variability of products and possible methods of meeting the objective are suggested in the present paper.

II. ORIGINAL PREPARATION AND CHARACTERIZATION OF α''-$Fe_{16}N_2$

α''-$Fe_{16}N_2$ was first prepared during an investigation of the Fe-N system. The solubility of molecular nitrogen in iron is negligible and so Fig. 1 is not a true equilibrium diagram because the nitrogen is not at one atmosphere pressure. Different phases and exact compositions within a phase are readily obtained by nitriding with NH_3:H_2 gas mixtures in which the N potential, $a_N = k.p_{NH_3}/p_{H_2}^{3/2}$, can be precisely controlled.

N-austenite (γ) exists above 590 °C and is a fcc arrangement of Fe atoms with N randomly occupying up to one in ten of the octahedral interstices. The γ' nitride Fe_4N also has a fcc Fe-atom arrangement but with one in four of the octahedral holes occupied in a perfectly ordered manner; see Figs. 2 and 3.

When γ is quenched rapidly from above 600 °C the Fe-atom arrangement changes from fcc to approach that of bcc

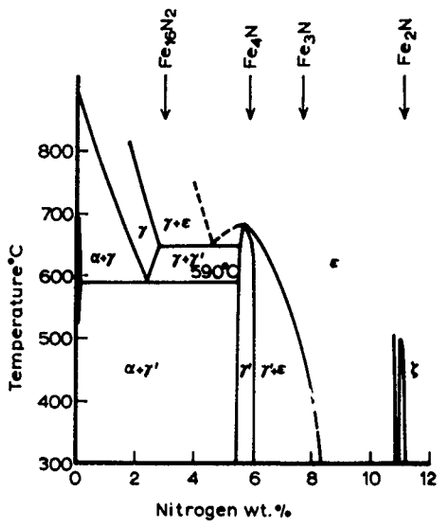

FIG. 1. The Fe-N phase diagram.

α-Fe. However, the N atoms have insufficient time to move from the interstices they occupied in the austenite and the extra holes created by the fcc–bcc transition remain empty. The result is a bc tetragonal martensite (α') of the same composition as the parent austenite, and where up to a maximum of one in ten of the holes at the midpoints of the c edges and the centers of the C faces are occupied by N (the N^z sites). Figure 4 shows a variable position for the Fe atoms; where a hole is occupied, the Fe atoms are pushed apart in the c direction; when the hole is empty the Fe-atom positions are the same as in α-Fe. Dimensions of unfilled and filled octahedra are shown by Fig. 5.

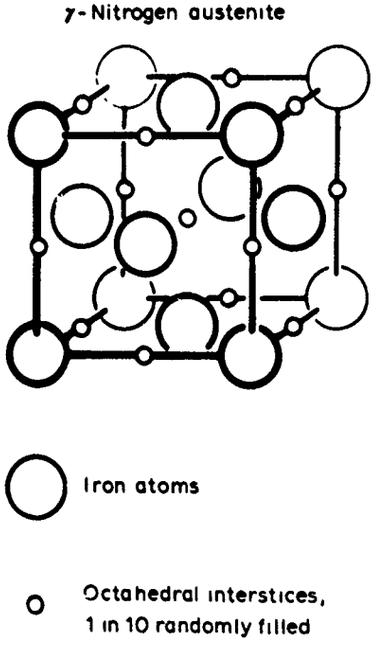

FIG. 2. γ phase, N-austenite.

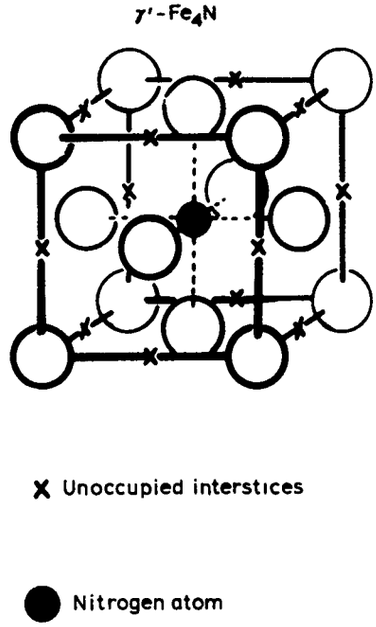

FIG. 3. γ phase, Fe_4N.

When N-martensite (α'), obtained by quenching γ, is tempered below 590 °C, the phase diagram indicates that the products should be $\alpha+\gamma'$. Instead they are $\alpha+\alpha''$. The $Fe_{16}N_2$ unit cell (Fig. 6) consists essentially of eight ($2\times2\times2$) distorted bcc cells of α-Fe with N atoms occupying 2 of the 48 octahedral interstices in a perfectly ordered manner, i.e., 2 of the 16 N^z sites with 16 N^x and 16 N^y sites com-

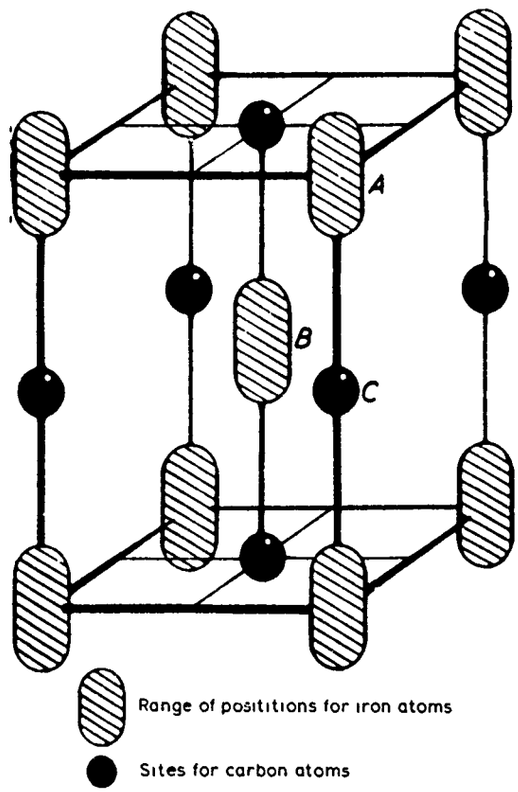

FIG. 4. α' phase, N-martensite.

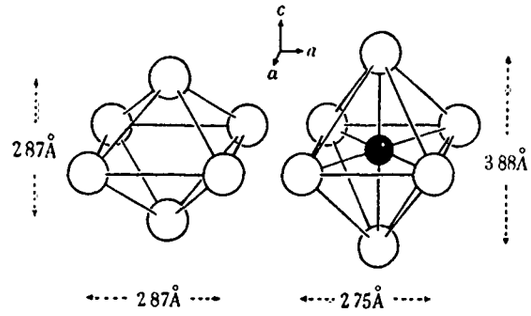

FIG. 5. Unfilled and filled octahedra in bcc α-Fe.

pletely empty. The Fe atoms are in three different crystallographic sites: $4(e)$ and $8(h)$ which form the octahedra coordinating the two N atoms and which, within experimental error, are all equidistant from a N atom; and sites $4(d)$ which have no nearest N-atom neighbors.

Figure 7 shows that α'' viewed along [110] is a distorted $\gamma'Fe_4N$ with alternate N atoms missing. Thus, in both structure and composition, $Fe_{16}N_2$ ($=Fe_4N_{0.5}$) is midway between bcc α-Fe and fcc γ'-Fe_4N. In all the Fe-N phases (α, α', α'', γ, and γ') the filled octahedra (NFe_6) are all the same size; only their numbers and distribution change.

III. THE FORMATION OF α' AND α'' PHASES

Figure 8 shows x-ray powder photographs of N-martensites (α') prepared by quenching austenites (γ). As the N content increases, the increasing tetragonality of α' is shown by the increasing separation of the component reflexions of the "tetragonal pairs" $M2$, $M4$, $M6$, and $M8$, i.e., (101) and (110), (002) and (200), etc. The maximum N content of γ, and hence of the α' that forms from it, is $\gtrsim$10 N/100 Fe and so it never reaches Fe_8N (12.5 N/100 Fe). Even the highest N-martensite must give α-Fe+α'' on tempering; it can never give pure α''. Further, α' is not produced isothermally from γ. It is formed only during cooling, and

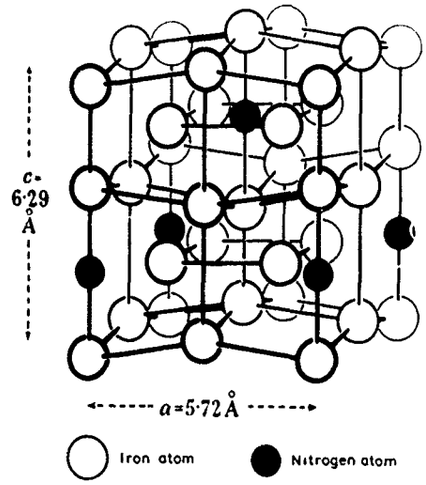

FIG. 6. Structure of α''-$Fe_{16}N_2$.

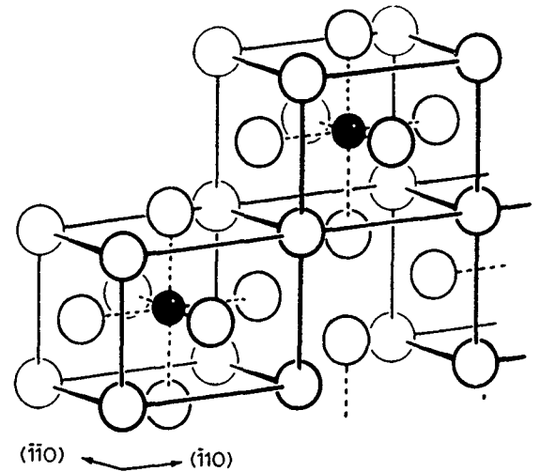

FIG. 7. The structure of α'' considered as a distorted fcc lattice.

the M_s temperature—the temperature at which transformation starts—decreases as the N concentration increases. For high-N contents which might be expected to produce high-N α' phases and hence purer $Fe_{16}N_2$, M_s is at subzero temperatures. Also, the stresses set up when γ transforms to α' inhibit further transformation and the effect increases as M_s decreases.

To summarize, low-N-content austenites produce, by quenching and then tempering, a mixture of $\alpha+\alpha''$ with only a small proportion of α''. High-N austenites produce more α'', up to perhaps 50%, but with some α and a large amount of nonmagnetic retained austenite (γ).

It is also important to appreciate that when α' is tempered at low temperatures, the α'' does not form instantaneously. The N atoms in localized regions gradually cluster together to produce a martensite of higher N content and hence of greater tetragonality with concurrent formation of ferrite. Figure 9 shows x-ray photographs of N martensite (2.0 wt % N; 8.1 N/100 Fe) aged at 80 °C. With increasing time, the separation of the paired reflections $M2$, $M4$, ..., $M10$ gradually increases, showing increasing tetragonality and hence increasing N concentration of α'; compare Fig. 8. Even when the tetragonality c/a reaches that of α'', corre-

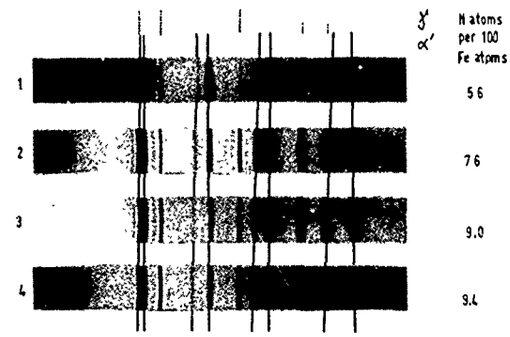

FIG. 8. X-ray powder photographs of N martensites (with retained γ) with increasing N content.

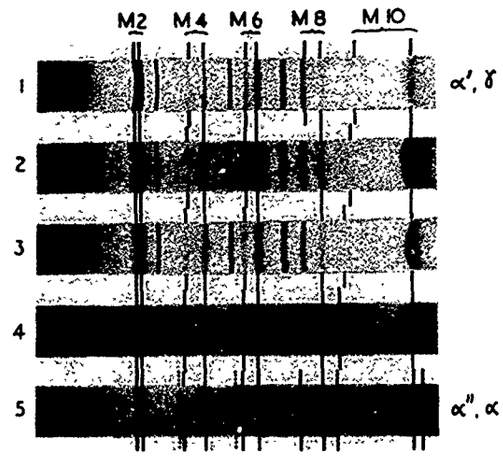

FIG. 9. X-ray powder photographs of N martensites (2.0 wt % N=8.1 N/100 Fe) aged at 80 °C for increasing times.

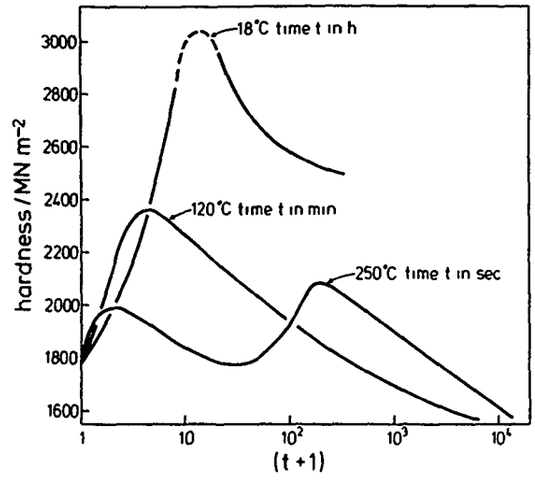

FIG. 11. Hardness curves for quench-aged N ferrite, 0.07 wt % N.

sponding to an α' composition Fe_8N, weak reflections due to N-atom ordering that are characteristic of the $Fe_{16}N_2$ structure are not observed; these appear only after further prolonged tempering.

IV. AGING NITROGEN FERRITE

Another way of producing α''-$Fe_{16}N_2$ is by precipitation from supersaturated N ferrite. The solubility of N in α-Fe is a maximum at 590 °C, 0.1 wt %=0.4 at. %. On quench aging α containing ~0.07 wt % N, the phase diagram of Fig. 10 indicates that γ'-Fe_4N should be precipitated. Instead, optical and electron micrography, XRD, and electron-diffraction evidence, together with the hardness curves of Fig. 11, show that at 250 °C α'' is first precipitated within seconds and then dissolves and is replaced by equilibrium γ'. At 120 °C the α'' remains and is transformed to γ' only after very long times. After 10 h aging at room temperature the quenched ferrite shows a remarkably high hardness for such a small N concentration with no evidence from optical microscopy of any precipitation. Only an electron micrograph at a magnification of ~0.5×10^6 reveals a structure identical with the classical Guinier–Preston zones in Al:4 wt % Cu; see Fig. 12.

A combination of techniques, (i) x-ray measurements of unit-cell dimensions, (ii) internal friction, (iii) transmission electron microscopy, and x-ray and electron diffraction, allows the complete quantitative characterization of nitrogen in iron and iron alloys; see Jack[13] and references therein. Nitrogen in the aged N ferrite (α) of Fig. 12 is clustered as a nonrandom solid solution of disc-shaped GP zones. Figure 13 is an (002) lattice image of α containing 0.05 wt % N, i.e., $Fe_{500}N$, after aging for 15 h at 23 °F. The (002) interplanar spacing of 1.49 Å within the cluster corresponds with a composition $Fe_{20}N$ whereas the adjacent ferrite with which the cluster is completely coherent has the N-free spacing of α-Fe, i.e., 1.43 Å. Further aging continues to increase the N content in the localized clustered regions until, after reaching Fe_8N, N ordering slowly occurs to give α''-$Fe_{16}N_2$. The 1.57 Å spacing shown in Fig. 14 is not unequivocal evidence of α'' even though this is the d value for (004) of α'' for which $c=6.28$ Å. The same d value is shown by the (002) planes

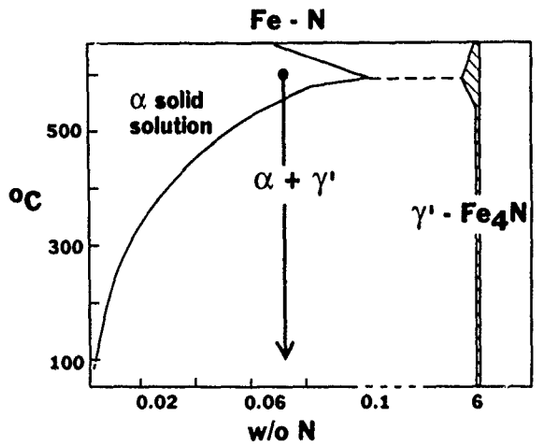

FIG. 10. Part of the Fe-N system.

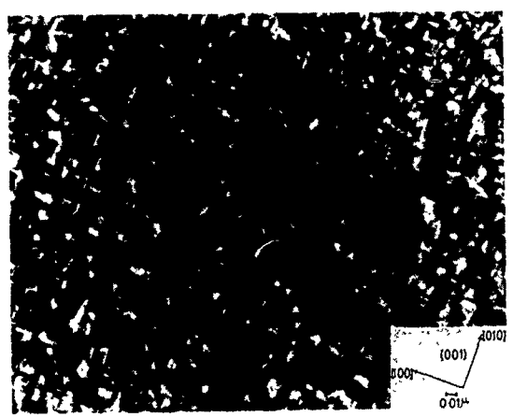

FIG. 12. TEM of Fe:0.07 wt % N quench-aged 16 h at 21 °C; foil normal [001].

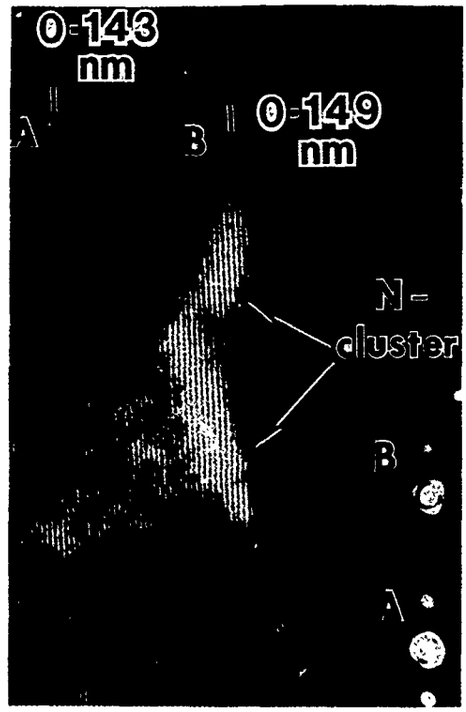

FIG. 13. (002) lattice image of a N cluster ($Fe_{20}N$) in Fe:0.05 wt % N ($Fe_{500}N$) aged 15 h at 23 °C.

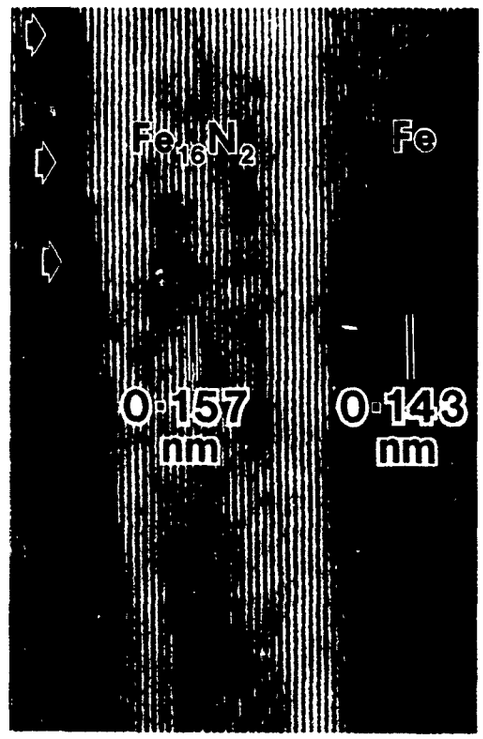

FIG. 14. (004) lattice image of α''-$Fe_{16}N_2$ in Fe:0.05 wt % N aged 46 h at 100 °C.

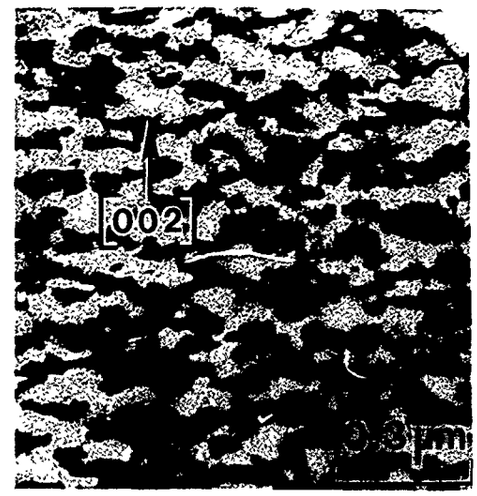

FIG. 15. Stress-oriented N-atom clusters in aged Fe:0.06 wt % N.

of α'-Fe_8N and evidence of the N-atom ordering characteristic of α''-$Fe_{16}N_2$ comes from additional reflections in the electron- and x-ray-diffraction patterns.

It is worth noting that aging under an applied mechanical stress produces clusters and then α'' platelets in only one preferred cube orientation. As shown in Fig. 15, the plane of the plates is perpendicular to the applied extensive stress.

The aging of N ferrite fully supports the evidence of N-martensite tempering that α'-Fe_8N is obtained in a penultimate stage with a tetragonality c/a equal to that of α'' but without the N-ordering characteristic of $Fe_{16}N_2$.

V. BULK α''-$Fe_{16}N_2$

The production of bulk α'' as powders or foils has followed essentially the 1951 preparative method via γ and α'. For reasons given in Sec. III, all three laboratories have produced mixtures, the phase compositions of which have been determined by either XRD[10] or Mössbauer spectroscopy.[11,12] Huang *et al.*[10] claim 56% α'' with $J_s = 2.65 \pm 0.15$ T corresponding to 2.95 ± 0.15 μ_B per Fe atom—a 34% increase over that of α-Fe. Coey *et al.*[11] produce >40% α'' with smaller magnetization values of $J_s = 2.3 \pm 0.2$ T and 2.45 ± 0.15 μ_B at ~0 K; these are only about 10% higher than for α-Fe but are in broad agreement with the band-structure calculations. Bao *et al.*[12] start from hydrogen-reduced Fe_2O_3 and convert up to 30% into α''. They claim that the measured moment is in agreement with a "dramatically large magnetization," i.e., $\sigma_s = 310$ emu g^{-1}, but the experimental evidence for this is not convincing.

VI. DISCUSSION AND CONCLUSIONS

The limited work so far carried out on bulk α''-$Fe_{16}N_2$ has not resolved the controversy concerning the existence of a giant magnetic moment iron nitride. This is partly due to preparative limitations whereby less than 50% of the product mixture is α''. The variation in the magnetic properties of thin films is explicable by differences in N-atom ordering,

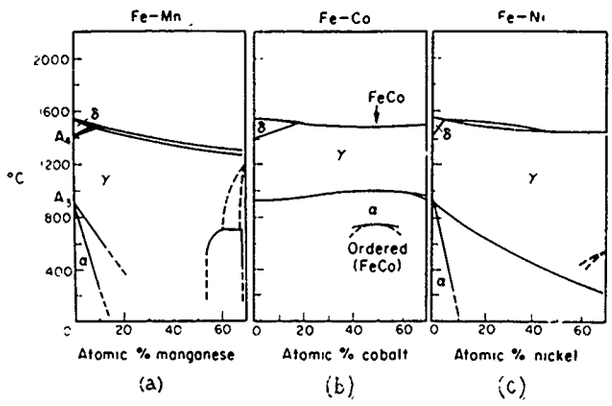

FIG. 16. Phase diagrams: (a) Fe-Mn, (b) Fe-Co, (c) Fe-Ni.

and the existence of α'-Fe_8N which, superficially, is indistinguishable from α''-$Fe_{16}N_2$ but which might have different magnetization values.

Bulk preparation of 100% α'' is essential. By the conventional route this is possible by extending the N content of γ until it includes Fe_8N. Only three elements, Mn, Co, and Ni, are γ stabilizers and extend the γ-phase field. From the phase diagrams of Figs. 16(a)–16(c), additions to Fe of Mn and Ni reduce markedly the M_s temperature but Co does not. Although detailed phase relationships in the Fe-Co-N system are not known, it is suggested that small alloying additions of Co would extend the γ-phase limit to include $(Fe,Co)_8N$. The M_s temperature will not thereby be lowered and it is not expected that Co additions will reduce the magnetization of the final α'' phase.

It is well established[14] that alloying elements which lower the activity coefficient of N in Fe (i.e., f_N^X where, for example, X is Mo, Mn, Ta, Cr, Nb, V, and Ti) also stabilize the transformation stages of the homogeneous precipitation to temperatures higher by about 500 °C. Small additions of these elements might be expected to stabilize α''-$(Fe,X)_{16}N_2$ to temperatures of 600–700 °C.

It is also established that both the quench aging of carbon-nitrogen ferrite[15] and the tempering of carbon-nitrogen martensite[16] give an α''-$Fe_{16}(C,N)_2$ carbonitride phase. The effects of carbon on the properties and stability of α'' are not known.

These observations suggest that there is ample scope for a wide exploration of α'' alloy phases that might be more easily prepared and have greater thermal stability than the pure α''-Fe-N phase.

The possibility of nitriding at low temperatures by mechanical alloying is attractive but, although a supersaturated bcc Fe-N phase with up to 14.5 at. % N is claimed[17] in Japan by ball-milling iron powder in NH_3 at room temperature, there is no trace of α'' and the magnetization decreases rapidly as the N concentration increases. Similar negative results were obtained by Foct[18] in France.

At temperatures where α'' is relatively stable ($\gtrsim$250 °C), its nitrogen activity a_N is higher than that of the more stable γ'-Fe_4N and so a higher nitrogen potential is required to produce it by gaseous nitriding; surface nucleation of γ' must be avoided. By the conventional $\gamma \rightarrow \alpha' \rightarrow \alpha''$ route, low-N-content austenite transforms completely to low N-martensite which, on tempering, gives $\alpha''+\alpha$. If this mixed phase, prepared as a finely divided (10 μm) powder, is then nitrided in the appropriate NH_3:H_2 gas mixture at <250 °C the α'' regions will act as nuclei and will grow at the expense of α, eventually producing 100% α''. In nitriding, the slowest rate-controlling step is at the surface, and so it is essential to maintain a scrupulously clean surface and clean grain boundaries. Adsorped oxygen or other active species (e.g., sulfur) will inhibit completely the nitriding reaction. Even at 200 °C the diffusivity of N in Fe is high enough to ensure homogeneity of 10 μ powder particles provided that surfaces are perfectly clean. It is now suggested that this quench tempering of low-N-content γ, followed by low-temperature gaseous nitriding, should also be explored to produce 100% α''-$Fe_{16}N_2$.

The metastable α''-$Fe_{16}N_2$ phase may have a magnetic moment up to 50% higher than that of pure bulk α-Fe. This article addresses the following issues. (i) Can epitaxial films of α''-$Fe_{16}N_2$ be prepared phase pure? Yes, but there are some doubts. (ii) Can powders of α''-$Fe_{16}N_2$ be prepared phase pure? Not yet. (iii) Is the Mössbauer spectrum due to α''-$Fe_{16}N_2$, to martensite, or to something else? Most assign it to α''-$Fe_{16}N_2$. (iv) What is the specific saturation magnetic moment of α''-$Fe_{16}N_2$? Some claim it is close to that of α-Fe, most claim that it is much larger. (v) Is the high moment due to α''-$Fe_{16}N_2$, or to some other phase?

I. INTRODUCTION

In 1950 Jack first reported[1,2] the metastable phase α -$Fe_{16}N_2$ in a study of the Fe-N phase diagram, which resembles the Fe-C phase diagram.[3] The α''-$Fe_{16}N_2$ phase is formed from α'-*N*-martensite Fe_xN with $6<x<11$, in the temperature range $150\,°C<T<300\,°C$ by a nitriding, quenching, and tempering process.[2] It also precipitates at the strain boundaries of supersaturated "nitrogen ferrite" (α-Fe_xN) and during the normal aging of α'-*N*-martensite.[4]

Kim and Takahashi reported a high magnetic moment (saturation magnetic flux density $B_s=2.58$ T) in a polycrystalline Fe-N film, deposited by Fe evaporation in N_2 on a glass substrate, and attributed these dramatically large values to the partial presence of α''-$Fe_{16}N_2$ (estimated $B_s=2.83$ T);[5] this synthesis could not be replicated [6] This B_s for α''-$Fe_{16}N_2$ was about 30% larger than that of bulk α-Fe ($B_s=2.20$ T).[7]

Sugita and co-workers[8,9] formed thin films of α''-$Fe_{16}N_2$ by molecular beam epitaxy on Fe(100)|GaAs(100); B_s was largest (2.66 T) for the thinnest (7 nm) films.[9] B_s rose to 2.8 T for 100 nm films.[10] Nakajima and Okamoto implanted N_2^+ in epitaxial α-Fe|MgO(100), to get partially ordered α'-*N*-martensite and α''-$Fe_{16}N_2$; annealing in vacuum at 150 °C increased the α''-$Fe_{16}N_2$ fraction from 16 to 24 wt %, but the magnetic moments were not dramatic.[11]

Gao and Doyle formed α''-$Fe_{16}N_2$ on sputtered single layer Fe-N films, with a specific saturation magnetic moment of 247 emu g^{-1}.[12] An effort to get α''-$Fe_{16}N_2$ from α-Fe and γ'-Fe_4N at 300 °C failed.[13] Takahashi and co-workers reported on sputtered films containing α''-$Fe_{16}N_2$, but the magnetic moments were low.[14]

A practical synthesis of α''-$Fe_{16}N_2$ has been sought in acicular[15] or equant[16] small particles, in larger particles,[17–19] and in large particles and foils.[7] Opinions differ on the large reported magnetic moment: Coey wonders whether one is looking "at revolutionary results or egregious errors."[20]

II. SYNTHESIS

α''-$Fe_{16}N_2$ was first made by nitriding Fe, quenching, then tempering[3] (Table I). One can start with γ-Fe_2O_3 (obtained from goethite γ-FeOOH), reduce it to α-Fe by H_2 gas at 450 °C, nitride under H_2:NH_3 gas (volume ratio 7:1 to 10:1) at 650–700 °C, quench the resulting γ-*N*-austenite to 77 K, thus forming α'-*N*-martensite, then temper the sample under N_2 gas at 120–200 °C for several hours, yielding α''-$Fe_{16}N_2$.[15] There is a time-to-temperature (TTT) diagram for its formation.[21]

A second approach is to strain or age α'-*N*-martensite: oriented needles of α''-$Fe_{16}N_2$ grow at the strain boundaries.[22–25] A third method is to grow Fe films epitaxially, under a low-pressure NH_3-N_2 gas, by molecular beam epitaxy (MBE), on GaAs(100)[9] or on $In_{0.2}Ga_{0.8}As$(100).[26] A fourth way is to grow an Fe film on MgO(100), and then implant N_2^+ ions.[11] The first and second methods cannot usually provide phase-pure α''-$Fe_{16}N_2$; the third and fourth methods can yield better purity, but in impractically small samples.

III. PHYSICAL PROPERTIES

α''-$Fe_{16}N_2$ crystallizes in the tetragonal space group *I*4/*mmm*, with three unique Fe positions[2] (Table II). Table III lists the x-ray reflections of α''-$Fe_{16}N_2$ and of other phases (α-Fe, γ-*N*-austenite, γ'-Fe_4N, or α'-*N*-martensite) at the N mol fractions X_N at which the phases are stable closest to the theoretical $X_N=0.111$ of α''-$Fe_{16}N_2$. Many reflections are overlapped.

The structure evolves from α-Fe to α'-*N*-martensite to α''-$Fe_{16}N_2$, as one adds N atoms gradually in the structure and tempers it.[2,3] In pure α-Fe (bcc), one should consider the "empty" octahedron of four next-nearest neighbor Fe atoms in the *ab* plane ("equatorial" Fe-Fe distance=2.866 Å), plus two body-centered Fe atoms along **c** above and below that plane ("axial" Fe-Fe distance=2.866 Å, axial Fe-equatorial Fe distance=2.482 Å): in its center is the "octahedral hole." In the solid solution of N in Fe called α'-*N*-martensite, the entry of an N atom into this hole distorts the octahedron: for $X_N=0.0859$, there is a contraction in what becomes the martensitic $a_{\alpha'}b_{\alpha'}$ plane (equatorial Fe-Fe distance=2.75 Å), and a dilation in the $c_{\alpha'}$ direction (axial Fe-Fe distance=3.88 Å); these empty and "filled" octahedra occur randomly along the three axes, to yield a tetragonal unit cell with sides $a_{\alpha'}=b_{\alpha'}=2.850$ Å, $c_{\alpha'}=3.091$ Å for $X_N=0.0859$.[3] The martensitic nearest-neighbor Fe-N distance (octahedral coordination of Fe around N) is 1.94 Å.[3,36]

[a]Mn added to stabilize the γ-N-austenite phase at room temperature.

As tempering proceeds, a collective reorientation of the martensitic $c_{\alpha'}$ axes occurs, clusters or Guinier–Preston zones form, and finally, a full ordering ensues into the tetragonal α''-$Fe_{16}N_2$ structure: the unit cell axes become $a_{\alpha''}=b_{\alpha''}=5.72$ Å ($\approx 2a_\alpha$), and $c_{\alpha''}=6.30$ Å.[37] In α''-$Fe_{16}N_2$, the N atom is surrounded by a distorted octahedron of Fe atoms: four equatorial Fe3 atoms at 2.01 Å, two axial Fe2 atoms at 1.95 Å. Atom Fe1, at Wyckoff site 4d, does not have close N atoms, and should most resemble Fe in α-Fe. Atom Fe2 (4e) has a distorted octahedron of neighbors: one axial N, four equatorial Fe3, and one axial Fe2. Atom Fe3 (8h) has seven closest neighbors: one N, two Fe2, and four Fe1. The inclusion of N causes very close Fe-Fe distances (Fe2-Fe2 and Fe2-Fe3). One can designate Fe2 as 1nn, Fe3 as 2nn, and Fe1 as 3nn: this indicates the first, second, and third nearest-neighbor Fe atoms to the N atom. In α'-N-martensite the Fe-N distance is quite different for 1nn than 2nn, while in α''-$Fe_{16}N_2$ they are very close. The paucity of diffraction data for α''-$Fe_{16}N_2$ gave only approximate values of the parameters z/c (Fe2), and x/a (Fe3).[2] α''-$Fe_{16}N_2$ is most likely a daltonide, or "line phase," with precise N stoichiometry.[2,3]

The 002 and 006 reflections have been seen for epitaxial and sputtered thin films[10,12,33,35,38] but not in powder samples.[2]

One can determine the uptake of N in γ-N-austenite or α'-N-martensite from the unit cell constants,[17,36] using the equations in Table III. One can assess the mol fractions of the various phases by calculating[17,18] x-ray line profiles from the solved crystal structures.[39]

For epitaxial films, the relative crystal orientation is α''-$Fe_{16}N_2$(110)‖Fe(001), and α''-[001]‖Fe [110],[9,30] and α''-$Fe_{16}N_2$(001)‖InGaAs(001).[29,30] For sputtered films on MgO, the orientations are α''-$Fe_{16}N_2$(001)‖MgO(001) and α'' [110]‖MgO [100], or α''(211)‖MgO(101) and α'' [011]‖MgO [001].[14]

TEM diffraction patterns for 7 nm films of α''-$Fe_{16}N_2$‖Fe‖GaAs show the less intense reflections 200, 020, 0$\bar{2}$0, $\bar{2}$00; and the more intense ones: 1$\bar{1}$0, 220, 040, 2$\bar{2}$0, $\bar{2}$20, 040, $\bar{2}\bar{2}$0, and $\bar{4}$00.[9] Similar results were seen for films of α''-$Fe_{16}N_2$‖Fe(001)‖InGaAs(001),[29] and for sputtered films.[12] TEM of α''-$Fe_{16}N_2$ has been seen in fine powders.[16]

Spin-polarized linearized muffin-tin orbital calculations yield magnetic moments at the three sites of α''-$Fe_{16}N_2$

[a]Seen only in thin films (Refs. 10, 12, 14, 33, 35, and 38).
[b]α''-$Fe_{16}N_2$ reflections that are fairly intense and do not overlap badly with other reflections.

(Table IV), and moments close to experiment for Fe_3N and for γ'-Fe_4N.[7,44] An augmented spherical wave calculation has been done.[45] The maximum magnetic moment is assigned to site Fe1. The average calculated values are considerably below the large experimental thin-film values.

There are qualitative similarities between the Fe-N and Fe-C phase diagram. In the Fe-N diagram, the ordered N-Fe compounds (line phases, with narrow ranges of X_N) are γ'-Fe_4N and ζ-Fe_2N; α''-$Fe_{16}N_2$ is a metastable line phase; the phases γ and ϵ are stable for wide ranges of X_N; α'-*N*-martensite is metastable over a moderate range of X_N.

The name α''-$Fe_{16}N_2$ denotes the occupancy of the unit cell and its evolution from α-Fe and α'-*N*-martensite. An alternate name Fe_8N has been used.[13,15,45,48]

The Mössbauer data for α''-$Fe_{16}N_2$ are collected in Table V, together with comparable data for other phases of interest (α-Fe, α'-*N*-martensite, γ'-Fe_4N).

The Mössbauer spectrum of α''-$Fe_{16}N_2$ differs from that of α'-*N*-martensite. The three sextets seen for α''-$Fe_{16}N_2$ can be assigned with certainty to the three sites Fe1, Fe2, Fe3 of Table II only if the expected 4:4:8 relative intensities are obtained[49] (which identifies the 8*h* site Fe3) and if the signs of all the electric field gradients are known. The Mössbauer hyperfine fields H_{hf}=296, 316, and 399 kOe[49] were first assigned to Fe2 (site 4*e*, 1*nn*), Fe1 (site 4*d*, 3*nn*), and Fe3 (site 8*h*, 2*nn*), respectively.[50] This assignment is customary for iron alloys and for α'-*N*-martensite: H_{hf} (relative to α-Fe) decreases for the first nearest neighbors, increases dramatically for the second, then converges from above to the pure α-Fe value for third, fourth, etc., nearest neighbors.[50]

For α''-$Fe_{16}N_2$ this assignment is not supported by the relative Mössbauer line intensities[2,15,16,38,49] or by the band structure results, which assign the highest moment to site Fe1.[7,44,45] The new assignments in Table V give the largest

TABLE IV. Calculated magnetic moments (in Bohr magnetons μ_B) at sites in the α''-$Fe_{16}N_2$ lattice (Refs. 7, 44, 45), and distances from the N atom.

[a]These two assignments are uncertain, and could be interchanged.

[b] This datum is considered incorrect (Ref. 54).

H_{hf} to Fe1, the smallest to Fe2, and the value closest to α-Fe to Fe3.

From the Mössbauer hyperfine fields, the magnetic moments have been estimated at the sites Fe1, Fe2, and Fe3 as either 3.8, 1.3, and 2.5 μ_B,[33,49] or as 2.98, 2.01, and 2.25 μ_B,[51] respectively. The average H_{hf} of the three sites of α''-$Fe_{16}N_2$ (weighted 4:4:8 for Fe1:Fe2:Fe3), shown as $\langle H_{hf} \rangle$ in Table V, is essentially identical to H_{hf} of α-Fe.[14] For the epitaxial thin films of α''-$Fe_{16}N_2$ on GaAs, one single Mössbauer line is reported:[29,30,47] is this due to low resolution, or to a different species?[2,14]

An important technological goal is to produce macroscopic samples of 100% phase-pure α''-$Fe_{16}N_2$. Table VI shows the estimated Fe at. % contributions from various samples. High mol fractions of α''-$Fe_{16}N_2$ were achieved by epitaxy on GaAs[9] or by topotactical N_2^+ implantation.[49] Nitriding thin foils in NH_3:H_2 yields 40%.[7] Large particle powders (6–9 μm) yield 50%.[17] For small particles, at most 38% conversion was reached.[15,16] For small particles, 7–15 at. % Mn was needed,[16] while for larger particles Mn was unnecessary.[7,17] One cannot achieve X_N=0.1111 in γ-*N*-austenite, so by quenching and annealing, one cannot get 100% α''-$Fe_{16}N_2$.[51] Ways to obtain phase-pure α''-$Fe_{16}N_2$ have been proposed.[55]

The magnetic data for various samples, and the inferred values for the α''-$Fe_{16}N_2$ fraction, are summarized in Table VII. The first few benchmark entries are for bulk and powder α-Fe, and γ'-Fe_4N, and for recently measured powder samples (6–9 μm) of α'-*N*-martensites with different N contents.[17,18] The dependence of the high moment on the N atom concentration is very roughly linear.[29] As the 002 x-ray reflection of α''-$Fe_{16}N_2$ grows in intensity, the saturation volume magnetization M_s increases to a maximum of 2307 emu cm^{-3}.[47]

The inferred values of the specific saturation magnetization σ_s for α''-$Fe_{16}N_2$ depend on the reliability of the estimates of the mol fractions of all the magnetic constituents. In small powder samples exposed to air, the moment due to pure bulk α-Fe (218 emu g^{-1}) is reduced by passivation of the surface to maybe 140 emu g^{-1}. This passivation is less important for very large particles and epitaxial films, so the bulk value can be used.

For some laboratories, tempering the nitrided sample at 150–200 °C increases the sample magnetization, e.g., from 177 to 189 emu g^{-1},[16] or from 182 to 189 emu g^{-1};[17] other laboratories report no increase,[34,35,38] or only a modest increase, e.g., from 218 to 226 emu g^{-1}.[34]

The coercivities H_c for α''-$Fe_{16}N_2$ are small; shape anisotropy was sought by growing acicular particles.[15]

If α''-$Fe_{16}N_2$ is heated at 160 °C for 21 days, it decomposes to α-Fe and γ'-Fe_4N;[2] a similar decomposition occurs if one heats it to 200 °C for one week.[60] For α''-$Fe_{16}N_2$ particles (35 at. % Fe; 15 at. % Mn) kept at room temperature for six months the Mössbauer spectrum did not change.[60]

The high magnetization observed for epitaxial films of α''-$Fe_{16}N_2$ on GaAs or InGaAs(001) decreases reversibly with increasing temperature between −269 °C (B_s=3.1 T, μ=3.4 μ_B) and +400 °C (B_s=1.0 T), with a Curie temperature of 540 °C; above 400 °C this magnetization decreases irreversibly.[29] By annealing a rf sputtered film at 500 °C for 1 h, the moment density increases from about 225 to 253 emu g^{-1}, and the x-ray lines due to α''-$Fe_{16}N_2$ sharpen, while

[a]Using 218 or 220 emu g^{-1} for α-Fe.
[b]Using 140 emu g^{-1} for small particles of α-Fe.

for another sample the same treatment decreases the moment from 247 to 212 emu g^{-1}, and the α''-$Fe_{16}N_2$ lines disappear.[12] For films made by sputtering or by evaporation the moment drops when the temperature reaches 200–250 °C.[14]

Since α''-$Fe_{16}N_2$ powders are not stable above about 200 °C,[2,60] it has been speculated that epitaxial films with large magnetic moments contain a different phase.[14]

IV. CONCLUSIONS

α''-$Fe_{16}N_2$ is a fascinating magnetic system. The evidence for a very large moment (>280 emu g^{-1}) for α''-$Fe_{16}N_2$ comes from epitaxial thin films,[5,9,26,30,31,46,47] from some sputtered films,[12] and from medium[17,18] and small particle[15,16] studies. Already, α'-*N*-martensite has a moment considerably higher than that of α-Fe.[18,32,33] The high magnetization of the epitaxial films has even been ascribed to some unknown phase.[14]

The "dissenting" evidence against large moments comes from foils,[7] large particles,[7] N_2^+ ion-implanted films,[31,32,33,38] some sputtered films,[14] and from theoretical studies.[7,44,45,51] It is tempting to dismiss the theoretical results, since theory often fails us. All these arguments, pro and con, rest on x-ray or Mössbauer estimates of the magnetic constituents present in the samples, and on how well the samples resist to air oxidation.

To answer Coey's challenge,[20] many are convinced that we are facing a "real value," not an "egregious error."

ACKNOWLEDGMENTS

The authors are very grateful to Dr. Yutaka Sugita and Migaku Takahashi, and to Professors J. M. D. Coey, William D. Doyle, Kenneth H. Jack, and W. Edward Wallace for illuminating discussions. The work has been supported by the Advanced Research Projects Agency, funneled through the Advanced Tape Project of the National Storage Industry Consortium.

The magnetization of bulk $\alpha''Fe_{16}N_2$ (invited)

J. M. D. Coey
Physics Department, Trinity College, Dublin 2, Ireland

Evidence for giant magnetic moments in the metastable nitride $\alpha''Fe_{16}N_2$ is reviewed, with reference to the related stable nitride $\gamma'Fe_4N$ and αFe. It is concluded from a survey of electronic structure calculations, Mössbauer spectra, and magnetization measurements on bulk multiphase samples that the average iron moment in $\alpha''Fe_{16}N_2$ at $T\sim0$ lies in the range 2.3–2.6 μ_B. A significantly larger moment of about 2.9 μ_B appears on the $4d$ sites which have no nitrogen neighbors.

I. INTRODUCTION

Alpha-iron is a weak ferromagnet with an incompletely filled $3d^{\uparrow}$ subband. The electronic configuration is approximately $3d^{\uparrow 4.4}3d^{\downarrow 2}4s^{0.6}4p^{0.8}$, giving a magnetic moment per atom $\mu_{Fe}=2.2$ μ_B. It is actually the saturation polarization J_s, related to the magnetic moment per unit volume M_s by $J_s=\mu_0 M_s$, which is important for technical applications; J_s for iron at room temperature is 2.15 T. There is scope for increasing the moment by modifying the density of states and moving the position of the Fermi level in the d band, but if they are to improve the magnetization, these changes must be accomplished with as little increase as possible in lattice volume.

The greatest polarization that has been achieved in iron-based substitutional alloys is $J_s=2.45$ T, in $Fe_{65}Co_{35}$. Iron ions with atomic moments as high as 5 μ_B for the $3d^{\uparrow 5}$ configuration of Fe^{3+} are obtained by charge transfer in ionic compounds, yet J_s in ferrites does not exceed 0.6 T because the order is ferrimagnetic and most of the volume is occupied by nonmagnetic O^{2-}.

The quest for greater iron magnetization is currently focused on interstitial compounds, particularly those where nitrogen is accomodated in octahedral voids in the iron lattice. Nitrogen in cubic $\gamma'Fe_4N$ occupies the $1b$ body-center site in an fcc lattice, so the $1a$ cube corner and $3c$ face-center iron sites become inequivalent. The ordered, metastable iron nitride $\alpha''Fe_{16}N_2$ discovered by Jack in 1951[1] has a related structure where only half of these octahedral interstices are occupied by nitrogen (Fig. 1). The tetragonal cell contains eight bcc units, and the structure can be regarded as lying midway between αFe and $\gamma'Fe_4N$.[1] The $4d$ site in $\alpha''Fe_{16}N_2$ is analogous to the $1a$ site in $\gamma'Fe_4N$ and the $4e$ and $8h$ sites in $\alpha''Fe_{16}N_2$ are analogous to the $3c$ sites in $\gamma'Fe_4N$, except that they have only one nitrogen neighbor instead of two.

The magnetic properties of $\alpha''Fe_{16}N_2$ remained unexplored until 1972 when Kim and Takahashi produced thin films where αFe was the major phase by evaporating iron in nitrogen. Some of these films were found to have a polarization as high as 2.64 T, and the polarization of pure $\alpha''Fe_{16}N_2$ was inferred to be 2.76 T, corresponding to an average iron moment of 3.0 μ_B.[2] In recent years, other Japanese groups have made films containing $\alpha''Fe_{16}N_2$ by different methods, with quite variable results.[3–10] Most remarkable are those of Sugita and co-workers at Hitachi, who produced films by molecular-beam epitaxy on $(Ga_{0.8}In_{0.2})As$ substrates where the polarization of $Fe_{16}N_2$ was found to be 2.9 T.[5] They have corroborated their result by a ferromagnetic-resonance experiment.[9] The corresponding average moment per iron atom μ_{av} is 3.2 μ_B at room temperature, rising to 3.5 μ_B at $T\sim0$. Other workers, however, report values of magnetization of their thin films which are much closer to that of αFe.[8]

Here we review the evidence of electronic structure calculations, Mössbauer spectra and bulk magnetization measurements regarding the site and average moments in αFe, $\alpha''Fe_{16}N_2$, and $\gamma'Fe_4N$. Experimental investigations of $\alpha''Fe_{16}N_2$ have been hindered by the lack of bulk, single-phase samples of the metastable α'' phase.

II. ELECTRONIC STRUCTURE CALCULATIONS

Self-consistent spin-polarized electronic structure calculations have now developed to the point where it is routinely possible to deduce the ground-state spin moments in iron-group ferromagnetic alloys to within about 0.1 μ_B. The moment of iron itself is accurately reproduced.[11] Linearized muffin-tin orbital (LMTO) calculations for $\alpha''Fe_{16}N_2$ and other iron nitrides were carried out by Sakuma[12–14] and many others,[15–21] varying the unit cell volume, c/a ratio, and special position parameters. These LMTO calculations are based on the atomic spheres approximation, which is well

justified by the charge-density distributions obtained by Coehoorn *et al.* using a first-principles full potential (FLAPW) approach.[22] Matar has used the augmented spherical wave (ASW) method[23,24] and there have also been some cluster calculations.[25,26] Results of these calculations for $\gamma' Fe_4N$ and $\alpha'' Fe_{16}N_2$ are summarized in Tables I and II, respectively.

It can be seen in Table I that the calculations for $\gamma' Fe_4N$ give average and site moments which agree quite well with those measured experimentally by magnetization and neutron diffraction (2.98 μ_B/Fe on 1a, 2.01 μ_B/Fe on 3c, μ_{av}=2.25 μ_B/Fe).[27] In the case of $\alpha'' Fe_{16}N_2$, the atomic positions depend on two special position parameters,[1] which have not been determined precisely. However, these parameters and the c/a ratio can be varied over a reasonable range in the computer. When this is done, there are small variations in the site moments, but in no case does the average moment per iron atom exceed 2.50 μ_B. An exception is the cluster calculation of Li,[25] which gives an average moment of 3.3 μ_B/Fe, but this method greatly overestimates the moment of α-Fe, and it cannot be regarded as quantitatively reliable. Larger moments are also reported in an "LDA+U" calculation which involves an on-site Hubbard interaction U,[44] but the approach does not appear to have been tested on α Fe or γ' Fe_4N.

In $\alpha'' Fe_{16}N_2$, $\gamma' Fe_4N$ and other interstitial iron nitrides[20,28] there is a tendency for all iron moments to increase as the lattice is expanded by interstitial nitrogen. This is counteracted to some extent by sp-d hybridization at those iron sites which have nitrogen neighbors. However, iron atoms which are next-nearest neighbors of nitrogen see their moments increased. The local density of states for 4d sites in $\alpha'' Fe_{16}N_2$ and 1a sites in $\gamma' Fe_4N$ indicates strong ferromagnetism at these sites. The increase of the next-nearest-neighbor iron moments in nitrides was explained by Kanamori,[29] by analogy with the increase of iron moment in $Fe_{65}Co_{35}$.[29] The iron neighbors of nitrogen hybridize with the nitrogen sp orbitals, which decreases the spin splitting and lowers the effective iron potential, especially for the 3$d\downarrow$ states. These iron atoms then have some of the character of cobalt in the Fe-Co alloys. Interaction with iron atoms which are next-nearest neighbors of nitrogen increases the amplitude of wave functions at the latter in the antibonding states of the 3$d\downarrow$ band whereas it will decrease the amplitude of the

bonding states of the $3d\downarrow$ band. The decrease of occupied states in the $3d\downarrow$ band is compensated by a shift in spectral weight to occupied states in the $3d\uparrow$ band. Hence the moment of the next-nearest-neighbor iron is raised.

Large iron moments in $\alpha''Fe_{16}N_2$ can be achieved in LMTO calculations by expanding the lattice. Ishida *et al.*[15] show that the average iron moment reaches 3.0 μ_B when the lattice volume is increased by 50%, but the polarization of the expanded lattice is only 2.0 T.

III. MÖSSBAUER SPECTRA

Before considering the Mössbauer spectrum of $\alpha''Fe_{16}N_2$, it is useful to look at those of αFe and $\gamma'Fe_4N$, whose interpretation in unambiguous. Alpha-iron has a single site with cubic symmetry where the hyperfine field is 33.8 T at $T\sim0$. The spectrum of $\gamma'Fe_4N$ (Fig. 2) exhibits two clearly resolved subspectra with hyperfine fields of 36.6 and 23.5 T in an intensity ratio 1:3 which are identified with the $1a$ and $3c$ sites, respectively. (The $3c$ spectrum is split into two barely resolved components with a 2:1 intensity ratio because the field gradient axis may lie parallel or perpendicular to the magnetization direction.[17,30,31]) The calculated Fermi contact hyperfine fields agree well with the measurements (Table I).

The distinctive feature of the Mössbauer spectrum of $\alpha''Fe_{16}N_2$ is the hyperfine component with B_{hf}=41 T,[21,32-38] which is attributed to iron in $4d$ sites. The subspectra of iron in $4e$ and $8h$ sites, which form an octahedron around the nitrogen interstitial, have hyperfine fields of 31 and 32 T, respectively. This assignment is in accord with that of Nakajima *et al.*, based on conversion-electron spectra of ion-implanted films,[37] and with previous work on bulk samples.[19,32,38] It also agrees with the order of the hyperfine fields calculated by Coehoorn *et al.* using a full potential linearized augmented plane-wave method.[22] Moriya *et al.*[33] assigned the highest field to the $8h$ site, but their interpretation is inconsistent with the expectation that $8h$ and $4e$ sites,

each with one nitrogen neighbor, should have similar hyperfine fields.[38] The spectrum of $\alpha''Fe_{16}N_2$ obtained after stripping off the other constituents is shown in Fig. 3. Fitted hyperfine parameters are given in Table III.

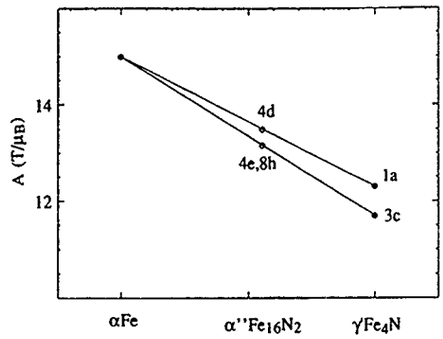

FIG. 4. The relation between iron site moment and hyperfine field for $\alpha''Fe_{16}N_2$ interpolated from data on $\gamma'Fe_4N$ and αFe.

It is not a straightforward matter to infer the site moments from the hyperfine fields. Writing $B_{hf}=A\mu_{Fe}$, the "constant" A is -15 T/μ_B for αFe, but values lying anywhere from -11 to -17 T/μ_B can be found for different iron sites in iron-rich alloys. (Mössbauer data usually give the magnitude, but not the sign of the hyperfine fields.) There are several different contributions to B_{hf} which have different dependences on μ_{Fe}.

$$B_{hf}=B_{cp}+B_{val}+B_{orb}+B_{dip}. \quad (1)$$

The leading term B_{cp} due to spin polarization of the $1s$, $2s$, and $3s$ core orbitals is strictly proportional to the $3d$ spin moment, with $A=-11.3$ T/μ_B. It is the contribution of the valence electrons B_{val} which depends on the chemical bonding that varies most with the compound or the sites considered. The orbital contribution B_{orb} is often neglected because the orbital moment is quenched in itinerant ferromagnetic iron alloys (typically it is less than 0.1 μ_B). The classical dipolar field B_{dip} at the nucleus is also small (<1 T). Evaluations of the hyperfine fields due to spin moments in electronic structure calculations reproduce the observed trends, but tend to underestimate B_{hf} by up to 5 T.[22] The calculations

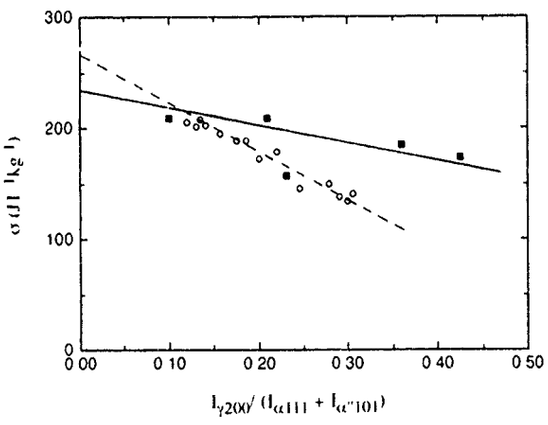

FIG. 5. Extrapolations to deduce the magnetic moment of pure $\alpha''Fe_{16}N_2$ using x-ray intensities for phase analysis. Experimental data sets are those of Huang *et al.* (see Ref. 41), circles and dashed line and Coey *et al.* (see Ref. 19), squares and solid line.

give the first two terms in Eq. (1), known as the Fermi contact interaction, which depend on the unpaired spin density at the nucleus.

Here we adopt an empirical approach to evaluate the factor A at the three sites in $\alpha''Fe_{16}N_2$. It can be deduced for $1a$ and $3c$ sites in $\gamma'Fe_4N$, from the site moments measured by neutron diffraction,[27] and the hyperfine fields in Table II. The values for $\alpha''Fe_{16}N_2$ are then deduced by interpolation between αFe and γFe_4N, as shown in Fig. 4. The site moments and the average iron moment shown in parentheses on the bottom line of Table II are obtained. Note the large moment of 3.0 μ_B/Fe on $4d$ sites, but the average value is only 2.6 μ_B/Fe.

IV. MAGNETIC MEASUREMENTS

Mitsuoka *et al.*[39] estimated the magnetic moment of bulk $\alpha''Fe_{16}N_2$ some years ago as 2.6 μ_B/Fe. There have been several recent reports of magnetic measurements on samples containing a significant proportion (<~50%) of $\alpha''Fe_{16}N_2$.[19,36,40,41] All materials were prepared by the $\gamma\rightarrow\alpha'\rightarrow\alpha''$ route originally used by Jack,[1] and described by him in more detail in a preceding paper.[42] Nitrogen has a solubility range extending up to 10 N/100 Fe in austenite (γFe) which is stable above 590 °C. Nitrogen austenite can be prepared by heating iron powders or foils in an atmosphere of flowing NH_3/H_2 at about 700 °C for several hours, then rapidly quenching to yield nitrogen martensite, thereby avoiding decomposition into the equilibrium phases, $\alpha Fe+\gamma'Fe_4N$. Prolonged annealing of the martensite at 120 °C for 7 days yields samples composed of αFe, γFe, and $\alpha''Fe_{16}N_2$ in varying proportions. Pure $\alpha''Fe_{16}N_2$ cannot be obtained by this method because the solubility of nitrogen in austenite is less than the required 12.5 N/100 Fe. Furthermore, the martensitic transformation is depressed to lower temperatures as the nitrogen content increases, so the nitrogen-rich samples tend to contain retained austenite, whereas the nitrogen-poor ones are mostly αFe.

The magnetization of these bulk samples is easily measured,[19,36,39–41] but *none has been found to possess a magnetization greater than that of αFe.* If $\alpha''Fe_{16}N_2$ really has a magnetization σ_s in excess of 300 J T^{-1} kg^{-1}, one would expect the nitrogen-poor samples at least to exhibit a magnetization greater than 220 J T^{-1} kg^{-1}, the value for αFe.

The inference of the magnetization of the α'' phase from measurements on phase mixtures relies on (i) quantitative analysis of the phases present and (ii) knowledge of the magnetization of each one. The phase analysis can be obtained from x-ray diffraction[41] or Mössbauer spectra.[19,36] Huang *et al.* use x-ray diffraction to deduce σ=272–286 J T^{-1} kg^{-1} at room temperature, corresponding to $\mu_{Fe}=2.94$ μ_B whereas Coey *et al.* base their quantitative phase analysis on the absorption areas of Mössbauer spectra taken at 15 K and deduce σ=225–270 J T^{-1} kg^{-1} corresponding to μ_{Fe}=2.3–2.6 μ_B and J=2.1–2.5 T. The Mössbauer method of phase analysis has the advantage that it probes all the iron in the sample, not just a surface region as is the case for x-ray diffraction. Bao *et al.* find that the magnetization of a single sample is consistent with a large magnetization for the α''

phase.[36] Sakamoto[40] deduces from annealing experiments that the magnetization of $Fe_{16}N_2$ has a higher value than that of pure iron.

A problem for inferring the α'' moment from γ-rich material is that the magnetic properties of nitrogen-austenite are not entirely clear. A broadened peak appears as the room-temperature Mössbauer spectrum, but it is uncertain that the broadening is exclusively due to the distribution of quadrupole splitting. A small magnetic hyperfine [illegible]tion with $B_{hf} \sim 2$ T might contribute. Electronic structu[illegible]ulations indicate the possibility of very weak ferromagnetism in expanded γFe before the transition to a high-moment state.

V. CONCLUSIONS

Most data on bulk $\alpha''Fe_{16}N_2$ indicate that the average iron moment lies in the range 2.3–2.6 μ_B. None of the results we have reviewed provide support for an average iron moment of 3.0–3.5 μ_B, as has been claimed for certain thin films.

The sites which carry the largest moments of $\sim 3.0\ \mu_B$ in the interstitial iron nitrides are those ($1a$ in γFe_4N, $4d$ in $\alpha''Fe_{16}N_2$) which are *next*-nearest neighbors of the nitrogen. The moments on the nearest-neighbor sites are much influenced by hybridization with the nitrogen *sp* orbitals.

The discrepancy with the results on the thin films of the Hitachi group in particular is unexplained. Extensive studies by Takahashi and co-workers[43] on films prepared by reactive sputtering and plasma evaporation indicate a value of σ_s of 230–240 J T^{-1} kg^{-1}. Possible considerations are surface effects and nitrogen order. Surface enhancement of magnetization might arise in very thin films. It is doubtful whether disordering the nitrogen can increase the moment, in view of results on mechanically alloyed material[21] and the increase of magnetization which accompanies annealing the nitrogen martensite.[36,40] However, one might imagine an ordered phase containing less nitrogen which contains more of the high-moment iron sites.

Although there may be no giant moment, the data indicate that $\alpha''Fe_{16}N_2$ is closer to strong ferromagnetism than αFe and they encourage further efforts to prepare the α'' phase in a pure form[42] and investigate alloy additions in order to optimize the properties for those applications that call for ferromagnetic material with the greatest possible polarization.

ACKNOWLEDGMENTS

The author is grateful to many co-workers who have participated in our investigations of metastable iron nitrides, particularly Dr. Qinian Qi, Kathy O'Donnell, Emmanuelle Touchais, and James O'Sullivan. He has benefitted greatly from the advice and encouragement of Professor K. H. Jack.

Single-phase, single-crystal $Fe_{16}N_2(001)$ films and Fe-11 at. %N martensite films of 200–900 Å thickness have been epitaxially grown on $In_{0.2}Ga_{0.8}As(001)$ substrates by evaporating Fe in an atmosphere of mixed gas of N_2 and NH_3, followed by annealing. The saturation magnetizations $4\pi M_s$'s for $Fe_{16}N_2$ and Fe-N martensite films have been measured to be around 29 and 24 kG at room temperature, respectively, and almost constant in the above thickness range by using a vibrating sample magnetometer. $4\pi M_s$ for Fe-N martensite films has been increased with ordering of N atoms caused by annealing and finally reached around 29 kG for $Fe_{16}N_2$. Mössbauer spectra have been measured for those films. The spectrum for Fe-N martensite films was a superposed one with hyperfine fields of 360, 310, and 250 kOe, similar to those previously reported for martensite. While the spectrum became simpler with ordering, finally reaching a single hyperfine field of 330 kOe for $Fe_{16}N_2$. $4\pi M_s$ of 29 kG for $Fe_{16}N_2$ (3.2 μ_B/Fe atom) and $4\pi M_s$ of 24 kG for martensite (2.6 μ_B/Fe atom) has not been explained based on the conventional band theory of $3d$ metal magnetism. Behaviors of Mössbauer spectra could not be understood based on the conventional concept either. Thus a new physical concept is likely to be needed for clarification of giant magnetic moments and Mössbauer spectra for $Fe_{16}N_2$ and Fe-N martensites.

I. INTRODUCTION

In 1972, Kim and Takahashi[1] found that Fe-N films, evaporated in a N_2 gas atmosphere, exhibit 25.8 kG for the saturation magnetization $4\pi M_s$ at room temperature, which is higher than that of pure Fe by 17%. Furthermore, they confirmed that the Fe-N films are polycrystalline, consisting of Fe and $Fe_{16}N_2$ crystallites and estimated the $4\pi M_s$ of $Fe_{16}N_2$ to be 28.3 kG from the volume fraction of $Fe_{16}N_2$ in the films. $Fe_{16}N_2$ is a metastable Fe-N compound with a bct structure, which was discovered by Jack[2] in 1951.

Quite recently, Komuro *et al.*[3,4] and Sugita *et al.*[5] have grown single-phase, single-crystal $Fe_{16}N_2$ films of around 500 Å thickness epitaxially on $In_{0.2}Ga_{0.8}As(001)$ substrates by using molecular-beam epitaxy (MBE) and found that the $4\pi M_s$ of $Fe_{16}N_2$ films is around 29 kG at room temperature and around 32 kG at 5 K. Those values are equivalent to the average magnetic moments of 3.2 and 3.5 μ_B per Fe atom at room temperature and 5 K, respectively. These are truely giant magnetic moments, much greater than the Slater–Pauling curves.[6]

More recently, $4\pi M_s$ of Fe-N films and powders formed by sputtering,[7–11] ion implantation,[12] and ammonia nitrification,[13–15] have been intensively investigated. In many cases, significant increases in $4\pi M_s$ for Fe-N or $Fe_{16}N_2$ have been found,[7,8,11–13] although the values are different. In contrast to these, Takahashi *et al.*[10] reported that a significant increase in $4\pi M_s$ is not observed for $Fe_{16}N_2$ films epitaxially grown on MgO substrates by reactive plasma sputtering. The reasons for the above different results of $4\pi M_s$ for $Fe_{16}N_2$ and Fe-N films remain to be clarified.

In this study, the effect of ordering of N atoms on $4\pi M_s$ and the film thickness dependence of $4\pi M_s$ have been investigated in detail for single-crystal $Fe_{16}N_2$ and Fe-N martensite films epitaxially grown on $In_{0.2}Ga_{0.8}As$ substrates by MBE. Also, the Mössbauer spectra have been measured for those films.

II. EXPERIMENT

A. Sample preparation

$Fe_{16}N_2$ and Fe-N films were prepared in an atmosphere of mixed gas of N_2 and NH_3 by using an MBE apparatus equipped with electron-beam evaporation sources. $In_{0.2}Ga_{0.8}As(001)$ single-crystal wafers were used as substrates because the lattice matching between $In_{0.2}Ga_{0.8}As$ (5.71 Å) and the a axis of $Fe_{16}N_2$ (5.72 Å) is very good. The substrates were etched by using 5:1:0.3 solution of H_2SO_4:H_2O:H_2O_2. After that, the substrates were mounted on a stainless-steel block with indium bonding and cleaned by heating at 675 °C for 5 min in the MBE chamber ($<1\times10^{-9}$ Torr). The temperatures of the samples were measured at the backside of the stainless block. The purity of Fe used as the deposition source was 99.999%.

The deposition conditions are listed in Table I. Those conditions were selected based on the trade off between epitaxial growth and introduction of around 11 at. % N into deposited films for forming $Fe_{16}N_2$. Among these, the deposition rate and the gas pressure were most critical. Film thicknesses were 200–900 Å.

TABLE I. Deposition conditions of Fe-N and Fe films on InGaAs(001) substrates.

	Fe-11 at. % N	Fe
Base pressure (Torr)	1×10^{-9}	←
Gas	N_2+20%NH_3	vacuum
Substrate temperature (°C)	200	250
Deposition rate (Å/s)	0.02–0.03	0.1
Pressure during deposition (Torr)	$1–2\times10^{-4}$	5×10^{-7}

Pure Fe films were prepared on $In_{0.2}Ga_{0.8}As(001)$ substrates in vacuum of 5×10^{-7} Torr for comparison with Fe-N films and reference for measurements.

B. Characterization

Nitrogen concentrations in those films were measured by using x-ray photoelectron spectroscopy (XPS) and Auger electron spectroscopy (AES). Figure 1 shows the intensity ratio of N 1*s* to Fe 2*p* peaks of XPS versus N concentration curve used as calibration. The relationship was obtained using standard Fe-N powder samples with various concentrations. Concentrations of Fe-N films used in this study were around 10–11 at. % N as shown in Fig. 1. The depth profile of the concentration was obtained by AES.

The film thicknesses were measured routinely by using a needle contact feeler gauge. Some of the obtained values were checked by comparing with the thicknesses measured by using the cross-sectional transmission electron microscopy (TEM) images as shown in Fig. 2. The agreement between both data is very good, suggesting an error of measurement of less than ±3% with the exception of one point.

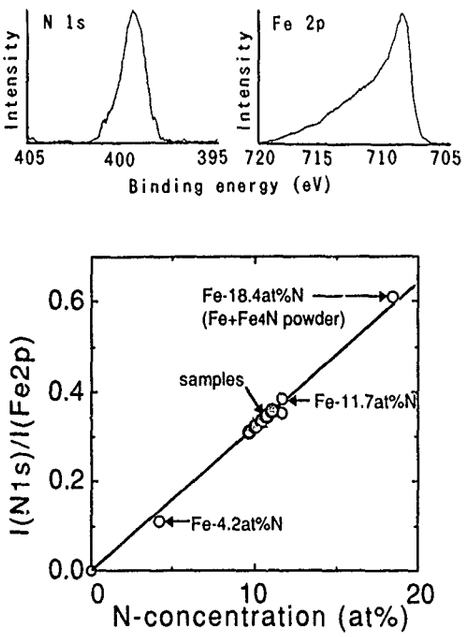

FIG. 1. The intensity ratio of N 1*s* to Fe 2*p* peaks of XPS as a function of N atom concentration in standard Fe-N powder samples along with Fe-N films used in this study.

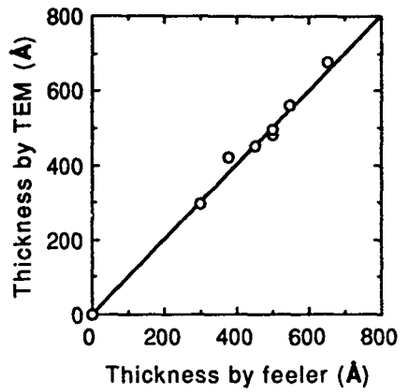

FIG. 2. Comparison between film thicknesses measured with a cross-sectional TEM and a needle contact feeler gauge.

The crystal structures of the samples were investigated by the x-ray-diffraction (XRD) method using monochromatic Cu $K\alpha$ radiation. Also, the crystallinity of the films was evaluated with reflection high-energy electron-diffraction (RHEED) analysis.

The saturation magnetizations $4\pi M_s$'s of the films were measured with a vibrating sample magnetometer (VSM). Samples were circular plates of 8 mm diameter which were formed very accurately by using photolithography and etching using HNO_3. Therefore the measurement error of $4\pi M_s$ obtained was likely to be less then ±5% (sample volume ±3%, VSM ±2%).

Mössbauer spectra were measured by using a conversion electron-type apparatus. Samples were coated with around 100 Å thick Au layers for protection against oxidation. Before and after the Mössbauer measurements, $4\pi M_s$ was measured and made sure to remain the same by a VSM.

III. RESULTS AND DISCUSSION

A. Effect of ordering of N atoms on $4\pi M_s$

Fe-11 at. % N films of around 500 Å thickness were prepared with changing annealing time after the deposition of the films. Annealing was carried out at 200 °C in vacuum of 10^{-8} Torr. Figures 3(a)–3(c) show XRD patterns for unannealed, annealed (40 h), and fully annealed (90 h) samples. In Fig. 3(a), peaks for $Fe_{16}N_2(\alpha'')$ are not seen, but only the (002) peak for Fe-N martensite (α') is seen at 58.1°. This shows that N atoms are located in disorder. In this case also, a RHEED pattern of straight fine streaks is seen, which suggests that the film is a high quality single crystal. In Fig. 3(b), the α''(002) peak appears at around 28.1°, but it is much smaller than the peak at 58.1° corresponding to α'(002) and α''(004). The ratio is around 0.04. Taking into consideration that the ratio of the peak intensity of α''(002) to α''(004) is calculated to be 0.125 for $Fe_{16}N_2$, the film is considered to be a mixture of α' and α''; that is, ordering of N atoms occurs partially. In Fig. 3(c), the α''(002) peak becomes stronger and the intensity ratio of two peaks is around 0.1, showing that the film is single-phase $Fe_{16}N_2$ with full ordering of N atoms in a bct structure. This is confirmed by a RHEED pattern of fine streaks with half period of pure Fe.

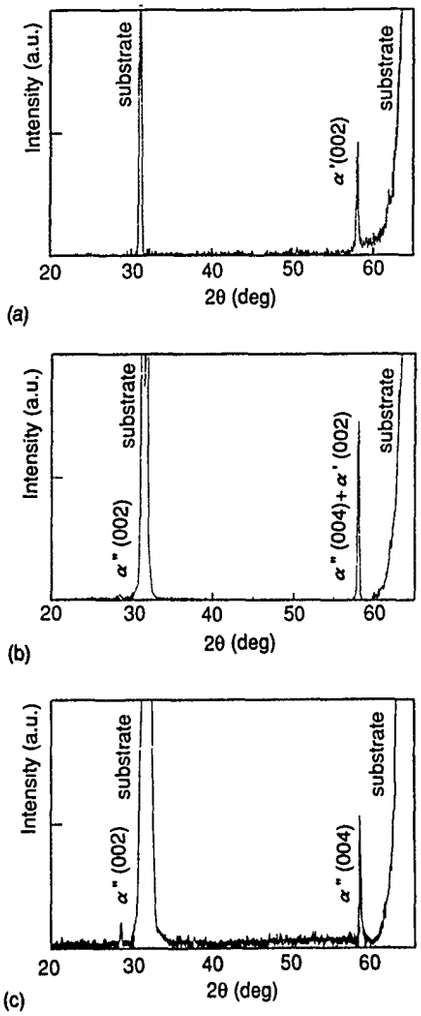

FIG. 3. XRD patterns for unannealed and annealed Fe-11 at. % N films. (a) Unannealed, Fe-N martensite (α'); (b) annealed at 200 °C for 40 h, $\alpha'+\alpha''$; and (c) annealed at 200 °C for 90 h, $Fe_{16}N_2(\alpha'')$.

Thus the ratio of $\alpha''(002)$ peak to $\alpha''(004)$ and $\alpha'(002)$ peaks can be a measure of ordering N atoms in Fe-N films. The lattice parameters for α'' are 6.33 Å (c axis) and 5.71 Å (a axis), which are close to previously reported values.[2]

Magnetization curves for the above samples measured with a VSM are shown in Fig. 4. $4\pi M_s$ for an Fe-N martensite (α') film is 24 kG and that for an $Fe_{16}N_2(\alpha'')$ film is 29 kG. For an intermediate film, $4\pi M_s$ is 27 kG, an intermediate value of α' and α''. The relationship between $4\pi M_s$ and ordering of N atoms is shown in Fig. 5. $4\pi M_s$ is increased monotonically from 24 kG for α' up to 29 kG for α'' with ordering of N atoms or the intensity ratio of $\alpha''(002)$ peak to $[\alpha''(004)+\alpha'(002)]$ peaks. The deviation of data is rather large. This is due to inaccuracy of measurement of weak $\alpha''(002)$ peak intensities. However, the above relationship is clear.

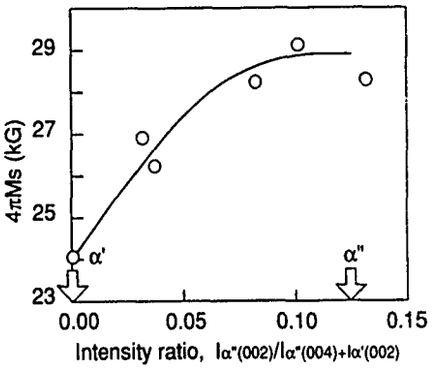

FIG. 5. The relationship between $4\pi M_s$ and ordering of N atoms expressed by $I\alpha''(002)/I[\alpha''(004)+\alpha'(002)]$.

As shown in Fig. 4, all samples exhibit low remanence. Possibly stripe domains are formed by strong perpendicular anisotropy;[16] that is, the magnetization tilts upwards and downwards from the films plane periodically.

B. Film thickness dependence of $4\pi M_s$

$4\pi M_s$'s for $Fe_{16}N_2$ and Fe-N martensite films are shown as a function of the film thickness from 200 to 900 Å in Fig. 6. For comparison, the data for epitaxially grown Fe films of the same thickness range measured in the exactly same way are shown.

$4\pi M_s$ for $Fe_{16}N_2$ films is around 29 kG and does not depend on the film thickness in this range at all. This means that the giant magnetization for $Fe_{16}N_2$ originates from the bulk properties of $Fe_{16}N_2$, not from the surface. $4\pi M_s$ for Fe-N martensite films is around 24 kG and also does not depend on the film thickness. Quite large deviations are seen in the thinner thickness region, but this is due to the difficulty of detecting partial formation of small amount of

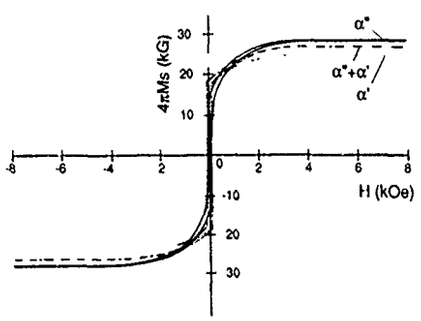

FIG. 4. Magnetization curves for unannealed and annealed Fe-11 at. % N films as shown in Fig. 3. α', dotted line; $\alpha'+\alpha''$, dashed line; α'', solid line.

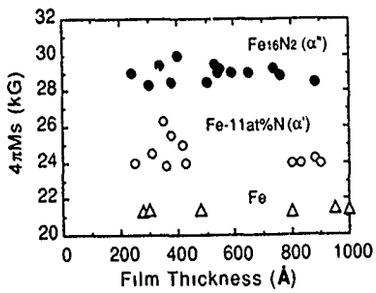

FIG. 6. Film thickness dependence of $4\pi M_s$ for $Fe_{16}N_2$ and Fe-N martensite films along with Fe films.

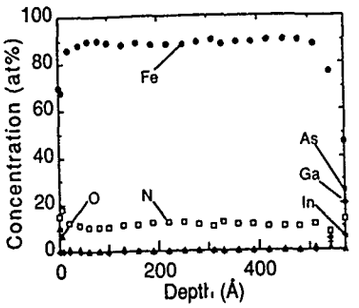

FIG. 7. AES profile for an $Fe_{16}N_2$ film.

$Fe_{16}N_2$ in Fe-N martensites. Here it should be noticed that $4\pi M_s$ for pure Fe films is around 21.5 kG over the thickness range, which is very similar to the bulk value previously reported. This confirms that the accuracy of the measurement of $4\pi M_s$ of films in the thickness range is very high and the obtained $4\pi M_s$'s for $Fe_{16}N_2$ and Fe-N martensite are correct. Furthermore, $4\pi M_s$ for $Fe_{16}N_2$ was confirmed to be 28 kG also by FMR[16] independently of VSM measurements.

Figure 7 shows a typical AES profile for a 550 Å thick $Fe_{16}N_2$ film. The concentrations of Fe and N atoms are just around 89 and 11 at. % for $Fe_{16}N_2$, respectively, through the film thickness, except for 10–20 Å thick regions of the top and bottom surfaces of the film. This is consistent with the above data of $4\pi M_s$ independence on the film thickness. The concentrations of impurities such as oxygen atoms are much smaller than 1% except for the top surface of the film.

C. Mössbauer spectra

Mössbauer spectra for Fe-N martensite, intermediate, and $Fe_{16}N_2$ films are shown in Fig. 8. As shown in Fig. 8(a), the spectrum for an Fe-N martensite film with $4\pi M_s$ of 24 kG is a complicated one, being superposed with three kinds of hyperfine fields of 360, 310, and 250 kOe. This is substantially similar to previously reported data[17,18] for Fe-N martensite foils. The spectrum for a film of partial ordering with $4\pi M_s$ of 27 kG becomes simpler as shown in Fig. 8(b). The spectrum is still a superposed one, but a hyperfine field of around 330 kOe appears clearly. For an $Fe_{16}N_2$ film with $4\pi M_s$ of 29 kG, the spectrum becomes very clear with the single hyperfine field of 330 kOe as shown in Fig. 8(c). The same spectra are observed for five different $Fe_{16}N_2$ samples prepared at different times. The spectrum is quite different from previously reported data for $Fe_{16}N_2$ precipitates formed from Fe-N martensite powders[19] by 100 °C annealing and N ion implanted Fe-N films including $Fe_{16}N_2$.[20] The previous data are rather similar to that for martensite or intermediate ones as shown above.

The hyperfine field of 330 kOe for $Fe_{16}N_2$ is very similar to that for pure Fe. Apparently it seems contradictory that the hyperfine fields are almost the same, although the magnetic moments are very different. However, the relationship between the magnetic moment and the hyperfine field is very complicated and not definite, since the magnetic moment originates from the polarization of $3d$ electrons, while the

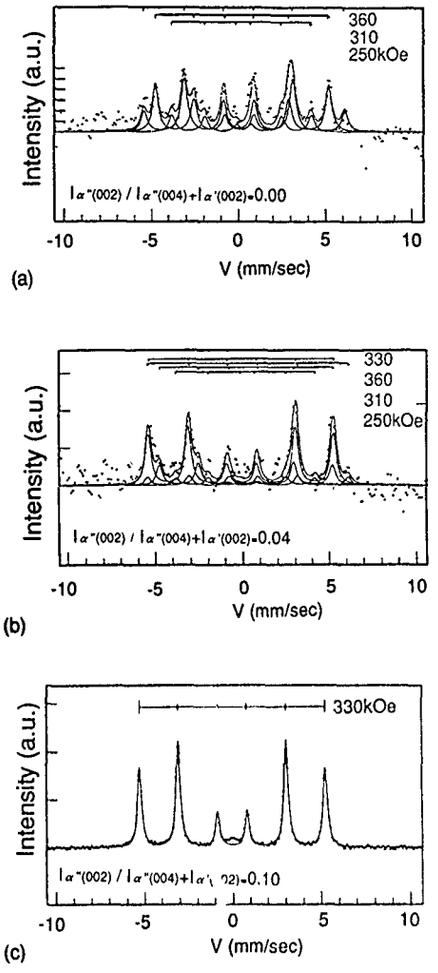

FIG. 8. Mössbauer spectra for unannealed and annealed Fe-11 at. % N films. (a) Fe-N martensite (α'), (b) Fe-N intermediate ($\alpha'+\alpha''$), and (c) $Fe_{16}N_2(\alpha'')$.

hyperfine field comes from that of $1s$, $2s$, and $3s$ electrons. Therefore the above experimental results cannot be said to be contradictory based on the simple linear relationship.

D. Origin of giant magnetic moment

The magnetic moment for $Fe_{16}N_2$ has been calculated using the local spin-density functional approach by Sakuma[21] first and then by several scientists.[22–26] All the calculated average magnetic moments are around 2.4–2.5 μ_B per Fe atom. These are much smaller than the experimental value of 3.2 μ_B per Fe atom for $Fe_{16}N_2$ and smaller than 2.6 μ_B per Fe atom even for Fe-N martensite. Therefore the conventional theoretical approach is inadequate for discussion on the issue of the giant magnetic moment. In the above calculations, the volume expansion effect and the charge-transfer effect between Fe sites due to the introduction of N atoms are treated automatically. Therefore some other new effects of N atoms such as local binding between Fe and N atoms should be taken into consideration in addition to the above-mentioned two effects. In discussing the issue, it is important to notice that the magnetic moment increases with ordering of N atoms from 2.6 to 3.2 μ_B per Fe atom, al-

though the bct structure remains the same. Also, it should be noticed that the hyperfine field for $Fe_{16}N_2$ is 330 kOe and the same for three kinds of Fe sites with different distances to N atoms.

As for the different values of $4\pi M_s$ and Mössbauer spectra for $Fe_{16}N_2$ and Fe-N reported by different authors, it is likely that some of them come from the difference in ordering and/or concentration of N atoms. Also, some impurities such as oxygen atoms might suppress the enhancement of magnetic moment in some cases. However, the reasons for this remain unclear yet.

IV. CONCLUSIONS

Single-crystal $Fe_{16}N_2$ and (Fe- around 11 at. % N) martensite films of 200–900 Å thickness have been grown epitaxially on $In_{0.2}Ga_{0.8}As(001)$ substrates by MBE. $4\pi M_s$'s for $Fe_{16}N_2$ and Fe-N martensite films have been confirmed to be around 29 and 24 kG at room temperature, respectively. $4\pi M_s$ for Fe-N martensite films has been found to increase with increase in ordering of N atoms by annealing and finally reach around 29 kG for $Fe_{16}N_2$.

$4\pi M_s$'s for $Fe_{16}N_2$ and Fe-N martensite films were almost constant in the range of the film thickness from 200 to 900 Å.

Mössbauer spectrum for Fe-N martensite films was found to be a superposed one with hyperfine fields of 360, 310, and 250 kOe. The spectrum became simpler with increase in ordering, finally reaching a spectrum with a single hyperfine field of 330 kOe.

$4\pi M_s$ of 29 kG for $Fe_{16}N_2$ (3.2 μ_B/Fe atom) and 24 kG for Fe-N martensite (2.6 μ_B/Fe atom) has not be explained based on the conventional band theory of $3d$ metal magnetism. Behaviors of Mössbauer spectra could not be understood either. Thus a new physical concept is concluded to be needed for clarification of giant magnetic moments and Mössbauer spectra for $Fe_{16}N_2$ and Fe-N martensite.

In order to determine the value of the intrinsic magnetic moment of the α'' phase, the films of nitrogen-martensite with various N content were fabricated under various reactive sputtering conditions. The magnetic moment of $(\alpha''+\alpha')$-$Fe_{16}N_2$ films is discussed in connection with the change of the unit-cell volume of the bct structure and the degree of N site ordering in nitrogen-martensite. As a result, it is found that (1) the same structure as bulk α''-$Fe_{16}N_2$ is realized in the present films, (2) the saturation magnetization σ_s of the α' phase increases about 4% with increasing unit-cell volume of the α' phase, (3) the degree of N site ordering from α' to α''-$Fe_{16}N_2$ does not much affect σ_s, and (4) the experimentally obtained maximum value of σ_s for the $(\alpha''+\alpha')$-$Fe_{16}N_2$ film was 232 emu/g. The intrinsic value of σ_s in the α'' phase (in the perfectly ordered state) is proposed to be no more than 240 emu/g at 300 K.

I. INTRODUCTION

Recently, the present authors have established synthesizing processes for α''-$Fe_{16}N_2$ compound films on MgO (100) single-crystal substrates by using both reactive sputtering and plasma evaporation methods.[1,2]

However, the magnitude of the saturation magnetization σ_s for $(\alpha''+\alpha')$-$Fe_{16}N_2$ films with stoichiometric N content showed 226 emu/g for sputtered films and 232 emu/g for plasma evaporated films, respectively. The films thus fabricated did not show any giant magnetic moment, even though clear formation of $(\alpha''+\alpha')$-$Fe_{16}N_2$ phase was achieved. These values of σ_s in $(\alpha''+\alpha')$-$Fe_{16}N_2$ films agree well with the result of the recent theoretical band calculation,[3] and are completely different from the earlier results reported by various groups.[4–7]

Up to now, reported values of σ_s of the α'' phase (about 257–315 emu/g) were estimated ones (not directly measured) except for the films synthesized by MBE[7] (2.9 T directly measured, α'' single phase). The estimation of the value of σ_s in the α'' phase was carried out by using experimentally determined volume-averaged values of σ_s (240–260 emu/g)[4–6] after fixing the volume fraction of the α'' phase in whole films which consist of phase mixtures of α-Fe+α''-$Fe_{16}N_2$ and/or $\alpha+\alpha'+\alpha''+\gamma'$-$Fe_4N+\cdots$.

There still exist some physical problems concerning σ_s of the α''-$Fe_{16}N_2$ phase, especially for the multiphase films, namely, (1) the big difference among reported values of σ_s in the α'' phase, from 257 to 315 emu/g at RT, and (2) quantitative evaluation for fixing the volume fraction of the α'' phase in whole film. These physical situations lead to a conclusion that the intrinsic magnetic moment of σ_s in the α'' phase is still unknown.

On the other hand, for the single-crystal films with a single α'' phase prepared by the MBE method,[7] there also exists some physically contradictive problems: (1) No clear superlattice lines from the lattice planes including the a axis in the α'' phase were detected, even though a perfect site ordering of N atoms was realized;[8] (2) the hyperfine field Hi of the α'' phase was nearly equal to that of α-Fe (330 kOe) and no splitting of Hi due to three different Fe sites in the α''-$Fe_{16}N_2$ structure was observed,[8] even though σ_s showed 2.9 T ($\simeq$315 emu/g, assuming ρ=7.4 g/cm^3 for α''-$Fe_{16}N_2$); (3) σ_s of the fully ordered α''-$Fe_{16}N_2$ films changed reversibly within the temperature range up to 400 °C and an irreversible change of σ_s due to the phase transformation from α'' to $\alpha+\gamma'$ was not observed.[8] According to the experiment by Jack using powder, the α'' phase is metastable and it must decompose into $\alpha+\gamma'$ phases at about 200 °C.[10]

These experimental results lead to a physical conclusion that the appearance of the giant magnetic moment in α''-$Fe_{16}N_2$ films proposed by Kim and Takahashi and Komuro *et al.* are not simply attributable to the conventional α''-$Fe_{16}N_2$ structure. Therefore the origin of the giant magnetic moment arising from the nitrogen-martensite structure is still under question.

In the present study, in order to determine the value of the intrinsic magnetic moment of the α'' phase, nitrogen-martensites with various N content were systematically fabricated under various sputtering conditions. Also, the magnetic moment of $(\alpha''+\alpha')$-$Fe_{16}N_2$ film is discussed in connection with the change of the unit-cell volume of the body-centered tetragonal (bct) structure and the degree of N site ordering in nitrogen-martensites.

II. EXPERIMENTAL PROCEDURE

Fe-N films were fabricated by a facing target-type dc sputtering system under the selected plasma condition (Te =0.2 eV, Ne$\simeq 1\times10^{10}$ cm^{-3}). The base pressure of the sputtering chamber was below 3×10^{-7} Torr. An Ar-N_2 mixture was introduced to the sputtering chamber at 5 sccm (standard cc/min) with controlling N_2 flow ratio (0%–30%) under a fixed total pressure (1–10 mTorr).

MgO (100) and (110) single-crystal substrates were used. Before the film fabrication, substrates were baked at 200 °C for 2 h and cooled down to RT. This heat treatment was carried out in the evacuated sputtering chamber ($\simeq 2\times10^{-6}$ Torr).

Prior to the fabrication of Fe-N films, an α-Fe underlayer with thickness of 50 Å was deposited on MgO (deposition rate=33 Å/min; Ar pressure P_{Ar}=5 mTorr). Successively, an

 0021-8979/94/76(10)/6642/6/$6.00 © 1994 American Institute of Physics

Fe-N film with a thickness of 3000 Å was deposited onto the α-Fe underlayer (deposition rate=33–240 Å/min; pressure of Ar-N_2 mixture P_{total}=1–10 mTorr).

Annealing of the films after an air exposure was carried out at 150 °C for 2–20 h in a vacuum atmosphere below 5×10^{-6} Torr.

Values of the saturation magnetization σ_s of the films were determined by a vibrating sample magnetometer (VSM) measurement. Conversion electron Mössbauer (CEM) spectra were obtained at RT. The velocity was referred to the pure α-Fe.

Structure analysis of the films were made with a Co $K\alpha$ x-ray diffractometer (XRD) equipped with a graphite monochrometer and a pole figure attachment. Schultz's reflection method was used for the determination of lattice constants and preferred orientation of grains. Contents of nitrogen atoms in the films were determined by electron spectroscopy for chemical analysis (ESCA). Calibration of nitrogen contents were made by using the value obtained from ϵ-$Fe_{2-3}N$ foil (24.2 at. % N) for a standard sample.

N contents in the films increased with increasing N_2 flow ratio. In the case of the film deposited at P_{total} of 5 mTorr and N_2 flow ratio of 18%, the N content was found to be about 11 at. %, which is the same value as the stoichiometric N content of the α''-$Fe_{16}N_2$ phase.

III. RESULTS AND DISCUSSION

A. Structure

According to Jack,[10,11] in the α' phase, N atoms occupy randomly the octahedral interstices at the midpoints of the c edges of the bct cell (0, 0, $\frac{1}{2}$), and the centers of the C faces, ($\frac{1}{2}$, $\frac{1}{2}$, 0). As a result, the lattice constant c of the α' phase is elongated from 2.866 to 3.195 Å and the lattice constant a is shortened from 2.866 to 2.832 Å, respectively, depending on the N content.

The α'' phase has an ordered N site location of the octahedral interstices. The unit cell of the α'' phase contains eight of the expanded bct pseudo-unit cells and has dimensions $a'=2a$ and $c'=2c$, where a and c are the lattice constants of the pseudocell. In the larger true unit cell, the symmetry is also bct, since the α'' phase can be identified by observing reflections from this larger true unit cell for which $(h+k+l)$, Miller's index, is even. Based on this structural knowledge, phase identification is carried out in the present films.

In the case of a MgO(100) single-crystal substrate, a diffraction line from the (002) plane of the α'' phase, $\alpha''(002)$, which is expected to appear around 33° for 2θ, was not observed in an as-deposited state. Only $\alpha'(002)$ was clearly observed in the high angle region. The peak position of $\alpha'(002)$ shifted from 75° to 68° for 2θ with increasing N_2 flow ratio. This shift to lower angle of 2θ is simply explained by the elongation of the c axis of the bct structure of the α' phase. By taking into account the N concentration dependence on lattice constants a and c in nitrogen-martensite,[11] the N content of the α' phase in the present films was found to increase with increasing N_2 flow ratio. This result agrees well with that of ESCA measurements.

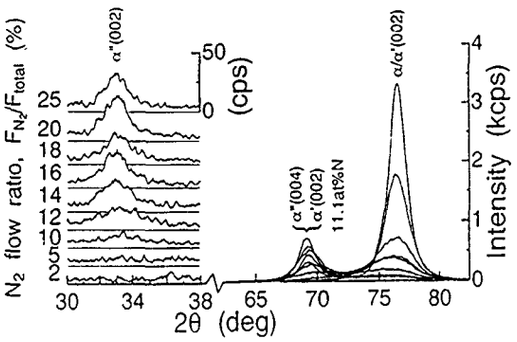

FIG. 1. X-ray diffraction patterns for the films fabricated under P_{total}=5 mTorr, deposition rate=240 Å/min after annealing at 150 °C for 2 h.

In Fig. 1, typical changes of XRD patterns of the films after annealing are shown. After annealing, $\alpha'(002)$, which had been observed in an as-deposited state, split into two diffraction lines. One corresponds to $\alpha''(004)$ and/or $\alpha'(002)$ with satisfying stoichiometric N content of α''-$Fe_{16}N_2$ (11 at. % N). The other corresponds to $\alpha(002)$ of slightly deformed α-Fe. Furthermore, simultaneously at around 33° for 2θ, $\alpha''(002)$, which is the diffraction line from the larger true unit cell of the α'' phase, came to be clearly observed. This fact means that the ordering of N atoms was promoted by annealing while retaining the bct structure and the α'' phase with stoichiometric N content was synthesized.

The unique diffraction patterns from (103), (105), (112), (114), and (213) planes of the α'' phase, including the a axis for ($\alpha''+\alpha'$)-$Fe_{16}N_2$ film, are shown in Fig. 2. As seen in the

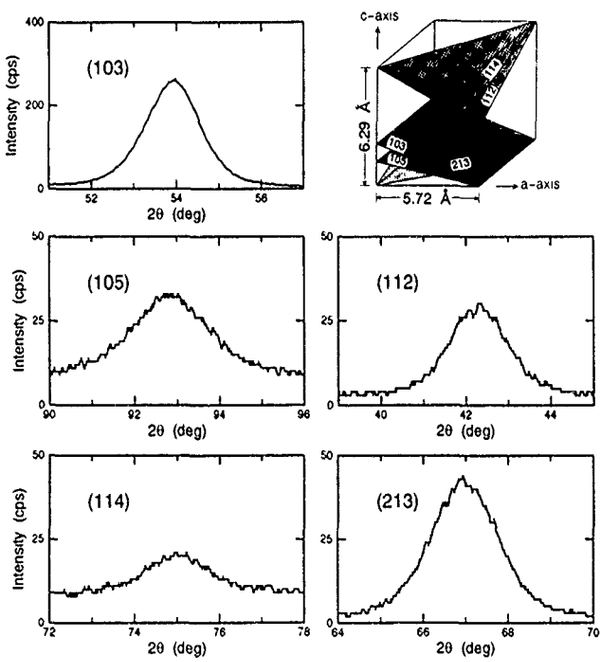

FIG. 2. The unique diffraction patterns from (103), (105), (112), (114), and (213) planes of the α'' phase including the a axis for ($\alpha''+\alpha'$)-$Fe_{16}N_2$ film fabricated under P_{total}=10 mTorr, F_{N_2}=12%, deposition rate=33 Å/min, and annealed at 150 °C for 2 h.

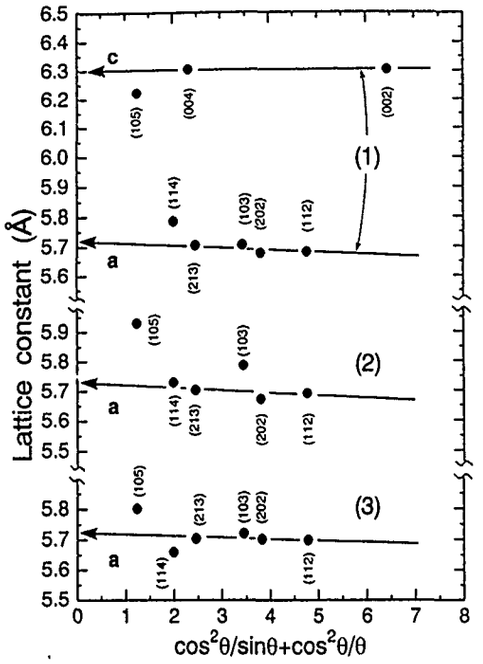

FIG. 3. The lattice constants a and c of the α'' phase, determined by various unique diffraction lines of the α'' phase, plotted against the Nelson–Riley function. Fabrication conditions of the films: (1) P_{total}=10 mTorr, F_{N_2}=16%, deposition rate=240 Å/min, annealed at 150 °C for 2 h; (2) the same as (1) annealed for 20 h; (3) P_{total}=10 mTorr, F_{N_2}=12%, deposition rate=33 Å/min, annealed at 150 °C for 2 h.

figure, the existence of the α'' phase was reconfirmed by these clear unique diffraction lines. In order to determine accurate lattice constants a and c of the α'' phase, the lattice constants a calculated from each plane are plotted against the Nelson–Riley function[12] ($\cos^2\theta/\sin\theta+\cos^2\theta/\theta$) in Fig. 3. In the figure, the reflections marked (3) correspond to the film shown in Fig. 2, and those marked (1) and (2) correspond to $(\alpha''+\alpha')$-$Fe_{16}N_2$ films prepared by different experimental conditions. As a reference, the lattice constant c calculated from $\alpha''(002)$ and $\alpha''(004)$ is also shown as (1). Each extrapolated value of the lattice constants a and c of the present films coincided with that of the α''-$Fe_{16}N_2$ precipitates in bulk powder reported by Jack.[10] Therefore it is concluded that the α'' phase formed in sputtered films has the same structure as the bulk α'' phase.[13]

While in the case of a MgO(110) single-crystal substrate, a preferred grain orientation of (211) and (112) of the α' phase was found in an as-deposited state. By annealing, unique diffraction lines of the α'' phase, $\alpha''(211)$, and $\alpha''(112)$, were observed. Therefore it was found that the α'' phase with a preferred orientation of (211) of the α'' phase can also be synthesized even on MgO(110) substrates. Through the whole result, relationships concerning the crystal orientation between α''-$Fe_{16}N_2$ structure and MgO are shown in Table I.

TABLE I. Crystal orientation relations between α''-$Fe_{16}N_2$ and MgO.

MgO(100)	MgO(110)
$\alpha''(001)\|\|MgO(001)$	$\alpha''(211)\|\|MgO(101)$
$\alpha''[110]\|\|MgO[100]$	$\alpha''[011]\|\|MgO[001]$

B. Magnetic moment

1. Dependence of magnetic moment on N_2 flow ratio

Values of σ_s in an as-deposited state increased slightly with increasing N_2 flow ratio, and took a maximum of 220 emu/g around a N_2 flow ratio of 15%. The N content of the films, which showed the broad maximum in σ_s, was nearly equal to the stoichiometric N content of $Fe_{16}N_2$ (11 at. %). The values of σ_s for annealed film with stoichiometric N content of $Fe_{16}N_2$ (11 at. %) ranged from 213 to 226 emu/g. The average values of σ_s for Cu-coated films were 228 emu/g for the film consisting of the α' phase and 232 emu/g for the film consisting of $(\alpha''+\alpha')$-$Fe_{16}N_2$ phases. The difference of the value of σ_s between coated and noncoated ones may mainly be caused by the surface oxidation due to the adsorbed oxygen at the film surface introduced by venting the chamber with air. In the case of films deposited on a MgO(110) substrate, the value of σ_s in $(\alpha''+\alpha')$-$Fe_{16}N_2$ was 210 emu/g (non-Cu-coated). As a whole, maximum values of σ_s of about 232 emu/g were obtained for $(\alpha''+\alpha')$-$Fe_{16}N_2$ films in the present study. This experimentally determined value was definitely smaller than the value reported as a giant magnetic moment of 2.9 T.[7]

2. Dependence of magnetic moment on unit-cell volume

Figure 4 shows the changes of σ_s against unit-cell volume of the α' phase with various N contents in an as-deposited state. In the figure, 1/8 of the unit-cell volume of the bulk α''-$Fe_{16}N_2$ is indicated. Filled marks correspond to

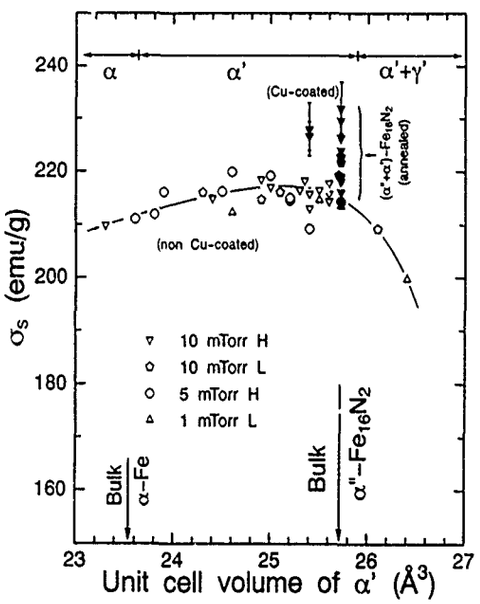

FIG. 4. The changes of σ_s against unit-cell volumes: (1) α' phase with various nitrogen contents in an as-deposited state, and (2) annealed $(\alpha''+\alpha')$-$Fe_{16}N_2$ films with and without Cu coating. H and L correspond to high (240 Å/min) and low (33 Å/min) deposition rates, respectively

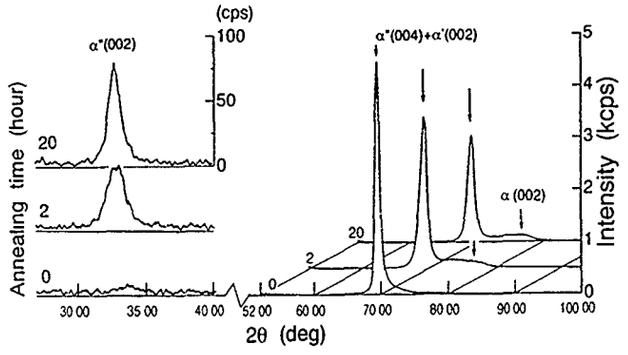

FIG. 5. The change of x-ray profiles against annealing time for the film with stoichiometric N content of the α'' phase (11 at. %) sputtered under P_{total}=10 mTorr, F_{N_2}=10%, and deposition rate=33 Å/min.

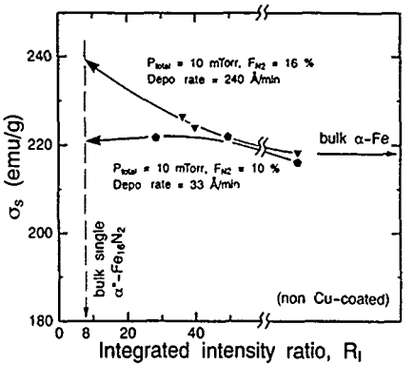

FIG. 6. The change of σ_s against the integrated intensity ratio R_I for the films sputtered under P_{total}=10 mTorr, deposition rate=33 and 240 Å/min, F_{N_2}=10% and 16%, non-Cu-coated.

the annealed $(\alpha''+\alpha')$-$Fe_{16}N_2$ films with stoichiometric N content. In the same figure, σ_s for the Cu-coated films are also shown.

For the films consisting of α' single phase (in an as-deposited state), the values of σ_s increased slightly with the increment of the unit-cell volume. At the unit-cell volume of about 25.5 Å^3 (α' phase with 11 at. % N), σ_s showed 228 emu/g on average (Cu-coated) and this value was about 4% higher compared to that of bulk α-Fe.

In the case of annealed $(\alpha''+\alpha')$-$Fe_{16}N_2$ films (Cu-coated), the value of σ_s showed 232 emu/g on average, and were about 2% larger than that of each as-deposited film, while the unit-cell volume of the α'' phase is always constant and coincided with that of the bulk α'' phase (see Fig. 3). The unit-cell volume of the α'' phase with 11 at. % N is equal to that of the α''-$Fe_{16}N_2$ phase within the accuracy of this experiment. Therefore the change of σ_s by annealing in nitrogen-martensite with 11 at. % N content cannot be discussed as a function of the change of unit-cell volume of a bct structure caused by the phase transformation from α' to α'' phase. In the next section, as a second physical factor the degree of N site ordering in nitrogen-martensite will be discussed in connection with the change of σ_s.

3. Dependence of magnetic moment on N site ordering

To evaluate the degree of N site ordering in the bct structure of nitrogen-martensite, two factors should be taken into account. One is the change of the integrated intensity of the $\alpha''(002)$ line which is the unique superlattice diffraction from the α'' phase. Another is the integrated intensity ratio of $\alpha''(004)+\alpha'(002)$ to $\alpha''(002)$, R_I, namely

$$R_I \equiv [I^{\alpha''}{}_{(004)}+I^{\alpha'}{}_{(002)}]/I^{\alpha''}{}_{(002)}.$$

The calculated value of R_I is about 8 for the ideal structure of the α'' phase.[14]

Figure 5 shows the change of XRD profiles against annealing time for the film with stoichiometric N content of the α'' phase (11 at. %). From these profiles, the intensity of $\alpha(200)$ was relatively very weak and any diffraction lines from the γ' phase were not observed. After annealing for 2 h, $\alpha''(002)$ came to be observed clearly. By annealing further for 20 h, the integrated intensity of $\alpha''(002)$ increased about 20% compared to that of 2 h. On the other hand, the experimentally determined value of R_I changed from 50 to 28 with the increase of annealing time.

Therefore, from these experimental results (1) the increase of the integrated intensity of $\alpha''(002)$ and (2) the change of R_I approaching to the ideal value of 8, the increase of degree of N site ordering in nitrogen-martensite, which directly corresponds to the increase of the volume fraction of the α'' phase in the films, is strongly promoted by annealing.

In Fig. 6, the changes of σ_s in $(\alpha''+\alpha')$-$Fe_{16}N_2$ films by isothermal annealing at 150 °C are shown against the integrated intensity ratio R_I. For one film σ_s increases slightly from 218 (as deposited) to 226 emu/g at R_I=36.4 (20 h). On the other hand, for another film, σ_s takes the value of about 222 emu/g at R_I=49 (2 h) and keeps a constant value even though R_I approaches to the value of 8. From these experimental facts, it was found that the degree of N site ordering in nitrogen-martensite does not much affect the increment of σ_s. The expected values of σ_s at R_I=8 (perfect ordered state in α''-$Fe_{16}N_2$) estimated by the simple extrapolation with using the data points of σ_s against R_I are no more than 222–240 emu/g, a value which is definitely smaller than the giant magnetic moment of 2.9 T.

4. Dependence of magnetic moment on temperature

Figure 7 shows the temperature dependence of σ_s in $(\alpha''+\alpha')$-$Fe_{16}N_2$ films with stoichiometric N content deposited on MgO (100) and (110) substrates, respectively. Heating and cooling were at 60 °C/h. On heating, the value of σ_s gradually decreased with increasing temperature. Around 200 °C a sudden discontinuous decrease of σ_s from 200 to 170 emu/g was observed. With further increasing temperature, σ_s decreased monotonously and reached about 130 emu/g at 400 °C, while on cooling, the change of σ_s with respect to temperature was completely different from that of heating, and no sudden change of σ_s was observed. The sudden discontinuous change of σ_s observed around 200 °C is considered to correspond to the phase change from $\alpha''+\alpha'$ to $\alpha+\gamma'$. Therefore the hysteresis in the σ_s-T curve is caused by this irreversible phase decomposition from

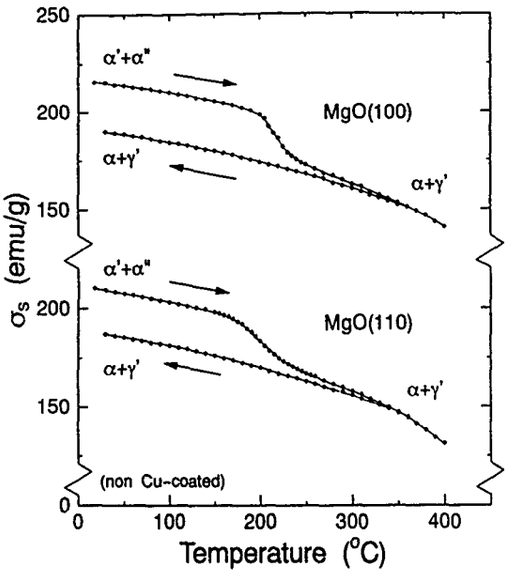

FIG. 7. The temperature dependence of σ_s in the films consisting of the α'' phase deposited on MgO (100) and (110) substrates fabricated under P_{total}=10 mTorr, deposition rate =240 Å/min, and F_{N_2}=16% after an initial anneal at 150 °C for 2 h.

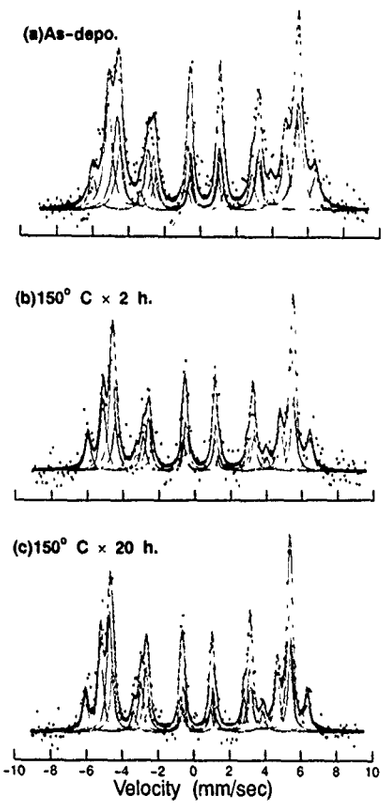

FIG. 8. Mössbauer spectra of $(\alpha''+\alpha')$-$Fe_{16}N_2$ film (non-Cu-coated) measured at R.T. (a) As-deposited, (b) annealed at 150 °C for 2 h, and (c) annealed at 150 °C for 20 h, respectively. The film was deposited under P_{total}=10 mTorr, deposition rate=240 Å/min, and F_{N_2}=16%.

TABLE II. Mössbauer parameters of the film deposited under P_{total}=10 mTorr, F_{N_2}=16%, deposition rate=240 Å/min. *Hi* is the hyperfine field, *I.S.* the isomer shift, *e.q.Q.* the quadrupole splitting, *Hwid* the distribution of *Hi*, and area the relative intensity, respectively.

Site	*Hi* (kOe)	*I.S.* (mm/s)	*e.q.Q.* (mm/s)	*Hwid* (kOe)	Area (%)
Fe(I)	289	0.01	−0.05	7.00	21.3
Fe(II)	316	0.17	0.04	7.00	31.3
Fe(III)	391	0.11	−0.05	7.00	11.2
α-Fe	335	0.02	−0.007	7.00	36.1
(As-deposited)					
Fe(I)	289	0.01	−0.05	4.00	17.8
Fe(II)	316	0.17	0.04	4.00	41.8
Fe(III)	391	0.11	−0.05	4 00	13.1
α-Fe	335	0.02	−0.007	4.00	27.3
(Annealed at 150 °C for 2 h)					
Fe(I)	289	0.01	−0.05	3.00	20.6
Fe(II)	316	0.17	0.04	3.00	37.7
Fe(III)	391	0.11	−0.05	3.00	12.5
α-Fe	335	0.02	−0.007	3.00	29.3
(Annealed at 150 °C for 20)					

$\alpha''+\alpha'$ to $\alpha+\gamma'$. The temperatures of this phase decomposition for the present films were good agreement with that of the α''-$Fe_{16}N_2$ precipitates in bulk powder reported by Jack.[10] The temperature dependence of σ_s observed in present experiments is found to be quite different from that of Gao and Komuro.[15,16]

C. Mössbauer spectrum

Figure 8 shows the change of Mössbauer spectra of the $Fe_{16}N_2$ film with stoichiometric N content by annealing. The spectrum in each film can be fitted into four hyperfine field interactions *Hi* of α phase, Fe(I), Fe(II), and Fe(III) of the $(\alpha''+\alpha')$-$Fe_{16}N_2$ phase. The fitted Mössbauer parameters are listed in Table II. As seen in the table, the large value of *Hi*, about 390 kOe, due to the Fe(III) site in nitrogen-martensite was detected in each film. Half widths of the peaks become narrower with increasing annealing time. This result corresponds to the promotion of N site ordering in nitrogen-martensite caused by annealing, and is in good agreement with the change of R_I and also the result of ion-implanted films reported by Nakajima.[14]

For the films examined presently, the average value of *Hi* was about 325 kOe, which was nearly equal to that of *Hi* of α-Fe. Therefore the value of σ_s in $(\alpha''+\alpha')$-$Fe_{16}N_2$ film of about 232 emu/g determined by VSM was consistent with the result of Mössbauer spectrum analysis. Based on the fitted Mössbauer parameters, the volume fraction of α-Fe was estimated to be 27% and 73% for the $(\alpha''+\alpha')$-$Fe_{16}N_2$ phase in annealed films. Using these values, the value of σ_s in the $(\alpha''+\alpha')$-$Fe_{16}N_2$ phase, $\sigma_{Fe_{16}N_2}$, is estimated by the following equation:

$$232^{exp}=\sigma_{Fe_{16}N_2}\times 0.73+\sigma_{\alpha\text{-}Fe}\times 0.27,$$

where $\sigma_{\alpha\text{-}Fe}$ is 218 emu/g. The obtained value of $\sigma_{Fe_{16}N_2}$ is 237 emu/g. Considering this calculated result and the result of the dependence of σ_s on R_I, the value of saturation mag-

netization of the α'' phase (perfect ordered state) should be no more than 240 emu/g, while the site population of the $(\alpha''+\alpha')$-$Fe_{16}N_2$ phase determined in this study was about 4:9:3, which is slightly different from the ideal ratio of 4:8:4 determined uniquely from the structure of α''-$Fe_{16}N_2$.

IV. SUMMARY

(i) $(\alpha''+\alpha')$-$Fe_{16}N_2$ films were synthesized on MgO single-crystal substrates by the reactive sputtering method. The result of the structural analysis using XRD and CEM revealed that the same structure as bulk α''-$Fe_{16}N_2$ is realized in the present films.

(2) The intrinsic value of saturation magnetization of the α'' phase (perfect ordered state) is proposed to be no more than 240 emu/g ($\simeq$2.4 μ_B per Fe atom in average) at 300 K.

Enhanced Fe moment in nitrogen martensite and $Fe_{16}N_2$ (invited)

W. E. Wallace and M. Q. Huang
Department of Materials Science and Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

Nitrogen martensite was prepared by treating fine Fe powder with NH_3/H_2 gas mixtures at temperatures around 665 °C. Upon quenching to a temperature T_q, the γ phase which had formed at the elevated temperature undergoes a martensitic transformation to form nitrogen martinsite (α' Fe-N alloy), a tetragonal material. Heat treating this material for 1–2 h at 140±10 °C produced the α'' phase $Fe_{16}N_2$. The α' phase occurred along with γ Fe-N. From x-ray line intensities, the amount of α' phase was ascertained. The α' phase exhibits a room-temperature moment of 250±10 emu/g. $Fe_{16}N_2$ is formed along with α Fe and also there is retained N-austenite. Using XRD and conventional magnetic measurement procedures, one obtained 280±10 emu/g for the saturation moment of $Fe_{16}N_2$. The experimental Fe moment, 2.88 μ_B, is in excellent agreement with the most recent band-structure calculations, 2.85 μ_B. The ternary systems $(Fe,M)_{16}N_2$ were studied with M=Mn or Ni. γ Fe-Mn nitride readily forms, but it does not undergo the $\gamma \rightarrow \alpha'$ transformation. The α' phase and possibly the α'' phase form in the Fe-Ni nitride.

I. INTRODUCTION

Iron nitrides have been known for many years.[1] Nitrogen cannot be introduced into Fe by treating it with nitrogen at normal pressures (i.e., 1–100 atm). However, iron can be nitrogenated to form the γ FeN phase by treating it with a mixture of 90 mol % H_2 and 10 mol % NH_3 at temperatures ranging from about 900 to 975 K. At these temperatures NH_3 is unstable with respect to its constituent elements by ~47 kJ. With a suitable catalyst, NH_3 will decompose and generate N_2 at pressures in the thousands of atmospheres at temperatures between 900 and 1000 K. For example, at 665 °C (938 K), the equilibrium pressure of N_2 is ~2400 atm. It is well known that Fe and its alloys are effective synthetic NH_3 catalysts and hence under the experimental conditions cited, N_2 is generated at high pressures, sufficiently high to force N atoms into the Fe lattice. This was shown many years ago in a study by Lehrer.[2]

Nitrogenation of Fe leads to a variety of phases: α, γ, γ', ϵ, ζ, α', α''. Fe-N is the terminal solid solution based on α Fe and it is a simple bcc. The γ phase, often called nitrogen austenite, is cubic. The Fe atoms in the γ phase are in a fcc arrangement with N partially and randomly occupying the octahedral interstices.[3] α' and α'' are phases derived from the γ phase by a martensitic transformation. Both α' and α'' are tetragonal materials[4] with $c/a \sim 1.1$. The ϵ phase is one in which the Fe atoms are in a cph arrangement.[5] The ζ phase is orthorhombic.[5] Very recently, Suzuki *et al.*[6] have reported the formation of FeN by reactive sputtering and have stated that it exists in the zinc-blende structure. Of the eight known Fe-N phases, the present paper is concerned primarily with only the γ, α', and α'' phases for reasons brought out below.

Introduction of nitrogen into the Fe lattice produces striking changes in the magnetism of phases in which Fe is magnetic. For example, the Curie temperature, shown in Fig. 1, in the ϵ phase varies from 300 to −250 °C as the concentration is varied, passing though a maximum at the composition $Fe_{78}N_{22}$. Another startling feature is the difference in magnetic properties of the γ and γ' phases. The former is nonmagnetic, whereas the latter is strongly magnetic with σ_{sat}=186 emu/g and $T_c \sim 761$ K. In each case the N atoms partially occupy the octahedral interstices in the Fe lattice. The principal structural difference between the γ and γ' phases is that the nitrogens are disordered in γ FeN but are ordered in γ' FeN (i.e., Fe_4N). How ordering of the (nonmagnetic) nitrogens can generate strong ferromagnetism in this material is not immediately evident. It undoubtedly originates with an altered band structure brought on by ordering of the nitrogens. Japanese workers have shown[7,8] that nitrogenation of Fe to form the $Fe_{16}N_2$ phase leads to a significant rise in magnetization. This has greatly intensified interest in the magnetism of Fe-N alloys.

In previous publications from this laboratory[9,10] it has been shown that nitrogen austenite can be formed by the method of Lehrer[2] and Jack,[3–5] i.e., by treating Fe powder with an NH_3/H_2 gas mixture at temperatures around 950 K. In the classic work of Jack, it was shown that upon quench-

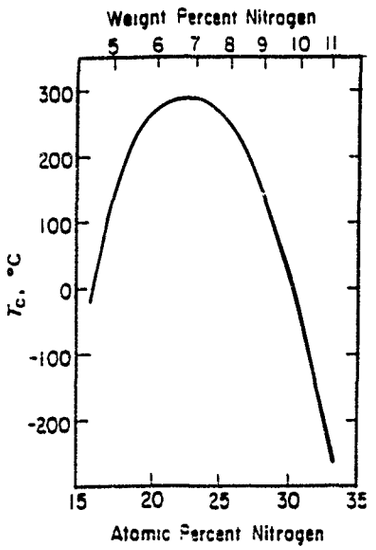

FIG. 1. T_c vs composition in ϵ Fe-N alloys, taken from H. A. Wriedt, N. A. Gokcen, and R. H. Nofzinger, Bull. Alloy Phase Diagrams **8**, 355 (1987).

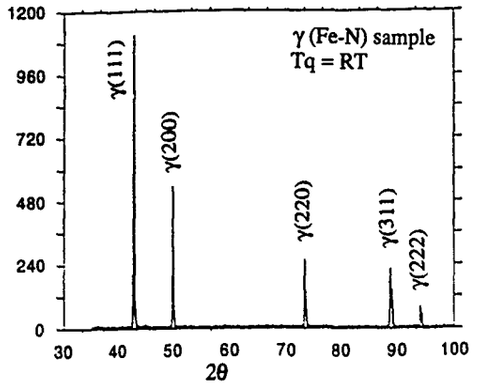

FIG. 2 X-ray-diffraction pattern of the Fe-N alloy containing 10.7 at. % nitrogen which has been quenched to room temperature. The pattern is characteristic of a single-phase fcc material. This indicates that by this treatment a single-phase alloy is produced. No α' Fe-N alloy is produced by this procedure.

ing, γ FeN undergoes a transition into the nitrogen analog of martensite (the α' phase). Jack also found that with heat treatment at temperatures ranging from 150 to 200 °C the α' phase transforms into the α'' phase, an alloy with the composition $Fe_{16}N_2$.

In previous work in this laboratory,[9,10] results were obtained that were similar but not identical to those obtained by Jack. The principal difference lay in the quenching procedures necessary to effect the $\gamma \rightarrow \alpha'$ transformation. In the work of Jack, quenching to room temperature was all that was needed to bring about the martensitic transformation, whereas the experience in this laboratory is that cryogenic temperatures are required, particularly for high N concentrations.

This dependence of conversion efficiency on quenching temperature and the necessity to quench to cryogenic temperatures was also observed by Bao *et al.*[11]

In the present work, the α' and α'' phases have been synthesized and studied magnetically. Results obtained for these alloys are reported herein, as well as those for ternary alloys in which 10–15 wt % of the Fe has been replaced by M, where M=Cr, Mn, Co, Ni, Cu, Ti, or Al.

II. FORMATION AND CHARACTERIZATION OF THE α' AND α'' Fe-N PHASES

A. Experimental details and results obtained for α' Fe-N alloys

A mixture of NH_3 and H_2 in the ratio $H_2/NH_3 \sim 9$ was flowed over 6–9 μm Fe powder at a temperature of 660–670 °C. The samples were then quenched to temperatures ranging from room temperature to liquid-helium temperature. The Cu radiation diffraction pattern for the sample containing 10.7 at. % N[12] is shown in Fig. 2. The material consists entirely of γ phase within the detection limit of this technique, perhaps 3%–5%. Upon cooling to liquid-nitrogen or liquid-helium temperatures, transformation of a substantial fraction of the material into the α' form occurs. Examples of the extent of the transformations and the conditions needed are given in Table I. The magnetization versus temperature behavior (see Fig. 3) is used to follow the $\gamma \rightarrow \alpha'$ transformation. The rise in magnetization upon cooling below 150 K is occasioned by the transformation of nonmagnetic γ Fe-N into the strongly magnetic α' phase.

TABLE I. α' phase formation by quenching γ Fe-N and moment for α' Fe-N.

Composition of alloy	T_q (K)[a]	wt % α' phase	Moment of α' Fe-N (emu/g)
at. % N			
6.4	RT[b]	87	240
8.1	RT	72	246
···	LN	82	···
10.7	RT	0	···
···	LN[b]	51	260
···	LHe[b]	56	···

[a] T_q=quench temperature.
[b] RT=room temperature ~20 °C; LN and LHe represent liquid N_2 and liquid He, respectively.

The data of Table I indicate that the $\gamma \rightarrow \alpha'$ transformation occurs at higher temperatures when the nitrogen concentration is low. The XRD pattern for the alloy containing 10.7 atoms of N per 100 atoms of Fe is shown in Fig. 4; this is for the sample (see Table I) which had been quenched to liquid-helium temperature. This alloy is a two-phase mixture consisting of the retained austenite phase (γ phase) and the martensitic (α' phase). The phase composition can be estimated from the observed line intensities of the two strongest peaks. There is a complication in that the γ (111) and α' (101) lines overlap at $2\theta \sim 43°$. The contribution of the α' (101) line to this line can be evaluated by conventional x-ray-diffraction theory. Using the methodology and nomenclature employed by Cullity,[13] $I_{\alpha'(110)}/I_{\alpha'(101)} = B_{\alpha'(110)}/B_{\alpha'(101)}$, where $I_{\alpha'(110)}$ and $I_{\alpha'(101)}$ are the intensities of the (110) and (101) lines of the α' phase and the B's are the quantities used by Cullity.

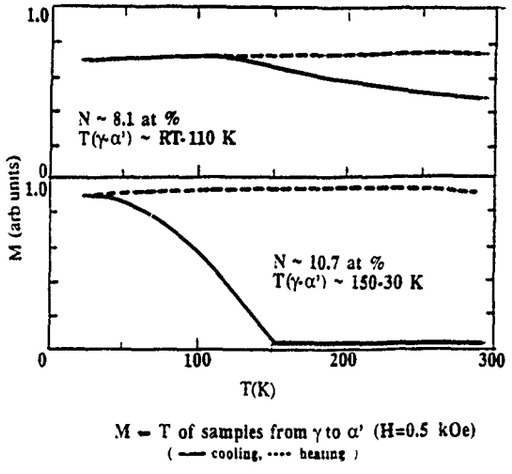

FIG 3. Two representative magnetization-temperature plots showing the rise in magnetization at low temperatures. The rise is due to the $\gamma \rightarrow \alpha'$ transformation, viz., the conversion of the nonmagnetic γ phase into the strongly ferromagnetic α' phase. The solid and dashed lines are for cooling and heating, respectively.

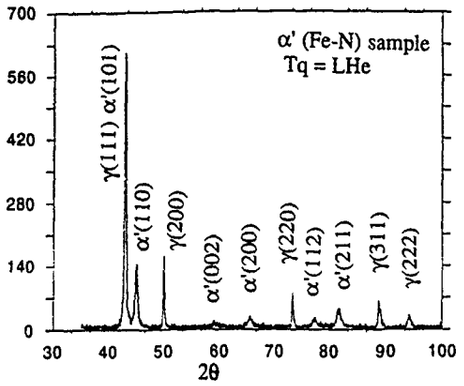

FIG. 4. X-ray-diffraction pattern for the γ alloy in Fig. 2 after cooling to liquid-He temperatur. lines appear which are characteristic of the α' Fe-N phase. Thus this alloy is a mixture of the γ and α' phases.

The B's involve the structure factor (F_{hkl}), multiplicity, and the Lorentz polarization. Using the expression and the measured value of $I_{\alpha'(110)}$, one can calculate $I_{\alpha'(101)}$. Knowing this, one can readily evaluate $I_{\gamma(111)}$, the contribution of the γ phase to the intensity of the peak at $2\theta \sim 43°$. Once this is known, one can evaluate the volume fraction V of the α' phase in the mixture from the expression:

$$I_{\alpha'(101)}/I_{\gamma(111)} = VB_{\alpha'(101)}/(1-V)B_{\gamma(111)}.$$

One can also make this calculation using other lines, $\gamma(200)$, $\alpha'(211)$, etc.

The volume fractions calculated by this procedure can be combined with the known densities to find the wt % of the phases present in γ, α' two-phase alloy. Up to 87% of the γ phase has been transformed (see Table I).

Results for several samples and involving different quenching conditions are shown in Table I. The moment calculated for α' Fe-N is 250 ± 10 emu/g.

B. Experimental details and results obtained for α'' Fe-N alloys

The procedure to form α'' Fe-N is as follows: (1) α' is first formed by the procedure described above. (2) It is then heat treated at 140 ± 10 °C (i.e., tempered) for 1–2 h, at which temperature the N atoms become sufficiently mobile to redistribute over the interstitial sites and convert the N-martensite into $Fe_{16}N_2$.

A number of samples containing the α' phase were heat treated in this fashion to form the α'' phase. Typical and characteristic XRD lines, (213) and (004) of the α'' phase, were observed after the tempering treatment (Fig. 5). This sample contained 10.0 at. % N. The original alloy was Fe rich compared to $Fe_{16}N_2$; hence, as the α'' phase formed, α Fe precipitates out. Thus there are four indications of the $\alpha' \rightarrow \alpha''$ conversion: (1) the appearance of lines characteristics of α Fe in the XRD pattern (see Ref. 9), (2) the development of the (213) line for the α'' phase, (3) shifts of other diffraction lines[9]—(202), (220), (400), (224), and (422)—with respect to the positions of the lines in the original martensite phase, and (4) the rise in moment during tempering.

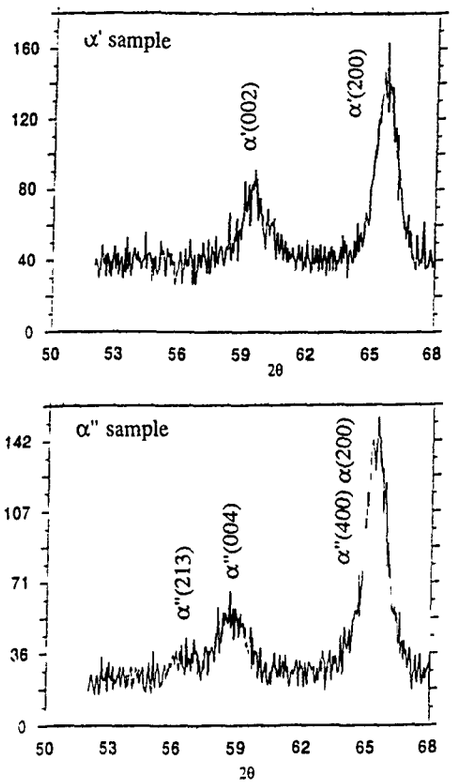

FIG. 5. Segments of the XRD patterns for α' and α'' phases. Lines are shifted and a new peak (213) appears. These changes and the rise in magnetism are indicative of the $\alpha' \rightarrow \alpha''$ transformation.

The lattice constants a and c are very close to those reported by Jack, $a = 5.718$ Å and $c = 6.290$ Å. The magnetic moment of the three-phase mixture increases from 182 to 189 emu/g as the α' phase transforms to α''. To evaluate the α'' moment, it is necessary to know the phase composition of the alloy. This information is obtained by the procedure described in detail in Ref. 9. A representative sample was estimated to contain 56% α'', 13% α Fe, and 31% γ. The estimated moment is ~285 emu/g for α''. The enhanced Fe moment of α'' Fe-N was observed in many samples. Results are summarized in Table II. It seems well established that Fe in $Fe_{16}N_2$ has an enhanced moment 30% larger than that for α Fe.

TABLE II. Phases in tempered α' Fe-N and the moment of $Fe_{16}N_2$. Two independent samples were studied for the 9.4 and 10.7 samples and three independent samples were studied for the 10.0 sample.

Composition of γ phase (at. % N)	wt % of phases			$Fe_{16}N_2$ magnetic moment (emu/g)
	γ	α	α''	
8.1	16	35	49	272
9.4	25	23	52	280
	25	27	48	283

III. MAGNETISM OF $(Fe,M)_{16}N_2$ WITH M=Mn OR Ni

Experiments have been carried out to prepare and characterize $(Fe,M)_{16}N_2$ in which M=Cr, Mn, Co, Ni, Cu, Ti, or Al. Because of space limitations, only results for the system in which M=Mn or Ni will be presented.

A. Experimental details

Fe-M (15 wt %) with M=Mn or Ni was prepared by mechanical alloying using a high-energy SPEX 800 ball mill. The milled powders were heat treated for 20 min at temperatures of 300–800 °C. The original powders were 100–300 mesh. The procedures for nitriding and magnetically characterizing the samples were as those used for Fe powder, except that higher temperatures for nitriding were employed. The nitrogen contents were estimated from the measured lattice parameters of the nitride.[9]

B. Results for Fe-Mn nitrides

Fe-Mn (15 wt %) was nitrided at 700–720 °C and then quenched to room temperature. Figure 6 shows the XRD pattern of one of the Fe-Mn nitrides. Analysis of the pattern shows the majority phase to be fcc. Three small impurity peaks at 2θ~34.5°, 40.5°, and 58.5° originate from Mn nitride, as was confirmed by making the Mn nitride and studying it by XRD. The magnetic moment of this sample was ~13 emu/g. There was no evidence of the α' or α'' phase. According to Bozorth,[14] Fe-Mn alloys in the γ region are nonmagnetic. Therefore we conclude the moment of this sample is due to a very small amount of the bcc Fe-Mn impurity phase.

The Fe-Mn (15 wt %) nitride was cooled to 10 K in an effort to induce the $\gamma \rightarrow \alpha'$ transformation. This effort was unsuccessful, as evidenced by the facts that (1) the XRD pattern was unchanged and (2) the moment was unaffected; there was no effect comparable to that in Fig. 3. This observation is not in conflict with the findings of Jack.[3]

C. Results for the Fe-Ni nitride

1. Formation of the α' phase

The situation here is more interesting than that for Fe-Mn nitrides. Figure 7 shows the diffraction pattern for Fe-Ni (15 wt %) nitride. This is a nitrogen austenite with a=3.601 Å. This material was obtained by nitriding the alloy powder (made by mechanical alloying) at 710–720 °C

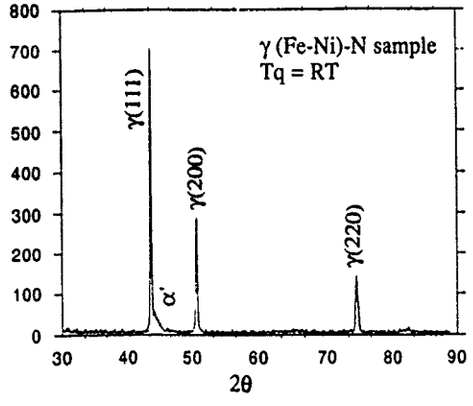

FIG. 7. XRD pattern of the nitride of $Fe_{0.85}Ni_{0.15}$, showing it to be an austenite.

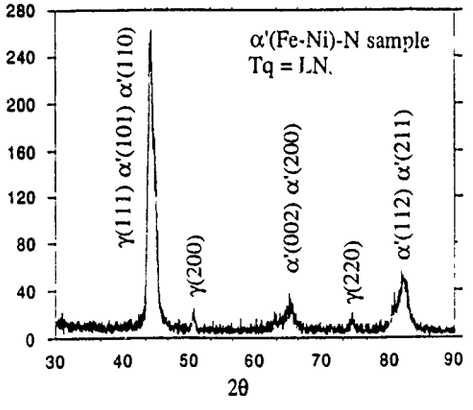

FIG. 9. XRD pattern of $Fe_{0.85}Ni_{0.15}$ nitride.

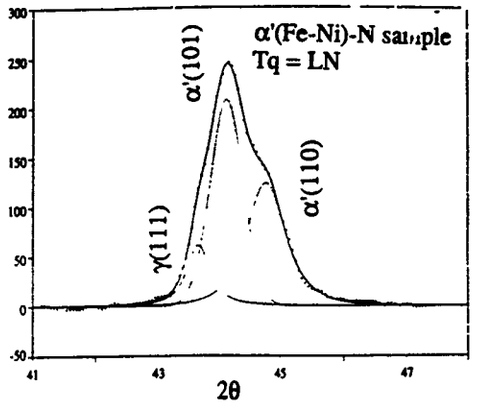

FIG. 10. Enlarged regions of the XRD pattern for the sample in Fig. 9.

and quenching to room temperature. This sample exhibited a moment of 48 emu/g. This moment is ascribed to the presence of a small amount of α' phase in the sample. Upon cooling to 10 K, the magnetism of the sample increases strikingly and irreversibly at temperatures 275–200 K (see Fig. 8). It appears that upon cooling to low temperatures the $\gamma \rightarrow \alpha'$ phase transformation is taking place. The measured moment rises to 186 emu/g. XRD (Figs. 9 and 10) confirms the formation of the α' phase. Its axial ratio is lower than that of Fe_8N. For α', $c=2.952$ Å, $a=2.855$ Å, and $c/a \sim 1.03$.

2. Possible formation of the α'' phase

Low-temperature heat treatment produced a further rise in moment. Heat treating 1 h at 120 and 150 °C gave moments of 193 and 197 emu/g, respectively. This provides suggestive evidence that under these conditions α' is being transformed into α''. However, this postulate was not confirmed by diffraction measurements. The characteristic α'' (213) line was not detected.

IV. CONCLUDING REMARKS

The magnetism of Fe-N alloys present many interesting features. The divergent magnetic behavior of the γ and γ' phases was referred to above. γ is nonmagnetic, where γ' is strongly ferromagnetic and yet, these alloys are structurally very similar, differing only in the way the (nonmagnetic) nitrogens are arranged in the interstitial sites. The fact that systems dilute in nitrogen undergo the martensitic transformation at higher temperatures is counterintuitive. A possible explanation for this surprising behavior is related to the existence of Fe_4N, the γ' phase, which is quite stable. As the nitrogen content increases, the γ phase becomes more like the γ' phase and becomes more stable. It is more resistant to the martensitic transformation, requiring lower temperature to bring on the $\gamma \rightarrow \alpha'$ transformation.

At present, information is lacking as to T_c and the anisotropy of the α' and α'' phases. In regard to T_c, as temperature is increased α' and α'' transform into α Fe and γ', making evaluation of T_c difficult, if not impossible. The presence of large amounts of α Fe in the α'' preparation obscures the true anisotropic features of $Fe_{16}N_2$. Efforts are under way to prepare α'' Fe-N which is freer of γ and α Fe.

One disconcerting feature of the studies of $Fe_{16}N_2$ has been that band-structure calculations have failed to indicate an enhanced Fe moment. See, for example, the results obtained by Sakuma.[15] however, a very recent treatment by Lai *et al.*,[16] including electron correlation effects, gives an Fe moment of 2.85 μ_B for $Fe_{16}N_2$. This is in excellent agreement with experiment as obtained in the present study, viz. 2.88 μ_B.

Strong evidence emerges from this study that Fe in $Fe_{16}N_2$ has a 30% enhanced moment compared to α Fe.

Enhancement of the formation of $Fe_{16}N_2$ on Fe films by Co additions (invited)

Yoshiharu Inoue, Shigeto Takebayashi, and Toshio Mukai
Advanced Materials and Technology Research Laboratories, Nippon Steel Corporation, 1618 Ida, Nakahara-ku, Kawasaki 211, Japan

Effects of Co additions on the formation of $Fe_{16}N_2$ have been investigated by observing nitrides formed on thin-film surfaces. Thin films of Fe-Co alloys with a (100) surface sputter-deposited on MgO(100) substrates are exposed to a mixed gas of NH_3 and H_2. The 16:2 nitride was observed to form on a surface of Fe-10 at. % Co film at a nitriding temperature of 500 °C. The formation temperature is 50 °C higher than for pure iron. The amount of the formed 16:2 nitride has been found to be 3× larger for Fe-10 at. % Co than for pure iron.

I. INTRODUCTION

There has been much attention to $Fe_{16}N_2$ since reconfirmation of its giant magnetization (2.9 T) by Kom.uro *et al.*,[1] which was stimulated by Kim and Takahashi's pioneering work.[2] $Fe_{16}N_2$ (16:2 nitride) is a metastable compound as discovered by Jack.[3] The crystal structure is body-centered tetragonal (bct) consisting of eight bcc cells distorted by interstitial N atoms. There are number of studies on the structure of nitrided ion-based alloys such as Fe-Ti, Fe-Mo, and Fe-Ni.[4] However, the enhancement of formation of the 16:2-type nitride by the third element additions has not been reported so far.

The purpose of the present paper is to show the first experimental evidence that Co enhances the 16:2 nitride formation. The following two points are considered to choose Co as the third element. The first point is that Fe maintains a bcc structure even after alloying with the third element; this is essential because $Fe_{16}N_2$ has an analogous bct structure.[3] The second point is that the third element does not undergo preferential nitridation; its chemical affinity for N is weaker or comparable to that of Fe. Co meets the above two requirements.

A surface-nitriding method is used for this investigation. The formation of iron nitrides on bulk iron surfaces on NH_3 gas-nitriding was studied by Inokuchi *et al.*[5] They reported that needle-shaped $Fe_{16}N_2$ precipitates form on the (100) surface. The present paper demonstrates that the Co-contained 16:2 nitride is granular and its amount is larger than the pure iron case.

II. EXPERIMENT

Fe-Co alloy films with a (100) surface were prepared as follows. First, Fe was deposited onto a MgO(100) single-crystal substrate and successively Co was deposited onto the Fe layer. Sputtering was performed with an Ar gas using an ECR made for Fe and a usual magnetron for Co. The total film thickness is 500 nm. The composition of Co was changed up to 30 at. % by changing the film thickness of Co. Alloying was performed by annealing at 750 °C for 120 min in a flowing H_2 gas. X-ray diffraction showed that the (100) orientation of the film is maintained after annealing.

The films were exposed to a mixed gas of 75% NH_3 and 25% H_2. The nitriding temperature was ranged from 450 to 550 °C. Annealing and nitriding were performed sequentially in an infrared furnace. The heat pattern is shown in Fig. 1. The structure of the nitride was determined by x-ray diffraction using Cu $K\alpha$ radiation. The morphology of the nitrides was observed through an optical microscope and a scanning electron microscope. Detailed analyses were performed by transmission electron microscopy (TEM) using a Hitachi 200 kV electron microscope with EDS (energy dispersion spectroscopy). TEM foils were prepared by ion milling. The samples were milled from the substrate side in order to reveal the surface structure.

III. RESULTS AND DISCUSSION

Figure 2 shows the x-ray-diffraction patterns for pure iron and Fe-10 at. % Co nitrided at 450–550 °C for 30 min. For pure iron, the $Fe_{16}N_2$ peaks were observed at a nitriding temperature of 450 °C, as shown in Fig. 2(a). At a nitriding temperature of 500 °C, the Fe_4N peak appeared instead of the $Fe_{16}N_2$ peak, as shown in Fig. 2(b). In the case of a nitriding temperature of 550 °C, the intensity of the Fe peak drastically decreased and the intensity of the Fe_4N peak increased as compared to the case of 500 °C, as shown in Fig. 2(c). This result indicates that the pure iron film is almost converted to a Fe_4N film.

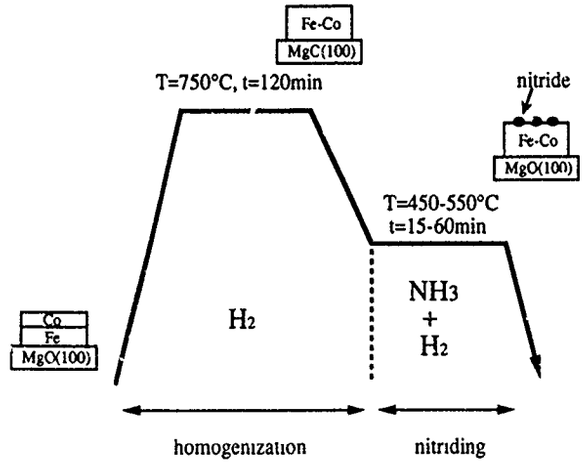

FIG. 1. Heat pattern for alloying and nitriding.

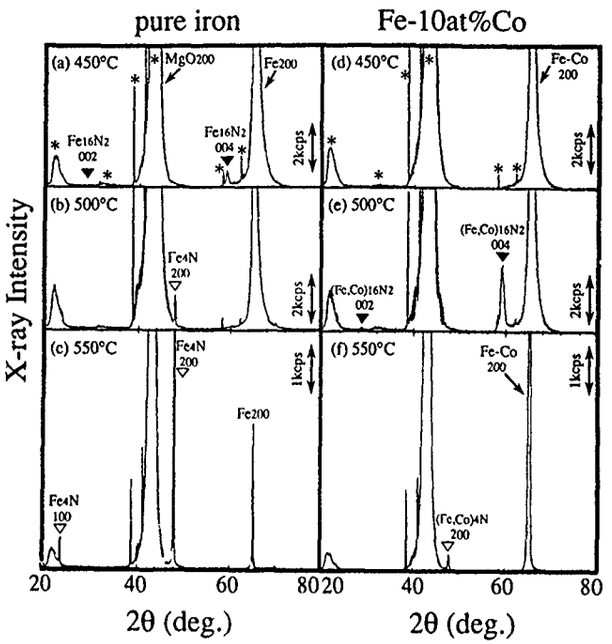

FIG. 2. X-ray-diffraction patterns for pure iron and Fe-10 at. % Co nitrided. The nitriding temperatures are (a) 450, (b) 500, and (c) 550 °C for pure iron and (d) 450, (e) 500, and (f) 550 °C for Fe-10 at. % Co. The nitriding time is 30 min. The mark (*) indicates the peaks from the MgO substrate.

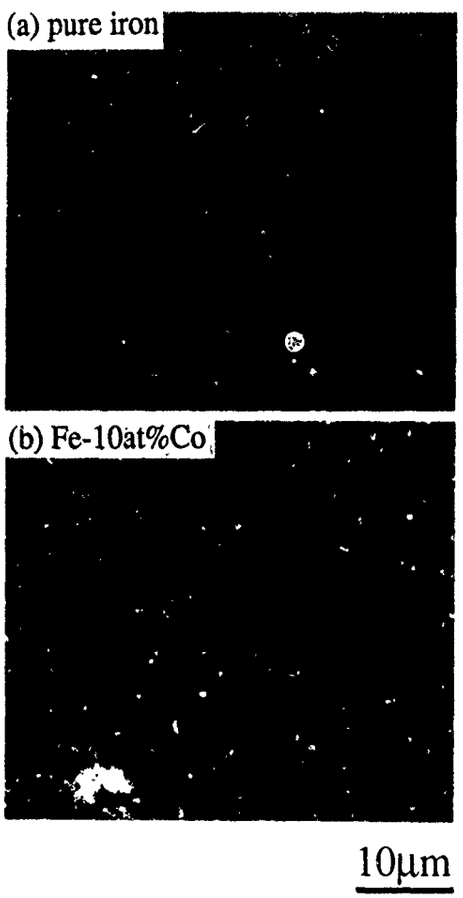

FIG 3. Scanning electron microscope images of the 16:2 nitride formed on (a) a pure iron film nitrided at 450 °C for 30 min and (b) a Fe-10 at. % Co film nitrided at 500 °C for 30 min.

FIG. 4. Bright field image of a granular precipitate on a Fe-10 at. % Co film nitrided at 500 °C for 30 min and the corresponding electron-diffraction pattern. The indices of the 16:2 nitride are also shown in the diffraction pattern.

For Fe-10 at. % Co, no nitride peaks were observed at a nitriding temperature of 450 °C as shown in Fig. 2(d). At a nitriding temperature of 500 °C, a strong 004 peak of the 16:2 nitride was observed. The 002 peak of the 16:2 nitride, which is an order reflection peak of the 16:2 nitride, was apparently observed [see Fig. 2(e)]. At a nitriding temperature of 550 °C, the 16:2 nitride peaks disappeared, as shown in Fig. 2(f). The intensity of the 4:1 nitride 200 peak is very weak as compared to that of the pure iron, indicating that the formation of the 4:1 nitride is suppressed by Co additions.

The nitridation behavior for the 16:2 nitride is different in the following two points. The formation temperature of the 16:2 nitride is 50 °C higher for Fe-10 at. % Co than for pure iron. The amount of the formed 16:2 nitride, which was calculated from the x-ray peak intensities, is 3× larger for Fe-10 at. % Co than for pure iron.

Figures 3(a) and 3(b) show the scanning electron microscope images of the 16:2 nitride which formed on a pure iron film nitrided at 450 °C and a Fe-10 at. % Co film nitrided at 500 °C, respectively. For the pure iron case, the morphology of the nitride is needle shaped. For the Fe-10 at. % Co case, granular precipitates were observed. From the x-ray-diffraction pattern in Fig. 2(e), the granular precipitate is assumed to be the 16:2 nitride.

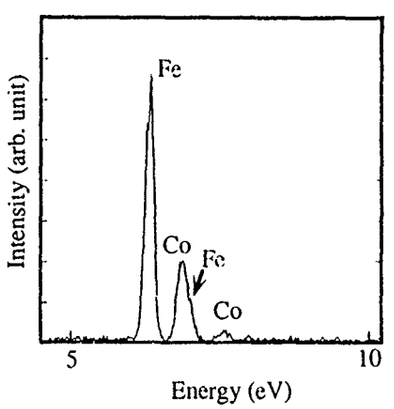

FIG. 5. EDS spectrum taken from a granular precipitate of the 16:2 nitride formed on a Fe-10 at. % Co film (the same precipitate as shown in Fig. 4).

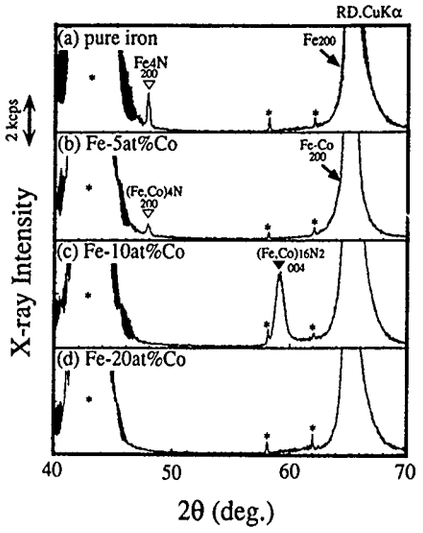

FIG. 6. X-ray-diffraction patterns of Fe-Co films with various Co contents nitrided at 500 °C for 30 min. The film compositions are (a) pure iron, (b) Fe-5 at. % Co, (c) Fe-10 at. % Co, and (d) Fe-20 at. % Co. The mark (*) indicates the peaks from the MgO substrate.

TEM observations were performed for the granular precipitate formed on Fe-10 at. % Co film. Figure 4 shows a bright field image of the granular precipitate and the corresponding electron-diffraction pattern. As shown in the diffraction pattern, we can observe weak spots at the midpoints between 000 and 400 spots. These spots are indexed by the 200 order reflections of the 16:2 nitride. Figure 5 shows an EDS analysis spectrum taken from the granular precipitate. The Co content of the precipitate was determined to be almost the same as that of the matrix bcc phase. From these results, the granular precipitate is determined to be a Co-contained 16:2 nitride, which can be denoted by $(Fe,Co)_{16}N_2$.

Figure 6 shows the x-ray-diffraction patterns for Fe-Co films with various Co contents nitrided at 500 °C for 30 min. For pure iron, only the Fe_4N peak was observed. As the Co content increases, the intensity of the 4:1 nitride peak decreases. At Fe-10 at. % Co, the 4:1 nitride peak disappeared and instead a strong 16:2 nitride peak appeared. Further increase in the Co content results in no nitride peaks, indicating harder nitridation for higher Co contents.

The stability of the Co-contained 16:2 nitride is discussed as follows. Due to a 10 at. % Co substitution, the lattice parameter of the bcc Fe-Co phase increases by 0.16% relative to that of the bcc pure Fe.[6] Assuming that the atomic volume of Co is the same as that of Fe, we presume that the interstitial sites are wider in the Fe-Co lattice than in the Fe lattice. This idea is supported by the fact that the solubility of nitrogen is increased by Co additions.[7] The 16:2 nitride is considered to be a nitrogen-ordered form of the tetragonal Fe-N solid solution, which is derived without changing the basic arrangement of Fe atoms in the bcc structure. Therefore, it can be speculated that the Co-contained 16:2 nitride also forms with less strain energy, leading to a higher stability. The observed enhancement of formation of the 16:2 nitride by Co additions can be related to the improvement of the stability of the 16:2 structure. Suppression of the 4:1 nitride formation by Co additions, as described in Fig. 2, may also benefit the 16:2 nitride formation.

IV. SUMMARY

We have newly found that Co additions enhance the formation of the 16:2 nitride. Granular 16:2 nitrides were confirmed to form on a (100) surface of Fe-10 at. % Co alloy. The formation temperature is 500 °C, which is 50 °C higher than that for pure iron. The amount of the 16:2 nitride is 3× larger than for pure iron. It is suggested that Co stabilizes the 16:2 structure.

The low temperature magnetic properties of arrays of scanning tunneling microscope (STM) fabricated ferromagnetic particles have been studied as a function of their dimension using a novel high sensitivity Hall magnetometer. Iron deposits with controlled shape and nanometer scale diameters (~25 nm) are formed using a STM to decompose a metalorganic precursor [$Fe(CO)_5$] in the active area of the measurement device. The hysteresis loops change significantly in going from nearly isotropic to oriented high aspect ratio (6:1 length to diameter) filamentary particles. In particles of intermediate aspect ratio and diameter the largest coercive field of 2.7 kOe is observed. This b· r as well as the characteristics of the Hall magnetometer (spin sensitivity of 10^{-14} emu/$Hz^{1/2}$) . ribed.

I. INTRODUCTION

The physical properties of ferromagnetic particles continue to be an active area of fundamental experimental and theoretical research. Advances in lithographic and measurement techniques are now permitting some of the basic tenets in the field of small particle classical magnetism to be critically tested. For example, measurements of a single acicular γ-Fe_2O_3 particle[1] and electron beam fabricated rectangular permalloy particles[2] are not consistent with the Néel–Brown[3] theory of thermally assisted magnetization reversal over a simple potential barrier. Usually this theory is the starting point in the analysis of more complex particulate media which have a distribution of sizes, shapes, and interactions. Magnetization reversal in elongated particles has also recently been re-examined theoretically. In idealized filaments Braun[4] finds that spatially localized magnetization fluctuations increase the switching rates and hence reduce the measured coercivities at finite temperature relative to the Néel–Brown theory. Real samples, of course, contain defects, ends, and surfaces that are not considered in this work but which are expected to play an important, if not dominant, role in the physics of magnetization reversal. Of fundamental interest is the mechanism of reversal in real particles—whether it is a classical coherent (Néel–Brown, Braun) or incoherent mode or, alternatively, heterogeneous nucleation and growth.[5] We have set out to study smaller noninteracting particles in which the competing effects can be highlighted by systematically varying the particle dimensions.

It is the purpose of this article to show how this is accomplished in scanning tunneling microscope (STM) nanolithographically produced small particle systems. STM and chemical vapor deposition techniques have been used to fabricate nanometer scale diameter (~25 nm) iron particles with a range of shapes from nearly isotropic to filamentary. Deposits are fabricated directly in the active area of a newly developed high sensitivity Hall magnetometer. With this device hysteresis loops of dilute particle arrays comprising 100–600 particles ($<10^{-11}$ emu) have been measured at low temperature. Moreover, the magnetic characteristics have been studied for a variety of particles sizes and shapes. In particles of intermediate aspect ratio (2.2:1 height:diameter) and diameter the largest coercive force is observed. This observation is not consistent with the well-known classical coherent or incoherent modes of reversal.[3,6] Further, from the hysteresis loops and array geometry we estimate the particle magnetization and interparticle interaction strength.

We begin with a brief review of the materials fabrication technique and characterization.[7] This is followed by a discussion of the magnetic measurements and analysis on particles of systematically varied geometry.

II. FABRICATION

Iron particles are formed by using a STM to decompose iron pentacarbonyl [$Fe(CO)_5$] which is metered into the mi-

croscope's ultrahigh vacuum chamber ($P=2\times10^{-10}$ T). To initiate the growth the substrate-tip bias is raised to 15 V and a current of 50 pA maintained in the presence of 30 μTorr of $Fe(CO)_5$. The STM feedback loop is *active* and maintains a constant current and thus constant height between the tip and growing deposit. When the deposit has reached the desired height above the surface the tip is retracted to stop the growth. The tip is moved to another location and the process repeated to form arrays.

Characterization by both Auger electron spectroscopy (AES) and transmission electron microscopy (TEM) indicate that relatively pure iron deposits are formed under these conditions. TEM shows that these consist of a polycrystalline bcc iron interior surrounded by a contamination coating in which the grain size is approximately the inner core diameter. AES reveals greater than 70 at. % Fe with a carbon remainder. The fact that the bcc phase is formed is evidence for greater purity of the deposits in their interior since the equilibrium phase of the Fe-C system above 0.4% carbon is fcc.[8]

The scanning electron micrographs in Figs. 1(A) and 1(C) show the extremes in dimensions we have fabricated and studied. The particle geometry, with the long axis perpendicular to the substrate surface, is highlighted in the oblique view presented in the micrograph. Note that from Figs. 1(A) and 1(C) the particle diameters progressively decrease from 42 to 17 nm while the ratios of height to diameter increase from 1 to 6. Although these measurements serve as a basis for comparing particle dimensions, contamination built up during observation as well as the finite resolution of the SEM cause systematic overestimates of the actual particle size.[9] The interparticle distance is approximately 130 nm and was chosen to minimize, as much as possible, the effect of interparticle interactions while building up enough overall moment for measurement. Magnetic measurements have been made on these samples as well as on some of intermediate dimensions.

III. MEASUREMENTS

Measurements were made using a novel high sensitivity magnetometer based on the Hall response in a semiconductor heterostructure. In contrast to integrated superconducting quantum interference device microsusceptometers,[10] this device allows for systematic investigations over a wide range of applied fields and temperatures. A high mobility

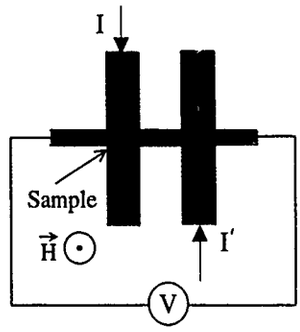

FIG. 2. Schematic of the Hall magnetometer showing the device layout and bridge measurement circuit. The sample is deposited into one Hall cross while the other serves as a reference. I and I' are independent current sources that float with respect to one another.

GaAs/$Ga_{0.7}Al_{0.3}As$ two-dimensional hole gas sample [$n_{2D}=3\times10^{11}$ cm^{-2}, $\mu(5\text{ K})=10^5$ cm^2/V s)] was wet chemically etched into the form depicted in Fig. 2 and a thin (30 nm) gold gate deposited over the active area of the device. The linewidths for the current and voltage probes ranged from 1 to 10 μm and the heterointerface was 100 nm below the surface. STM deposits were subsequently grown in the active area of one of the Hall crosses. The difference in Hall voltage between this sample cross and a closely spaced reference is measured using a bridge circuit (Fig. 2). With the bridge properly balanced, the resulting output voltage V is proportional to the sample contribution to the magnetic induction. This contribution can then be calculated using the measured Hall coefficient so that $\Delta B = V/RI$ where R is the Hall coefficient (~0.2 Ω/G) and I is the measurement current. Typically we use a 6.5 Hz ac current (~1 μA/rms) and lock-in detect the difference signal V.

In practice, a difference voltage is present even in the absence of a magnetic sample due to small variations in the Hall crosses (typically ~0.1%). This imbalance results in a signal proportional to the applied magnetic field which is minimized by adjusting the ratio I to I' at high field ($H \gg H_c$, the coercive field).

The large Hall response (~0.2 μV/G) in combination with good coupling of small samples to the device results in an excellent spin sensitivity. For example, the observed field noise of 0.1 G/Hz$^{1/2}$ (at 0.1 Hz, 5 K) in a 2 μm^2 device implies a spin sensitivity of 10^{-14} emu/Hz$^{1/2}$. Typically, signals from the STM arrays are 10 times this noise level. In addition, the sensor works over a large range of magnetic field and temperature. At low temperature, ballistic transport (on the scale of the magnetic arrays) reduces the responsivity. The quantum Hall effect and the associated nonlinear dependence of Hall voltage on magnetic field also changes the response at low temperature and high fields. Both the decreasing hole mobility and thermally activated switching of defects in GaAs cause the noise to increase with temperature. We have successfully used this magnetometer from 1 to 80 K with some decrease in performance with increasing temperature ($T>50$ K).

An array of particles of intermediate size [those in Fig. 1(B), referred to as sample (B)] placed in the active area of

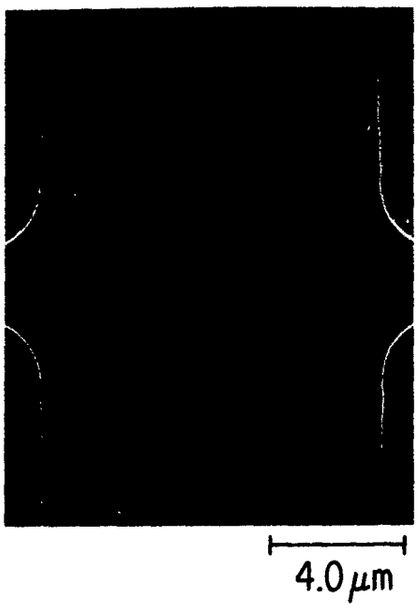

FIG. 3. SEM micrograph of a STM fabricated array [sample (B)] placed in the 10 μm×2.5 μm active area of a Hall magnetometer.

the magnetometer is shown in Fig. 3. An external field is applied perpendicular to the plane of the device and hence parallel to the long axis of the particles. Hysteresis loops are measured starting from a saturating field, ramping at a constant rate to the opposite field polarity and then back. Figure 4 shows the difference in induction, which is proportional to the sample magnetization, plotted versus the external field. Measurements were made at different temperatures and ramp rates. Under these conditions the coercive field has only a slight dependence on the measurement time and temperature

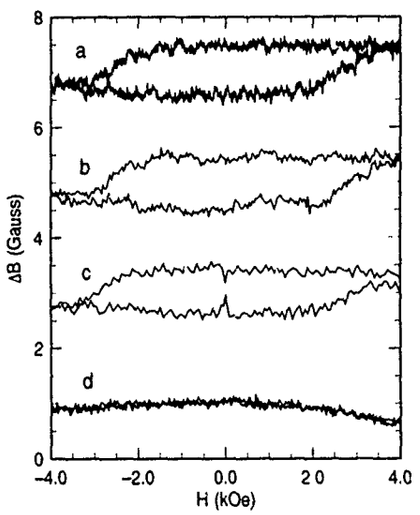

FIG. 4. Hysteresis loops for sample (B) measured from negative to positive saturation and back showing the difference in induction, which is proportional to the sample magnetization, versus external field. (a) 15 K, dH/dt =250 Oe/min, (b) 15 K, 1 kOe/min, (c) 5 K, 1 kOe/min, and (d) the difference between two reference crosses with no sample 5 K, 1 kOe/min. Plots are offset for clarity.

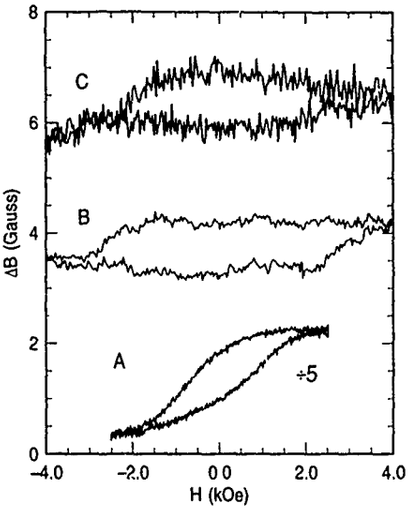

FIG. 5. Hysteresis loops as a function of particle dimensions. Measurements on sample (A) 5 K, 250 Oe/min, (B) 15 K, 1 kOe/min, and (C) 5 K, 500 Oe/min. These variations in measurement time and temperature do not affect the curves on the scale presented (as seen in Fig. 4). The increased noise in (C) is due to the smaller dimensions of the Hall cross (2 μm^2). In this case, the sample consists of only 100 particles with a total moment of $\sim 2\times10^{-13}$ emu.

and is approximately 2.7 kOe. The magnetization reversal occurs over a range ±0.4 kOe about the value. In Fig. 4(d), as a check, the same measurement was made using two reference crosses, neither of which contained a sample. This shows no hysteresis and only a small deviation from a constant value.

Magnetic measurements were made on arrays (A), (B), and (C) in Fig. 1 in order to study the dimensional dependence of the magnetic properties (Fig. 5). The shapes of the hysteresis loops change significantly in going from the nearly isotropic particles of sample (A) to the filamentary particles in (C). Most notably, the loops are increasingly square with more abrupt magnetization transitions. The change in sample magnetization also decreases due both to the geometry of the samples as well as to the decreasing moment per particle. The coercivity initially increases in more anisotropic particles [(A) to (B)]. Surprisingly, this is followed by a decrease in the more filamentary particles of sample (C). Samples intermediate in dimensions to (B) and (C) appear to confirm this trend.

The loop shape for sample (A) is close to that expected from the Stoner–Wohlfarth theory[11] for noninteracting uniaxial particles with randomly oriented easy axes. For instance, the remanence is 0.46 times the saturation magnetization close to the 0.5 predicted by SW. The coercivity is 640 Oe. Within this model the anisotropy field is $H_c/0.48$ or 1.33 kOe. Small deviations from isotropic shape would account for this entire anisotropy although a crystailine contribution might also be present (bcc Fe[6]~540 Oe). The demagnetization factors of a prolate ellipsoid of iron with axial ratio 1.17 is sufficient to explain this and within the range of measured particle asymmetries [$c/a=1.3\pm0.3$, Fig. 1(A)]. For the oriented elongated particles [samples (B) and (C)] increasingly

TABLE I. Summary of particle properties.

Sample	No. of particles	diam (nm)	c/a	m (emu/particle)	H_c (Oe)	diam (nm)[b]
A	500	42 ± 7	1.3 ± 0.3	1.0×10^{-14}	1324[a]	21
B	600	29 ± 2	2.2 ± 0.3	5.4×10^{-15}	2700	9
C	100	17 ± 1	5.8 ± 0.5	1.6×10^{-15}	2050	4

[b]Magnetic core diameter inferred from the magnetic moment and particle shape.

square hysteresis curves are also expected on the basis of the SW theory. In contrast to sample (A), these particles' easy axes are not randomly oriented but expected to be aligned with their long axes.

From the change in induction in going from positive to negative saturation the magnetic moment per particle can be estimated. In the dipole approximation this change in B field perpendicular to the heterointerface averaged over the sensor area is given by

$$\Delta B = \frac{2m}{S} \sum_i \int_S d\mathbf{r} \frac{1}{[z^2+(\mathbf{r}-\mathbf{r}_i)^2]^{3/2}} \times \left(1 - \frac{3z^2}{[z^2+(\mathbf{r}-\mathbf{r}_i)^2]}\right), \quad (1)$$

where m, the magnetic moment per particle, is the quantity of interest; $\mathbf{r}$ is a vector in the plane of the surface; $\mathbf{r}_i$ the position of the ith particle; S the surface of the Hall cross, and z the distance from the dipole's center to the heterointerface. The integral over the rectangular surface S of the Hall cross can be performed analytically and then summed over particles numerically to solve for m. This calculation approximates the actual nonuninform field distribution from the array geometry and position in the Hall bar by a spatially homogeneous average field in estimating the moment. For sample (B), we find $m=5.4\times10^{-15}$ emu. This is a factor of approximately 10 smaller than an estimate based on the bulk moment of Fe and our observations of the particle size. As previously mentioned, it seems appropriate to assume that the magnetic volume is smaller than that found from SEM measurements. Taking the measured magnetization of bcc Fe (1700 emu/cm^3) gives a magnetic volume of 3×10^{-17} cm^3 or equivalently a magnetic core only 9 nm in diameter, compared to the 29 nm diam measured from Fig. 1(B). This interior size is consistent with TEM observations on similar deposits.[9] Within this analysis, the aspect ratio of the magnetic volume would also be greater than the measured value. The results for the other samples are summarized in Table I.

From the particle moment the strength of the dipolar interactions between particles can be estimated. For a square lattice of oriented dipoles with spacing a, the interparticle interaction field due to nearest neighbors is $4m/a^3$. For sample (A) this is 20 G. Substantial contributions result from the long range nature of the dipole interactions. Including oriented neighbors out to four lattice spacings (48 particles) results in a field of 40 G. This is still much less than the anisotropy field and will play a role only in the tails of the magnetization transition. Interactions are less important in samples (B) and (C) due to their smaller moment per particle.

IV. DISCUSSION

Changes in the coercive force with dimensionality, notably the decrease in high aspect ratio smaller diameter particles, are not consistent with conventional coherent[10] or incoherent modes of spin reversal.[6] For instance, the curling mode, which is applicable only in larger diameter particles, predicts an increase in coercive field with decreasing diameter. In both coherent reversal and fanning models the coercive field increases with aspect ratio. For reference, coherent reversal in an iron particle of axial ratio 2.2 [like sample (B)], would require a field of 5.7 kOe—twice the observed value. Fanning, which postulates decoupled grains, at least can account for the magnitude of the observed switching field.

Recently, Braun has considered the role of nonuniform magnetization fluctuations in reducing the coercivity at finite temperature in elongated particles.[4] It is therefore worth estimating whether this theory applies to our measurements. Fluctuation effects are important when the thermal energy is comparable to the barrier height. For uniform coherent reversal, at zero field, the barrier is KV, the anisotropy volume product. To be specific, for sample (C) this is 10^4 K. At low temperature this implies that such reversal cannot occur until the applied field is very close to the intrinsic (zero temperature) coercivity. For example, at 5 K the particles switch when $H/H_c \sim 0.9$, with our measurement times. In Braun's theory, the energy is no longer proportional to the volume but the cross-sectional area of the particle, $8\sqrt{JK/c}\ A$. This is the energy density of a domain wall times the cross-sectional area, A. J is the exchange constant and c the lattice spacing. An estimation of this energy for sample (C) is also 10^4 K. Thus spatially nonuniform reversal requires the same amount of thermal energy as the uniform case due both to the large exchange and anisotropy energies. Only in far more filamentary particles does the nonuniform mode dominate. These estimations suggest that fluctuations cannot account for the observed reduction in coercivity.

As an alternative to the above models, the particle ends, surfaces, and defects might play an important role in determining the magnetic properties. For example, large demagnetization fields such as occur at the particle ends would favor a heterogeneous nucleation and growth of reversed domains as occurs in bulk ferromagnets.[5] Reversal would con-

sist of either the localized nucleation of a reversed domain and its subsequent propagation or the movement of an existent closure domain through the particle. Moreover, defects, such as grain boundaries, lower the barrier to domain nucleation. As the energy of a domain wall is proportional to its area these scenarios are qualitatively consistent with the observed decrease in coercive force in smaller diameter particles.

In summary, we have demonstrated the ability to fabricate and measure nanometer scale ferromagnets. Magnetic structures with well-defined geometries have been coupled to an electronic system. This is the basis for a novel high sensitivity magnetometer which relies on the Hall effect in a semiconductor heterostructure. In addition to investigations of magnetic nanostructures, this combination enables studies of the effect of local magnetic interactions on electronic properties and transport in semiconductors.

Recent studies have demonstrated the possibility of inducing amorphous latent tracks in metallic materials by GeV heavy ion irradiation. In the present work, 0.880 GeV ^{238}U beams have been used to induce ferromagnetic amorphous nanocolumns in nonmagnetic crystalline YCo_2 films. The loss of crystallinity deduced by x-ray analysis is in good agreement with the one determined by magnetic measurements. The Co magnetic moment in the columns is approximately equal to 1 μ_B, as in bulk amorphous YCo_2, but the ordering temperature (150 K) is strongly reduced with respect to the bulk. Magnetization measurements reveal the nanocolumns to be single domain. A perpendicular anisotropy is observed in samples irradiated at the smallest fluencies, which is interpreted to be due to shape anisotropy. A progressive decrease of the anisotropy with increasing fluence is observed and qualitatively described in terms of dipolar interactions between columns. At low temperature, the coercive field reaches 650 Oe. A simple nonuniform magnetization reversal process is suggested.

I. INTRODUCTION

The formation of defects by GeV heavy ion irradiation through inelastic scattering with the target electrons has recently been demonstrated for amorphous or crystalline metallic materials.[1–4] In particular, it has been shown that above an electronic stopping power threshold, the target could be locally amorphized. Two models have been proposed to describe the formation of amorphous latent tracks, based either on the mutual repulsion of highly ionized atoms (Coulomb explosion model[5]) or the heat transfer via phonons (thermal spike model[6]). Transmission electron microscopy (TEM) observations have revealed that under certain conditions, the irradiation-induced defects were stabilized in the form of cylindrical amorphous tracks along the ion path (latent tracks), with diameters in the range 20–50 Å.[7–9] In this study, we show that in Y-Co alloys it is possible to induce amorphous ferromagnetic nanocolumns in a nonmagnetic crystalline matrix. This allows magnetization reversal processes to be studied in an assembly of nanocolumns with a relatively well-defined size and shape, in which the amplitude of the dipolar interactions can be varied through the total fluence of the ion beam.

The formation of ferromagnetic columns in a nonmagnetic matrix is possible due to the fact that the magnetic properties of the binary Y-Co alloys depend drastically on whether the material is crystalline or amorphous. It is well known that in Y-Co compounds, the Co magnetic moment decreases as the Y content is increased through electron transfer into the $3d$ band and $3d$-$4d$ hybridization[10] (Fig. 1). As a result, Co-rich crystalline compounds are ferromagnets, whereas compounds richer in Y then YCo_2 are Pauli paramagnets. However, amorphous Y-Co alloys are ferromagnetic up to an Y:Co ratio of the order of 1:1.[11] This is due to the higher localization of the $3d$ electrons in the amorphous state when compared to the crystalline state, as a result of atomic disorder and of the relatively weaker density. In addition, the surrounding of a given Co atom is Co richer in the amorphous state where atoms are more or less distributed at random, as compared to the crystalline state where Y—Co bonds, chemically favored with respect to Co—Co bonds, can better be formed.

Crystalline thin films of YCo_2 were prepared and subsequently irradiated by U heavy ions in an attempt to induce amorphous tracks. The results of structural and magnetic analyses performed prior to and after irradiation are presented in the following.

II. EXPERIMENT

The samples were deposited at room temperature by dc sputtering with a deposition pressure of $1–3\times10^{-3}$ Torr. Two sets of films were prepared with the following compositions: Si(100)/Ta 1000 Å/YCo_2 1.5 μm/Ta 1000 Å (samples A) and Si(100)/Ta 500 Å/YCo_{11} 2300 Å/Ta 500 Å (samples

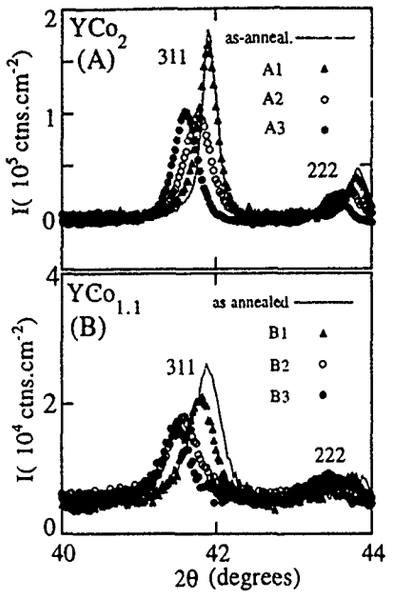

FIG. 2. Detailed view of the XRD patterns showing the 311 and 222 most intense reflections in the irradiated samples. The symbols refer to samples irradiated at fluence: A1 and B1 at 10^{12} ions/cm^2, A2 and B2 at 5×10^{12} ions/cm^2, A3 and B3 at 2×10^{13} ions/cm^2. For reference, the XRD patterns of the as-annealed samples are also shown (full line).

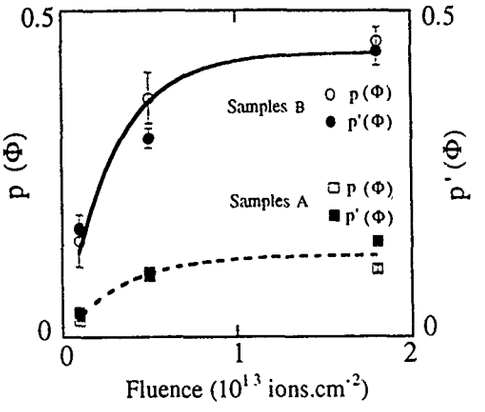

FIG. 3. Amorphous fraction as deduced by XRD [$p(\phi)$: open symbols] and by magnetic measurements [$p'(\Phi)=M_s(\phi)/M_s^{(a)}$: closed symbols]. $M_s^{(a)}$ is the spontaneous magnetization of bulk amorphous YCo_2. Data are fitted according to Eq. (2).

B). The compositions and thicknesses of the films were determined by Rutherford backscattering (RBS) and transmission electron microscopy (TEM). The as-deposited films were subsequently vacuum annealed at 550–600 °C for 1 h in order to crystallize the YCo_2 phase. The samples were then irradiated by 0.880 GeV ^{238}U ion beams at the GANIL accelerator in Caen, France. Three ion fluencies were selected: 10^{12} ions/cm^2 (samples A1 and B1), 5.10^{12} ions/cm^2 (samples A2 and B2) and 2×10^{13} ions/cm^2 (samples A3 and B3). Structural characterization was performed by quantitative x-ray diffraction analysis (XRD) on a θ-2θ diffractometer with Cu K_α wavelength. The magnetic properties were determined between 4.2 K and room temperature using either a VSM or a SQUID magnetometer.

III. STRUCTURAL CHARACTERIZATION

XRD and TEM analyses revealed the as-deposited films to be amorphous and the annealed films to be crystalline. The latter showed the diffraction pattern of the fcc YCo_2 Laves phase.[12] Samples A appeared to be single phase while in samples B, apart from the YCo_2 Bragg reflections, some additional peaks corresponding to a phase which could not be unambiguously identified were observed. However, considering the mean stoichiometry of the alloy ($YCo_{1.1}$) and the phase diagram of the Y-Co binary alloys,[13] one can infer that this phase could most likely be Y_9Co_7 and estimate the fraction of YCo_2 to be about 30% of the total volume. Y_9Co_7 is nonmagnetic in both the amorphous and the crystalline states.[12]

A detailed view of the YCo_2 311 and 222 peaks is represented in Fig. 2 for both sets of samples. When the irradiation fluence is increased, the peaks are broadened and their integrated intensities are decreased. We ascribe this loss of crystallinity to the appearance of irradiation-induced amorphous regions. A shift of the peaks toward smaller Bragg angles is also observed, which we ascribe to irradiation induced stresses. A detailed analysis of this effect is reported elsewhere.[14] The percentage $p(\Phi)$ of amorphized YCo_2 in the irradiated samples can be deduced by comparing the peak integrated area of the 311 Bragg reflection for each series of samples to the one measured before irradiation (Fig. 3). The equation describing the kinetics of defect creation can be expressed as:[15]

$$\frac{dv}{d\Phi}=\sigma_1(V_t-v)-\sigma_2 v, \tag{1}$$

where σ_1 is the amorphization cross section, σ_2 is the exclusion cross section, v is the amorphized volume and V_t the total sample volume. The exclusion cross section accounts for the fact that an ion track can be recrystallized if an incoming ion happens to hit a ring around it. This exclusion ring implies that a complete amorphization of the samples is impossible. In particular, it defines a minimum separation distance between the amorphous columns. Solving Eq. (1) leads to

$$p(\Phi)=\frac{v}{V_t}=\frac{\sigma_1}{\sigma_1+\sigma_2}\left(1-e^{-(\sigma_1+\sigma_2)\Phi}\right). \tag{2}$$

Assuming that defects consist of latent tracks expanding across the film thickness, σ_1 and σ_2 can be expressed as

$$\sigma_1=\frac{\pi D_1^2}{4}$$

$$\sigma_2=\frac{\pi(D_2^2-D_1^2)}{4}, \tag{3}$$

where D_1 is the diameter of the amorphous latent tracks and D_2 the diameter of the exclusion ring. Equations (2) and (3) were fitted to the experimentally deduced $p(\phi)$ enabling D_1 and D_2 to be determined. The fit yielded D_1=25 Å and D_2=50 Å for samples A and D_1=50 Å and D_2=60 Å for

samples B. The reasons for the difference in the track diameters for both series of samples, as well as for the reduced recrystallization effects in samples B [revealed by the linearity of $p(\Phi)$ up to higher fluencies] remain unclear. Differences in the microstructure of the specimens could play a role. A smaller average grain size, for example, can reasonably be expected to influence the processes involved in defect creation and annealing. TEM observations are in progress.

IV. MAGNETIZATION MEASUREMENTS

A. Magnetization measurements of unirradiated films

Magnetization measurements at 10 K have been carried out on both the amorphous as-deposited A and B samples as shown in Fig. 4. For samples A, a large susceptibility is obtained when the field is applied in the film plane. The spontaneous magnetization is 360 emu/cm^3, corresponding to approximately 1 μ_B/Co in agreement with the value already reported for bulk a-YCo_2.[11] When the field is applied perpendicular to the film plane, the magnetization varies accordingly to the demagnetizing field slope, which indicates that magnetocrystalline anisotropy may be neglected with respect to shape anisotropy. After the crystallization heat treatment in-plane magnetization measurements of the same sample yield a very small residual magnetization of the order of 5 emu/cm^3 (inset of Fig. 4). This residual ferromagnetic contribution can either originate from residual amorphous material or from the presence of magnetic crystallized phase, richer in Co than YCo_2 which could result from Y oxidation through the Ta capping layer.

In samples B, the spontaneous magnetization of the as-deposited amorphous films is weak (25 emu/cm^3). This is a consequence of the large Y content (see Fig. 1). The magnetization curves measured in-plane and out-of-plane are similar. A significant susceptibility is present up to 10 kOe. This is ascribed to superimposed paramagnetism, in agreement with the fact that the alloy stoichiometry is close to the critical concentration for the disappearance of magnetism. After heat treatment, the spontaneous magnetization is further reduced to 5 emu/cm^3, a value similar to that measured in annealed samples A.

B. Magnetization measurements on irradiated samples

After irradiation, magnetization measurements were initially performed on thermally demagnetized samples. The susceptibility of the virgin magnetization curve measured at 10 K along the easy direction is shown in the insets of Figs. 5 and 6. In all samples, the initial susceptibility is weak until the field reaches values of the order of the coercive field

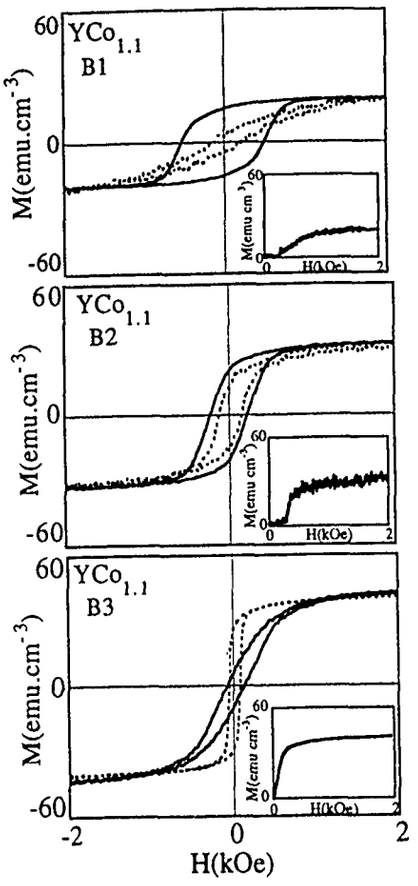

FIG. 6. Hysteresis loops measured in samples B in applied fields perpendicular (full line) and parallel (dashed line) to the film plane. Inset: first magnetization curves measured along the easy directions. (a) Sample B1 irradiated at 10^{12} ions/cm^2, (b) sample B2 irradiated at 5×10^{12} ions/cm^2, (c) sample B3 irradiated at 2×10^{13} ions/cm^2.

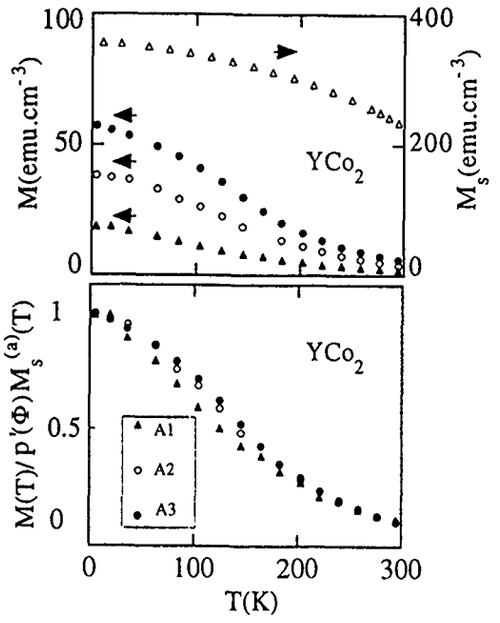

FIG. 7. (a) Temperature dependence of the magnetization $M(T)$ in a field $H=10$ kOe for samples A. (b) Temperature dependence of $M(T)/p'(\Phi)M_s^{(a)}(T)$. The prefactor $1/p'(\Phi)$ is used to normalize the data to bulk YCo_2.

measured on the hysteresis cycles. Considering the small size of the nanocolumns deduced from the analysis in the above section, this can be attributed to single domain behavior.

The magnetization loops measured at 10 K are reported in Figs. 5 (samples A) and 6 (samples B). The magnetization increases as the fluence is increased. This confirms the formation of amorphous ferromagnetic YCo_2 through irradiation. The fraction of amorphized film in samples A, $p'(\Phi)$, deduced from the variation with the ion fluence of the spontaneous magnetization $M_s(\Phi)$ and normalized with the ion fluence and normalized to the magnetization of bulk amorphous YCo_2, $M_s^{(a)}$, is reported in Fig. 3. $p(\phi)$ is in good agreement with the values of $p(\Phi)$ deduced from XRD analysis. Assuming continuous amorphous columns with diameter D_1 one deduces that the Co moment is $\mu_s=1.0\pm0.2$ μ_B/Co in all samples. This agrees with the value measured in the as-deposited amorphous films. A similar analysis can be carried out for samples B. However, because the sample is not single phase, the measured magnetization normalized to bulk YCo_2, $M_s(\Phi)/M_s^{(a)}$ must be multiplied by a factor α to match with $p(\Phi)$ values deduced from XRD. A value $\alpha=4$ is obtained. $1/\alpha$ represents the volume fraction of the YCo_2 phase in the whole sample; it is in fairly good agreement with the value of 30% estimated in Sec. III.

The temperature dependence of the magnetization measured in a field of 10 kOe for the A samples is shown in Fig. 7(a). This large field value was chosen to minimize possible superparamagnetic contributions. The magnetization decreases rapidly with temperature. An average ordering temperature can be located at about 150 K. The curves $M(T)/p'(\Phi)M_s^{(a)}(T)$, which compare the temperature dependence of the nanocolumns magnetization in the different samples, normalized through the factor $p'(\Phi)$ to account for the different proportions of amorphous phase in each sample, are identical [Fig. 7(b)]. However, there are serious differences with the temperature dependence of the magnetization in bulk amorphous YCo_2: The rate of decrease of $M(T)$ is enhanced and the Curie temperature is decreased ($T_c=380$ K for amorphous YCo_2). This can be ascribed to the reduced dimensionality of the nanocolumns.

C. Anisotropy in irradiated samples

The comparison of hysteresis cycles obtained for H applied, respectively, in-plane and out-of-plane shows that in samples irradiated at the lowest fluence (A1 and B1) the magnetization tends to be perpendicular to the film plane. This is consistent with the formation of elongated magnetic columns by irradiation since shape anisotropy favors the magnetization to lie along the column's long dimension. A remanent magnetization, which amounts to 0.2 M_s, is however obtained for the in-plane hysteresis loop, which reveals that the magnetization is not perfectly perpendicular to the film plane. This can be due either to the tracks not being

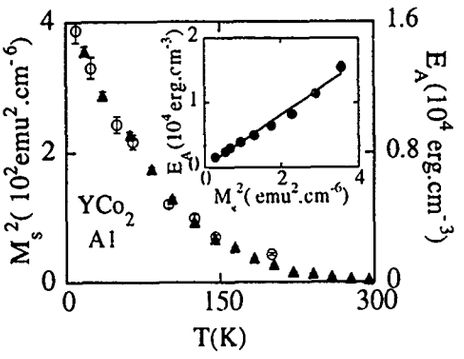

FIG. 8. Thermal variation of the anisotropy energy $E_A(T)$ in sample A1 (open symbols) compared to the square of the magnetization (closed symbols). Inset: variation of E_A as a function of M_s^2.

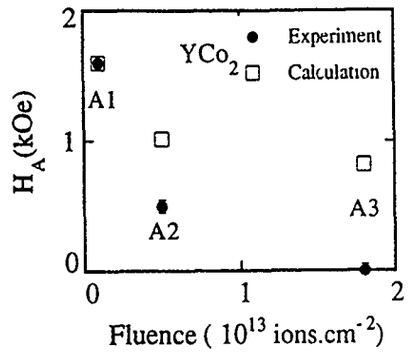

FIG. 9. Calculated (open symbols) and experimental (closed symbols) values of the mean anisotropy field as a function of the ion beam fluence (samples A).

exactly perpendicular to the film plane or to the magnetization deviating of the column axis. Further microstructural studies will be required to clarify this point.

The anisotropic behavior of samples A may however be discussed by neglecting to first approximation the deviation of the magnetization from the perpendicular direction. At 10 K, the anisotropy energy for the sample A1 is $E_A = 1.55 \times 10^4$ erg/cm^3 and the deduced mean anisotropy field is $H_A = 1.6$ kOe. The temperature dependence of the anisotropy energy is identical to that of M_s^2 (Fig. 8). This confirms that the anisotropy of the magnetic columns is dominated by shape anisotropy. Magnetocrystalline bulk or surface anisotropy may be neglected, in agreement with the low anisotropy value observed in the as-deposited Y-Co amorphous films (see Sec. II B).

To analyze the properties of sample A1, the total energy for a single column can be written as

$$E = 2\pi N_{\parallel} M_s^{(a)2} \cos^2\theta + 2\pi N_{\perp} M_s^{(a)2} \sin^2\theta + 2\pi p(\Phi) M_s^{(a)2} \cos^2\theta - 2\pi N_{\perp} p(\Phi) M_s^{(a)2} \sin^2\theta - M_s^{(a)} H \sin\theta, \quad (4)$$

where $N_{\parallel}$ and $N_{\perp}$ are the demagnetizing field coefficients, respectively, along the column's long dimension (perpendicular to the film plane) and perpendicular to it (parallel to the film plane), and θ is the angle between the magnetization direction and the film normal. The two first terms in Eq. (4) represent the particle self-dipolar energy, the two next terms represent the interparticle dipolar energy (see further) expressed in the continuous medium approximation [i.e., equivalent to the demagnetizing field created by a continuous film of magnetization $p(\Phi)M_s^{(a)}$] and the last term is the Zeeman energy. From Eq. (4), the anisotropy may be related to the demagnetizing field coefficients through

$$H_A = 4\pi\{N_{\perp}[1 - p(\Phi)] - N_{\parallel} - p(\Phi)\}M_s. \quad (5)$$

From Eq. (5) and with $N_{\parallel} + 2N_{\perp} = 1$, the values $N_{\parallel} \approx 0.1$ and $N_{\perp} \approx 0.45$ are obtained. These values suggest that the nanocolumns in sample A1 are not ideally elongated. The same feature has been reported for $NiZr_2$ alloys in which discontinuous elongated latent tracks were observed.[7] TEM observations are in progress in order to reveal the exact morphology of the tracks in our systems.

The anisotropy was also measured in samples A2 and A3, irradiated at higher fluences. When the fluence is increased to 5×10^{12} ions/cm^2 (sample A2) the magnetization curves are approximately identical whatever the direction of the applied field is. When the fluence is further increased to 2×10^{13} ions/cm^2 (sample A3), the easy magnetization direction lies in-plane. From the identical temperature dependence of the reduced magnetization in the three samples [Fig. 7(b)], one can assume that the columns are identical whatever the fluence is. The variation of the anisotropy field with the ion fluence must then originate from the rise of interactions between columns. Exchange interactions are generally isotropic in nature and it is thus legitimate to first order to consider dipolar interactions only. However, such dipolar interactions depend drastically on the initial zero-field magnetic configuration which in turn depends on exchange interactions between particles. For amorphous YCo_2 columns embedded in a Pauli paramagnetic matrix of crystalline YCo_2, exchange interactions between columns may be mediated by itinerant $3d$ electrons of the matrix. The very strong decrease in anisotropy observed with increasing ion fluence suggests that large dipolar interactions develop as the density of tracks in increased. This implies ferromagnetic coupling between neighboring columns, i.e., the formation of correlated regions with large average magnetization. This justifies the formulation used in Eq. (4) to express dipolar interactions.

The anisotropy field variation calculated for samples A according to Eq. (5) is reported in Fig. 9. It accounts for only half the total anisotropy variation. This suggests that the continuous medium approximation is not valid, especially at large ion fluencies. Statistical fluctuations in the column's distribution function, which would locally increase the dipolar interactions may have to be considered. Another possibility is that irradiation in recrystallized regions induces the formation of magnetic columns whose shape anisotropy is not as large as that of columns formed during first irradiation.

A discussion of the anisotropic behavior in samples B

leads to a very similar conclusion. It is not included in this article.

D. Coercivity

The low-temperature value of the coercive field reaches H_c=650 Oe in sample A1, that is half the value of the mean anisotropy field. It is known that for coherent rotation H_c is equal to H_A. However, in the case where shape anisotropy is involved, nonuniform magnetization processes, such as curling, are, in general expected to occur and to reduce the coercive field to values much lower than 1/2 H_A. The rather large value of the coercive field in the present case can be understood by considering that, as a consequence of the small diameter of the magnetic columns, curling cannot occur. A simple nonuniform process can be considered, consisting in a progressive reversal and rotation of the magnetization about the column axis. To the very first approximation, the dipolar energy is reduced by a factor of 4 with respect to a uniform magnetization perpendicular to the column axis (coherent rotation). The exchange energy is

$$E_{\text{Exch}}=\int_z A\left(\frac{d\theta}{dz}\right)^2 dz=\frac{A\Pi^2}{l}, \tag{6}$$

where A is the exchange constant, θ the angle between adjacent moments, and l the length over which rotation occurs. l is obtained by minimizing the exchange energy with respect to the dipolar energy. One obtains

$$l=\sqrt{\frac{2\pi}{N_\perp}}\sqrt{\frac{A}{M_s^2}}\,. \tag{7}$$

With $A=5\times10^{-7}$ erg/cm[16] and $M_s^{(a)}$=360 emu/cm^3, the domain wall length is l=600 Å.

The coercive field can be estimated from the above by expressing that for $H=H_c$, the Zeeman energy MH_cl is equal to the sum of the dipolar and exchange energies. This yields H_c=800 Oe, which is in reasonable agreement with the experimental value. For the samples A2 and A3 the coercive field is reduced to 300 and 150 Oe, respectively. This abrupt decrease can be explained by considering that magnetostatic interactions will produce an additional demagnetizing field expressed in the continuous medium approximation as $4\pi p(\Phi)M_s$. Comparison between the experimental and the estimated values of the coercive fields is shown in Fig. 10. It is somehow surprising that the variation of coercivity with fluence can be correctly described by this simple model whereas the same type of analysis does not properly account for the anisotropy field variation.

V. CONCLUSIONS

The original properties of magnetic nanocolumns produced by heavy ion irradiation have been discussed. The observed anisotropy in these systems has been attributed to shape anisotropy. A magnetization reversal process has been discussed in which dipolar interactions are not fully minimized because of the very small diameter of the magnetic columns. Further microstructural analysis and new irradiation experiments on other intermetallic compounds containing magnetic rare-earth elements are needed to allow a better understanding of the underlying mechanisms at the origin of anisotropy and coercivity.

Ferromagnetic wire and box arrays with widths and spacings in the range of 2–0.6 μm were successfully fabricated utilizing high-resolution electron-beam lithography and lift-off techniques. The box arrays possessed a unique magnetic switching mechanism. As the magnetic field decreased, the magnetic coherency between the boxes which are in a row first disappeared. Domain wall motion in each box occurred in the next step. The demagnetizing fields observed in the wire arrays with short spacings were different from those calculated by a model, in which the wires are isolated from each other. Ferromagnetic resonance measurement implied the appearance of interwire dipole-dipole interaction. Multilayered wire arrays were also prepared to study the magnetoresistive characteristics.

I. INTRODUCTION

The physical properties of materials with an artificial superstructure have attracted much attention.[1,2] This is because the effects from the periodicity and size are expected to be significantly different from those in the bulk states. In the past study, we have shown that metallic superlattices prepared by molecular-beam epitaxy possess unique structural[3] and magnetic[4] characteristics. An artificial periodicity along the film normal plays an important role in this uniqueness. Therefore, two- or three-dimensional composition modulation in materials should be proposed as the next research target. Though atomic-level control is still not possible in the preparation of such artificial structures, fine patterning in submicron size can be made using various lithography techniques. In the field of magnetism, microscopic arrays of ferromagnetic particles are prepared to study the basic problems, such as demagnetization process and interparticle interaction.[5,6]

In the present study, periodic arrays of ferromagnetic wires and boxes are fabricated as the first step toward two- or three-dimensional modification. The magnetic properties are discussed on the basis of results obtained from hysteresis loops, Bitter patterns, and ferromagnetic resonance (FMR) measurement. As one of the applications of the artificial structure, magnetoresistive characteristics of multilayered wire arrays are also studied.

II. EXPERIMENT

The wire and box arrays were fabricated utilizing high-resolution electron-beam lithography and lift-off techniques. 1-μm-thick poly(methyl methacrylate) resist films coated on Si (100) wafers were directly exposed by an electron beam with acceleration voltages between 25 and 50 kV. The typical exposure area (equivalent to sample size) was 10×10 mm^2. After baking at 473 K under N_2 atmosphere for 20 min, they were developed using methyl isobutyl ketone. Next, $Ni_{80}Fe_{20}$ alloys (wt %) which form simple wire or box arrays were deposited at the room temperature on to a lithographic resist mask. Ion beam sputtering was used for the preparation of $Ni_{80}Fe_{20}$/Co/Cu/Co multilayered wire arrays. The resist portions were finally removed with acetone. In order to study the effect of the interwire or interbox interactions, arrays with various widths (w) and spacings (s) between 0.6 and 2 μm were prepared. The artificial periodic structures formed were observed by scanning electron microscopy (SEM). Other structural characterization was done by x-ray diffraction (XRD) with CuKα radiation. Magnetic hysteresis loops were measured at room temperature using a vibrating sample magnetometer. Bitter patterns were observed under magnetic fields less than 55 G. The FMR measurements were made with an electron spin resonance spectrometer operated on the X band at 300 K. Magnetoresistance (MR) was measured at room temperature in a four-terminal geometry with a direct current (J).

III. RESULTS AND DISCUSSION

A. Structural characteristics of $Ni_{80}Fe_{20}$ arrays

All $Ni_{80}Fe_{20}$ wires and boxes prepared in this study have a thickness of 50 nm. Figure 1(a) shows the SEM images of the wire arrays with various widths and spacings. It is found that the widths are equal to the spacings as designed. The linearity and edge structure of each wire are good enough to discuss the physical properties. In the present study, we confirmed that the specimen with a width and a spacing of 0.6 μm possesses a sharp artificial structure. Though the box arrays also showed a clear periodic structure, the shape of each box rounded with increasing the exposure resolution, as shown in Fig. 1(b). The XRD patterns of the $Ni_{80}Fe_{20}$ arrays showed no peaks in the middle-angle region. The measurement system used possesses sufficient sensitivity to detect the diffraction from the arrays. Therefore, the crystallinity of the $Ni_{80}Fe_{20}$ wires and boxes is concluded to be low.

B. Magnetic characteristics of $Ni_{80}Fe_{20}$ arrays

The hysteresis loops obtained for the $Ni_{80}Fe_{20}$ box array with a width and a spacing of 1 μm are shown in Fig. 2. When the magnetic field (H) was applied parallel to a side of

the square (see Fig. 3). The magnetization (M) increased and/or decreased in two steps. The same behavior was also observed in the M-H curves measured under the condition where the magnetic field was applied at an angle of 45° to a side of the square. These observations suggest the presence of two kinds of magnetization switching mode in the box arrays. Figure 3 shows the Bitter patterns of the box array with a width and a spacing of 2 μm. Under 55 G, only a dim pattern was observed in each box, indicating the incomplete saturation. In contrast, under the same field, some patterns were linearly present between the boxes which are in a row. This indicates that magnetic coherency was induced in the box arrays. As shown in Figs. 3(a) and 3(b), the coherence direction was in accordance with that of the applied field. Here, no coherent patterns were observed in the box arrays with large spacings. Consequently, the interbox distance is expected to be responsible for the appearance of the magnetic coherency. Whether the boxes interact with each other or whether they are isolated from each other is a most interesting problem in the magnetism of the arrays. From this point of view, the above results are important. With decreasing field, the patterns between the boxes disappeared and the domain structure in each box became clear [see Fig. 3(c)]. Therefore, the demagnetization process observed in the box arrays can be understood as follows. As the first step, the magnetic coherency between the boxes disappears with decreasing magnetic field. The linear change of the magnetization, which is in the second step, reflects the wall motion in each box.

Figure 4 shows the M-H curves obtained at room tem-

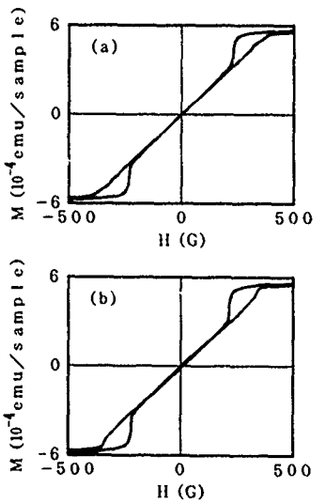

FIG. 2. M-H curves of $Ni_{80}Fe_{20}$ box arrays with a width and a spacing of 1 μm. (a) and (b) were measured under the condition where the H was applied parallel and at an angle of 45°, respectively, to a side of the square.

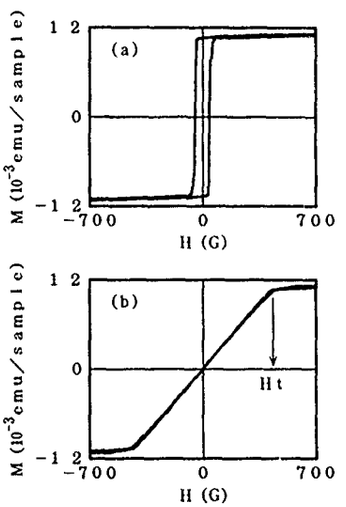

FIG. 4. M-H curves of $Ni_{80}Fe_{20}$ wire arrays with a width and a spacing of 1 μm. (a) and (b) were measured under the condition where the H was applied parallel and perpendicular, respectively, to the stripes.

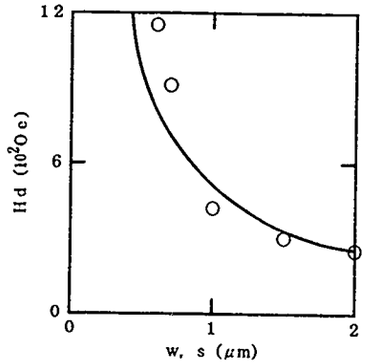

FIG. 5. Experimental (O) and calculated (–) H_d values of $Ni_{80}Fe_{20}$ wire arrays with various widths (w) and spacings (s).

perature for the $Ni_{80}Fe_{20}$ wire arrays with a width and a spacing of 1 μm. Rectangular loops were observed when the magnetic field was applied parallel to the stripes. The hysteresis feature indicates that the magnetization switching is attributable to only domain wall motion. The coercive field increased with decreasing wire width. Under the condition where the magnetic field was applied normal to the stripes, the magnetization linearly changed with increase and/or decrease in the magnetic field. The feature shows that only magnetization rotation is responsible for the switching process. Based on the magnetic data described above, the shape anisotropy is found to be induced in each wire, resulting in a magnetic easy-axis along the stripes. Here, no MR change was observed when the magnetic field was applied parallel to the stripes. Consequently, the induced anisotropy is concluded to be extremely strong. This prompted us to prepare multilayered wire arrays as described in Sec. III C. The demagnetizing fields (H_d) in the wire arrays were studied as the function of the width and spacing. Since the total field (H_t) for hard-axis saturation as noted in Fig. 4(b) is the algebraic sum of the anisotropy field (H_k) and the H_d,[7] the H_d value was experimentally determined by using Eq. (1)

$$H_d = H_t - H_k. \tag{1}$$

In the present study, 5 Oe, which has been obtained for a $Ni_{80}Fe_{20}$ thin film with no patterns, was used as the H_k value. In contrast, the H_d of the wire arrays, in which the wires are isolated from each other, can be calculated from the geometry and the saturation magnetization[8]

$$H_d = tM_s/w, \tag{2}$$

where t is the thickness (50 nm), M_s the saturation magnetization of the $Ni_{80}Fe_{20}$ (10 000 G), w the wire width. As shown in Fig. 5, H_d exponentially increased as the w and s values decreased. Here, it is worth noting that the difference between the experimental and calculated data increases with decreasing width and spacing. This suggests that the wires interact with each other. However, the observation does not prove it because both of the w and s values are parametrized. Therefore, a FMR measurement was carried out on the wire arrays. The samples were in a uniform rf field at 9.224 GHz in a TE_{011} cavity. A static magnetic field was applied perpendicular to the rf field. As shown in Fig. 6(a), when the static field was applied parallel to the stripes, uniform precessional mode was observed. On the other hand, under the condition where the magnetic field was applied normal to the stripes and parallel to the array plane, multiple resonances were observed at higher field than the main resonance. Such multiple resonances are similar to that corresponding to spin wave excitation.[9] However, the thickness of each wire is smaller than the wavelength of the spin wave. In addition, the multiple resonances observed in the present study were strongly dependent on the width and spacing in the wire arrays, as shown in Fig. 7. Therefore, some other mechanism must be proposed for the wire arrays. In this context, we note the role

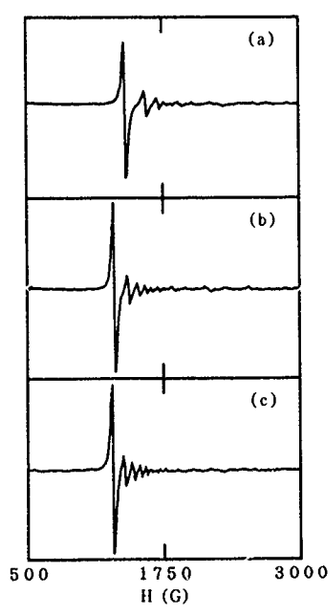

FIG. 7. FMR spectra of $Ni_{80}Fe_{20}$ wire arrays measured under the condition where the static field was applied perpendicular to the stripes. The width and spacing were (a) 1.0, (b) 1.5, and (c) 2.0 μm.

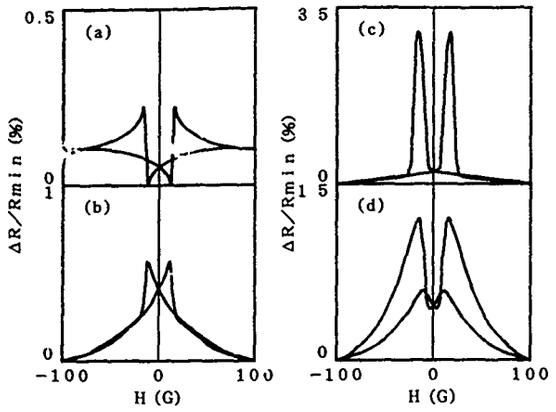

FIG. 8. MR curves of $Ni_{80}Fe_{20}$ (6.0 nm)/Co (0.6 nm)/Cu (2.3 nm)/Co (4.0 nm) multilayered wire array (a), (b) and film (c), (d). (a), (c) and (b). (d) were measured under the condition where the magnetic field was applied parallel and perpendicular, respectively, to the easy axis.

of dipole-dipole interactions in the stripes. This is because the dipolar coupling is effective over a long range. In the pioneering work by Nakatani, it has been suggested that magnetic dipolar standing waves are excited in the wire arrays.[10]

C. Magnetoresistive characteristics of $Ni_{80}Fe_{20}$/Co/Cu/Co multilayered arrays

Various multilayered materials containing "spin valves" display a large negative MR change when the moments of adjacent ferromagnetic layers are turned from antiparallel to parallel.[11–13] However, the magnetic moment is expected to form an angle of several degrees with another one in the plane. Therefore, we note the strong anisotropy induced in the wire structure as shown in Fig. 4. The shape anisotropy makes the magnetic antiparallel and parallel alignments in the multilayers complete. Figures 8(a)–8(d) show the MR curves of the $Ni_{80}Fe_{20}$ (6.0 nm)/Co(0.6 nm)/Cu(2.3 nm)/Co(4.0 nm) multilayered wire array and film. Here, the multilayered film sample was coprepared with the wire array. When the magnetic field was applied along the easy axis, the difference in the shape of the MR curves between the array and the film was distinct [see Figs. 8(a) and 8(c)]. Since the film sample possesses a normal MR change associated with the different coercive fields, the uniqueness is probably due to the wire structure. On the other hand, under the condition where the magnetic field was applied normal to the easy axis, the MR change in the wire array was likely steeper than that in the film, as shown in Figs. 8(b) and 8(d). The relation between the MR change and the demagnetization process of these samples is currently under investigation.

IV. SUMMARY

Wire and box arrays of $Ni_{80}Fe_{20}$ with widths and spacings in the range of 2–0.6 μm were successfully fabricated utilizing high-resolution electron-beam lithography and lift-off techniques. Bitter patterns of the box arrays indicated that magnetic coherency is induced between the boxes which are in a row under the magnetic field. Two kinds of magnetization switching modes were present in the box arrays. The demagnetizing fields of the wire arrays with short spacings were larger than those calculated by a model, in which the wires are isolated from each other. The multiple resonances observed in the wire arrays implied the appearance of inter-wire dipole-dipole interaction. The magnetoresistive characteristics of the $Ni_{80}Fe_{20}$/Co/Cu/Co multilayered wire array were preliminarily studied.

Ferromagnetic filaments fabrication in porous Si matrix (invited)

Sergey A. Gusev, Natalia A. Korotkova, Dmitry B. Rozenstein,[a] and Andrey A. Fraerman
Institute for Physics of Microstructures, Russian Academy of Sciences, 46 Ul'janova St., 603600 Nizhny Novgorod, Russia

We have fabricated Ni filaments by nickel precipitation into a porous silicon matrix, making Ni filaments of about 200 Å in diameter and 30 μm in length separated by ~500 Å silicon walls. This composite material demonstrates strong magnetic anisotropy perpendicular to the surface due to shape anisotropy of the Ni filaments.

I. INTRODUCTION

When a silicon wafer is electrochemically etched by anodization in hydrofluoric acid solutions a porous silicon (PS) layer is formed. Choosing appropriate etching conditions (electrolyte composition and current densities) which is specific for each silicon type, one can get a PS structure with cylindrical micropores oriented perpendicular to the surface. The remarkable properties of PS that are pertinent here are that its pores are very uniform in diameter and length, that the pores are parallel and the pore density, pore length and diameter can be controlled rather easily by varying electrochemical parameters and silicon doping.[1]. Typical pore diameters which could be obtained are in the range of 10–1000 Å and pore length is practically unlimited and controlled only by etching time. We used PS as a matrix to form ferromagnetic filaments by electrodepositing nickel into the pores. Starting the research we assumed this material to have a large perpendicular anisotropy due to shape anisotropy of ferromagnetic filaments. Some properties of small anisotropic magnetic particles in nonmagnetic matrix have been previously reported for Fe needles into Al_2O_3 matrix[2,3] and for Co rods in the same matrix.[4,5] In the present article we report on our experiments on the Ni filaments in porous Si matrix.

II. EXPERIMENT AND RESULTS

A. Anodization

We have anodized a *n*-type Sb-doped 0.01 Ω cm silicon substrate in the HF:ethanol (1:1) solution at 18–20° C with a dc current (100 mA/cm^2) for 5 min, getting the PS layer of 30 μm thickness. A JEM 2000 EXII electronic microscope was used to study PS structure. Scanning electron microscopy (SEM) observations of the sample split (Fig. 1) revealed that the pore diameter and the average separation between pores are ~200 and ~500 Å, respectively.

B. Nickel precipitation

After PS formation, nickel was electrodeposited into the pores using ac electrolysis in an electrolyte of the following composition: $NiCl_2 \cdot 6H_2O$ 185g/ℓ; boric acid 45 g/ℓ; *p*H ≃3.0. Nickel precipitation was carried out at 1-3 V, 50 Hz, and 18–20° C with nickel counterelectrode. The nickel concentration profile were studied by x-ray microanalysis with a LINK analyzer mounted on the electronic microscope, scanning along the sample split in the pore direction by the electronic spot. The Si $K\alpha$ and Ni $K\alpha$ lines intensity distribution (corresponding with the elements concentration profiles) along the sample depth are presented in Fig. 2.

C. Magnetic properties

To investigate magnetic properties of the obtained medium a ferromagnetic resonance (FMR) study of samples was carried out with electron paramagnetic resonance (EPR) spectrometer PS100X at rf 9.45 GHz in the magnetic fields up to 7 kOe. The angular anisotropy along the nickel filaments with the value in the range 300–2000 Oe depending on the sample structure. A representative angular dependence corresponding to 800 Oe uniaxial anisotropy is shown in Fig. 3.

The hysteresis curves for this sample were measured by vibrating sample magnetometer (VSM) and are presented in

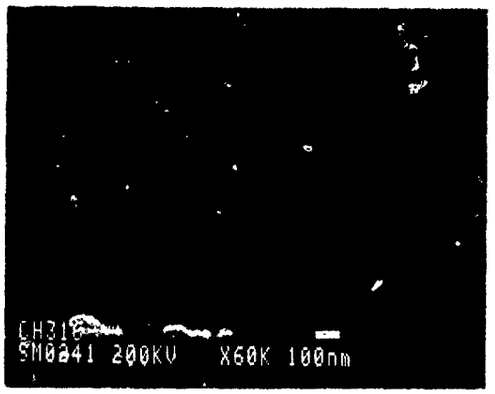

FIG. 1. SEM image of the porous silicon sample split along the pores. Substrate: *n*-type Si 0.01 Ω cm; electrolyte: HF:ethanol (1:1); etching current: 100 mA/cm^2. Average pore diameter, length 200 Å, 30 μm.

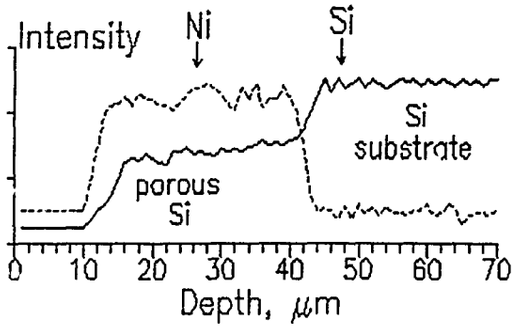

FIG. 2. The Si $K\alpha$ and Ni $K\alpha$ lines intensity distribution (corresponding with elements concentration profiles) of metallized porous layer determined by x-ray microanalysis.

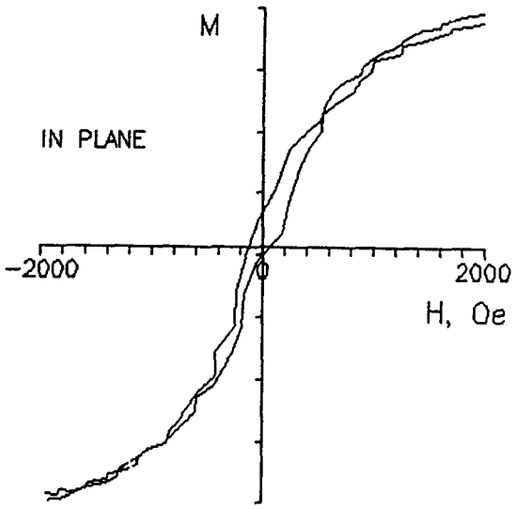

Fig. 4. The difference between the perpendicular and in-plane loops confirms the presence of perpendicular magnetic anisotropy.

III. CONCLUSION

The carried out magnetic measurements shows the perpendicular anisotropy material fabrication. Our investigation of this medium structure revealed that this material represents a set of nickel filaments with diameters $\leqslant 200$ Å and length ~ 30 μm separated by 500 Å silicon walls. It is known, that in a ferromagnetic cylinder with radius less than the exchange length magnetization is uniform along the radius.[5] The calculated exchange length for nickel is about 300 Å. So one can expect quasi-one-dimensional magnetic properties for the obtained Ni filaments with smaller diameters ~ 200 Å).

Single-domain magnetic pillar array of 35 nm diameter and 65 Gbits/in.^{2} density for ultrahigh density quantum magnetic storage

Stephen Y. Chou, Mark S. Wei, Peter R. Krauss, and Paul B. Fischer
Department of Electrical Engineering, University of Minnesota, Minneapolis, Minnesota 55455

Using electron beam nanolithography and electroplating, arrays of Ni pillars on silicon that have a uniform diameter of 35 nm, a height of 120 nm, and a period of 100 nm were fabricated. The density of the pillar arrays is 65 Gbits/in.^{2}—over two orders of magnitude greater than the state-of-the-art magnetic storage density. Because of their nanoscale size, shape anisotropy, and separation from each other, each Ni pillar is single domain with only two quantized perpendicular magnetization states: up and down. Each pillar can be used to store one bit of information, therefore such nanomagnetic pillar array storage offers a rather different paradigm than the conventional storage method. A quantum magnetic disk scheme that is based on uniformly embedding single-domain magnetic structures in a nonmagnetic disk is proposed.

I. INTRODUCTION

Perpendicular magnetic recording media have been considered by many as the media that will offer the largest storage density. Previously, several perpendicular recording media were developed and investigated. These include Co-Cr thin films with vertical grains,[1,2] barium ferrite powder with a perpendicular c axis,[3] and vertical ferromagnetic pillars plated through porous Al films[4] or plastics films with nuclear radiated tracks.[5] In all these media, the diameter of magnetic grains and the magnetization direction have a broad continuous distribution; the spacing between the grains varies and is uncontrollable; and each bit of information is stored over at least several magnetic grains.

In order to explore the ultimate size of a magnetic bit and the ultimate spacing between neighboring magnetic bits (therefore storage density), to improve understanding of the fundamental magnetics, and to develop new magnetic devices of high speed and high density, we have fabricated ultrahigh density arrays of single-domain nickel pillars using electron beam nanolithography and electroplating. The unique advantage of nanolithography is that the dimension of each pillar as well as the spacing between the pillars can be well controlled and uniform. Due to small size and shape anisotropy, each pillar is a single domain with magnetization perpendicular to the substrate. Moreover, each magnetic pillar can be used to store one bit of information. In this article we will discuss the fabrication process, magnetic force microscope (MFM) measurements, and the possibilities of a novel new recording paradigm offered by these pillars.

II. FABRICATION OF MAGNETIC PILLAR ARRAYS

A schematic of our fabrication process is shown in Fig. 1. A thin gold plating base was deposited or a silicon substrate. A high resolution electron beam resist, polymethyl methacrylate (PMMA), was then spun onto the substrate. Depending upon the desired pillar height, the thickness of the PMMA is typically 130 nm; however, 720 nm thick PMMA was also used in some cases. Dot arrays with diameters from 35 to 40 nm and spacings from 50 to 1000 nm were exposed in the PMMA using a high resolution electron beam lithography system with a beam diameter of 4 nm. The exposed PMMA was then developed in a cellosolve and methanol solution creating a template for the electroplating process. The sample was immersed in a nickel sulfamate type plating bath and nickel was electroplated into the template openings until the nickel thickness was near the template thickness. The plating rate, which is a function of plating current, template diameter, and template thickness, was well calibrated and was fixed at 45 nm/min for our work. After electroplating, the PMMA template was removed.

After fabrication, the pillars were examined using a scanning electron microscope (SEM) to verify the pillar dimensions. The resulting nickel pillars are uniform and have desired shape anisotropy. Figure 2 shows a SEM micrograph of a pillar array having a diameter of 35 nm, a height of 120 nm, and therefore an aspect ratio of 3.4. The pillar array has a period of 100 nm, and thus has a magnetic storage density of 65 Gbits/in.^{2} which is two orders of magnitude higher than the state-of-the-art storage. The pillars have a cylindrical shape with very smooth sidewalls.

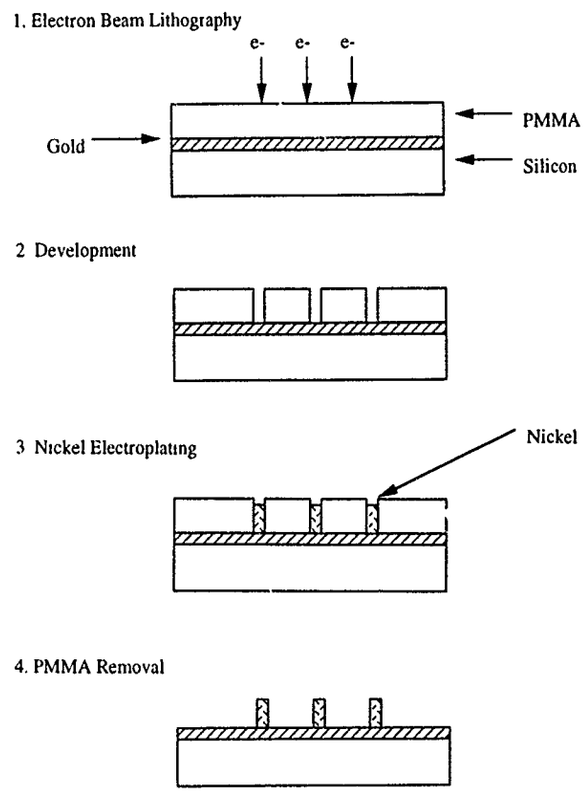

FIG. 1. Schematic of nanomagnetic pillar array fabrication process.

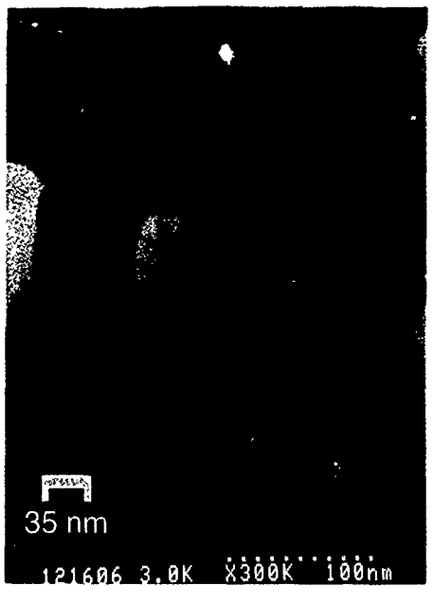

FIG. 2. SEM image of Ni pillar array of 35 nm diameter, 120 nm height, and a 100 nm spacing. The density is 65 Gbits/in.^{2} and the aspect ratio is 3.4.

Figure 3 shows a SEM micrograph of a second sample that was fabricated using 720 nm thick PMMA to obtain taller nickel pillars. These pillars have an average diameter of 75 nm, a height of 700 nm (therefore an aspect ratio of 9.3), and a period of 100 nm. Compared with the pillars in Fig. 2, these tall pillars have a cone shaped sidewall with an angle of 1.6° from vertical. Such cone shape results from the fact that during the plating, the Ni pillars conformed with the PMMA template that has a cone shape due to significant electron scattering in the thicker PMMA during the lithography.

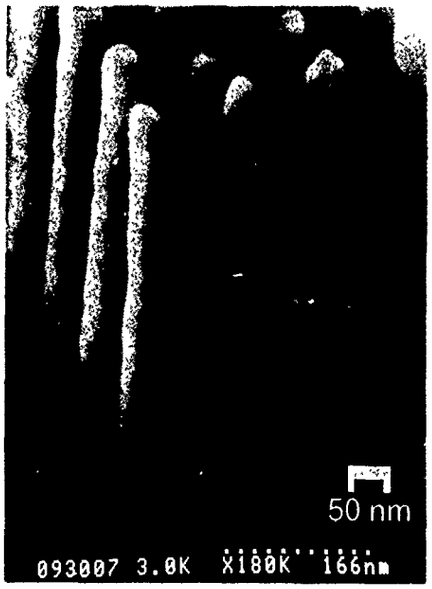

FIG. 3 SEM image of Ni pillar array of average 75 nm diameter, 700 nm height, and a 100 nm spacing. The density is 65 Gbits/in.^{2} and the aspect ratio is 9.3.

III. THEORETICAL ANALYSIS

We discuss the theoretical analysis of the nickel pillar arrays here and the characterization in the next section. First, theoretical calculation indicates that each nickel pillar should be single domain. Using Aharoni's formulas, the diameter for a prolate nickel spheroid with an aspect ratio of 3.4 to be single domain should be 52 nm or smaller.[6] In our case, the pillar diameter is 35 nm and therefore should be single domain.

Second, if each pillar is used to store one bit of information, such nanoscale pillar array storage has a rather different paradigm than the conventional storage. In conventional storage, each bit of information is stored over a number of magnetic grains which have a broad distribution in grain size, spacing, and magnetization direction. These distributions will result in the variation of the total magnetization of each bit stored and give rise to noise in reading. In the single-domain pillar array on the other hand, each bit is stored in a pillar which has only two quantized magnetization values: up or down in direction but equal in magnitude. Therefore, noise for each bit should be small. Certainly development of fabrication processes for these nanomagnetic pillar arrays is just the first step towards realization of this paradigm; methods for writing and reading information in such a media still need to be developed.

IV. CHARACTERIZATION

We have attempted to use a high resolution magnetic force microscope (MFM) operating at 300 mTorr to examine these ultra-high density pillar arrays, but were unsuccessful. The primary reason is that since the topology image and magnetic image are intertwined in MFM, the aspect ratio of our nanomagnetic pillars is so large that the topology image completely masks the magnetic image. Despite the difficulty in characterizing these nanomagnetic pillars, MFM measurements showed that horizontal nanomagnetic bars of 35 nm thickness and nanoscale widths are single domain, supporting our theoretical estimation that the nanomagnetic pillars should be single domain as well.[7]

Two other possible methods may be able to characterize the nanoscale magnetic pillars: scanning electron microscopy with polarization analysis (SEMPA) and magnetooptical Kerr effect microscopy (MOKE). Currently, we are pursuing these two studies. SEMPA analysis forms images by scanning a focused electron beam across a sample and detecting the spin polarization of secondary electrons. The magnitude and direction of the secondary electron's spin polarization is directly proportional to the magnitude and direction of the magnetization of the sample being scanned. MOKE analysis measures the magnetization of the pillars versus the magnetic field by detecting the rotation of polarization state of light reflected from a ferromagnetic sample. We have built a detection system that can detect a signal-to-noise ratio near 10^{-8} and are building a special probe station that will enable us to focus the laser beam to a diameter of 3–4 μm and position the beam to a specific location of the sample within 2 μm accuracy.

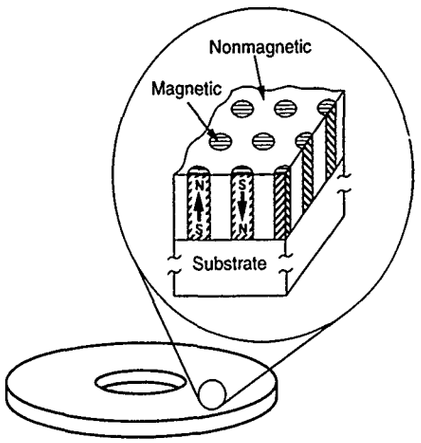

FIG. 4. Schematic of a quantum magnetic disk which consists of prepatterned single-domain magnetic structures embedded in a nonmagnetic disk.

V. QUANTUM MAGNETIC DISK

Based on these artificially patterned single-domain magnetic structures, we propose a new paradigm for ultra-high density magnetic disk: Quantum Magnetic Disk.[8] As shown in Fig. 4, a quantum magnetic disk consists of prepatterned single-domain magnetic structures embedded in a nonmagnetic disk. Each bit in the quantum magnetic disk is represented by a prefabricated single domain magnetic structure that has a uniform and well-defined shape, a prespecified location, and most importantly, a quantified magnetization that has only two states: the same in value and opposite in direction. In other words, the shape, magnetization, and location for each bit in a quantum magnetic disk are all quantized and predefined during the disk manufacturing. On the contrary, in a conventional magnetic disk where a bit is not defined at disk fabrication, the shape and magnetization of each bit have a broad distribution and the location of a bit can be anywhere on the disk. The quantum magnetic disk also differs from discrete track disk[9,10] and discrete segment disk[11,12] where the magnetization (both value and direction) of each bit can have a continuous and broad distribution.

The advantages of quantum magnetic disks over the conventional disks are apparent. First, the writing process in the quantum disk is greatly simplified, resulting in much lower noise and lower error rate and allowing much higher density. In the quantum disk, the writing process does not define the location, shape, and magnetization value of a bit, but just simply flips the quantized magnetization orientation of a prepatterned single-domain magnetic structure. The writing can be perfect, even though the head slightly deviates from the intended bit location and partially overlaps with other bits, as long as the head flips only the magnetization of the intended bit. But in the conventional magnetic disk, the writing process must define the location, shape, and magnetization of a bit. If the head deviates from the intended location, the head will write part of the intend bit and part of the neighboring bits.

Second, the quantum disk can track every bit individually, but the conventional disk cannot track all of its bits. This is because that in quantum disk each bit is separated from others by nonmagnetic material, but in the conventional disk many bits are connected. The individual-bit-tracking ability allows precise positioning, lower error rate, and therefore ultrahigh density storage.

Finally, reading in the quantum disk is much less jitter than that in the conventional disk. The reason is that in the conventional disk the boundary between bits is ragged and not well defined, but in the quantum disk each bit is defined with nanometer precision (can be less than the grain size) and is well separated from each other.

VI. SUMMARY

Using electron beam nanolithography and electroplating, arrays of Ni pillars on silicon that have a uniform diameter of 35 nm, a height of 120 nm, and a period of 100 nm were fabricated. The density of the pillar arrays is 65 Gbits/in.^{2}—over two orders of magnitude greater than the state-of-the-art magnetic storage density. Because of their nanoscale size, shape anisotropy, and separation from each other, each Ni pillar is single domain with only two quantized perpendicular magnetization states: up and down. Each pillar can be used to store one bit; such nanoscale pillar array storage offers a rather different paradigm than the conventional storage method. Certainly development of fabrication processes for such magnetic recording media is just the first step towards realization of this paradigm; methods for writing and reading information with such a media still need to be developed. MFM characterization of these pillars is unsuccessful at the moment due to large aspect ratio. Characterization using SEMPA and MOKE is in progress. Finally, based on the artificially patterned single-domain magnetic structures, a new paradigm for ultrahigh density magnetic recording media—the quantum magnetic disk is proposed.

Clusters of iron, cobalt, and nickel are produced in a laser vaporization source. The size distributions of the incident clusters are checked by time-of-flight mass spectrometry before deposition at low energy. Studying the near threshold photoionization, Co_n and Ni_n clusters exhibit an icosahedral structure while for iron, no clear structure emerges. Neutral clusters were deposited on different substrates at room temperature with thicknesses up to 100 nm in view to determine their structure and magnetic properties. A limited coalescence of the clusters is observed from high-resolution transmission electron microscopy. No icosahedron has been observed but cuboctahedron and interface twins between adjacent particles have been clearly identified in Ni films. Grazing incidence x-ray diffraction experiments reveal a classical phase with grain size around 6 and 4 nm for Fe and Ni films, respectively but an anomalous fcc phase for Co films and a very low grain size of 2 nm. The density of films determined by x-ray reflectivity was estimated to represent only 60%–65% of the bulk density. Magnetic behaviors studied by ferromagnetic resonance and SQUID magnetization measurements have been interpreted using the correlated spin glass model. Mössbauer spectra performed on Fe films at zero field revealed the presence of 20% of iron in the form of thin nonmagnetic oxide skin surrounding Fe grains which allow to find 2.2 μB per magnetic iron atom in agreement with macroscopic magnetic measurements. Nevertheless we found an anomalous reduced atomic moment for Ni film.

INTRODUCTION

Recently, magnetic properties such as exchange coupling or giant magnetoresistance mainly observed in metallic multilayers have been detected in other nanostructured systems. For example, Berkowitz *et al.*[1] and Xiao *et al.*[2] observed giant magnetoresistances in ultrafine Co-rich precipitate particles in a Cu-rich matrix. These samples were prepared by coevaporation taking advantage of the low solubility of Cu in Co. However, though this technique is limited to nonmiscible components, the adjustable cluster diameter is a new parameter in addition to the distance between particles as in thin film layers. Thus, studies on clusters and cluster assembled materials are of increasing interest.

The laser vaporization source of the laboratory[3] allows the obtention of an intense cluster beam of any size distribution (from few to a thousand atoms per cluster) and the synthesis of cluster assembled materials, even of the most refractory and of the most complex ones. The cluster size distribution is checked by time-of-flight mass spectrometry before deposition. Our source producing cold clusters with low kinetic energy, incident clusters do not fragment on the substrate and may conserve their intrinsic structures. Thus we succeeded in the stabilization of very small size fullerenes (C_{20}-C_{32}), never previously observed experimentally. We clearly evidenced that deposited carbon clusters presented the in flight-clusters fingerprint.[3]

Our challenge in depositing transition metal clusters is to synthesize new phases where the anomalous crystallographic structures of free clusters would be kept and to study the specific magnetic behavior of these weakly correlated entities on a substrate. Once more, we show that our technique leads to a random compact cluster stacking (RCCS).[3] Thus magnetic results could be interpreted by random anisotropy model with a scale law and in terms of localization of spin waves.

EXPERIMENT

Our cluster source is based on the technique of laser vaporization.[3–5] Roughly, a plasma is created in a vacuum cavity by Nd-YAG laser light. Synchronized with the laser, a high pressure (5 bars) helium pulse, injected in the cavity by a nozzle, thermalizes the plasma and cluster growth occurs. The nascent clusters are then rapidly quenched during the following isentropic expansion into vacuum (10^{-7} Torr).

Cluster size distributions are analyzed in a time-of-flight mass spectrometer. Studying the near threshold photoionization (performed with a frequency-doubled tunable dye laser pumped by a XeCl excimer laser), mass spectra of Co_n and Ni_n clusters exhibit oscillations and a series of magic numbers ($n=13,55,147,309,561,\ldots$) corresponding to an icosahedral or cuboctahedral atomic shell structure in the obtained mass range (50–800 atoms per cluster). A finer analy-

 0021-8979/94/76(10)/6676/3/$6.00 © 1994 American Institute of Physics

sis allows us to conclude for the icosahedral structure.[6] For iron clusters, the results are not so simple, indicating a competition between different regimes.[6]

Then, free neutral clusters are deposited with a kinetic energy in the 10–20 eV range on different substrates at room temperature with thicknesses up to 100 nm in view to determine their structure and magnetic properties.

SAMPLE CHARACTERIZATION

The typical size of supported clusters obtained from high-resolution transmission electron microscopy (HRTEM) was about 2–6 nm for an initial size distribution centered around 150 atoms for Fe and 300 atoms for Co and Ni clusters, respectively. No icosahedron was observed but cuboctahedra and interface twins between adjacent particles was clearly identified in Ni films. Quasispherical grain morphology existed in Fe film which could correspond to a bcc rhombic dodecahedron [110] according to the Wulff's theorem.[7] Grazing incidence x-ray diffraction (GIXD) experiments exhibit a classical bcc phase for Fe films but a fcc phase for both Co and Ni with a grain size extracted from the peak width of about 6, 4, and 1.5 nm, respectively, in agreement with electronic diffractions and TEM observations. The classical structure of cobalt being hcp, the fcc phase observed in Co films might be related to the icosahedral structure of the incident cluster beam. In fact, the icosahedron is expected to be the precursor of the fcc crystal. The small grain size and the reminiscence of a free cluster structure confirm the limited coalescence process due to a weak diffusion of metallic clusters on the substrate even at room temperature.

Rutherford backscattering spectroscopy showed that these porous films are composed of 20%–30% of oxygen for 70%–80% of metals. The density of the films, determined by x-ray scattering at very low angle in $\theta/2\theta$ mode and from rocking curve around the critical angle of the total reflectivity, was estimated to represent only 60%–65% of the bulk density.[8]

MAGNETIC PROPERTIES

Mössbauer spectra performed at room temperature on Fe films without magnetic field revealed the presence of the sextet of the metallic iron (with hyperfine field around 332 KOe and representing 80% of the signal) and of two doublets corresponding to 20% of ferric oxide (Fig. 1). Whereas the common isomer shift of both nonmagnetic signals is equal to 0.4 mm/s compared to the metallic iron, the quadrupolar splittings respectively equal to 0.9 and 2.4 mm/s allow us to differ two types of oxide. The first one is identified as a thin layer of nonstoechiometric Fe_3O_4 or/and a mixture of stoechiometric Fe_3O_4 and γ-Fe_2O_3 phases[9] (in agreement with the GIXD experiments on the most oxidized films[10]). The second one, not identified so far could be related to a free-cluster oxidation. These results allow to describe the supported clusters as pure iron core surrounded by a thin skin (2 or 3 monolayers[7]) of non-magnetic oxide. On the other hand, the intensity ratio of the sextuplet (321123) evidences a random spatial distribution of the magnetization at zero field.

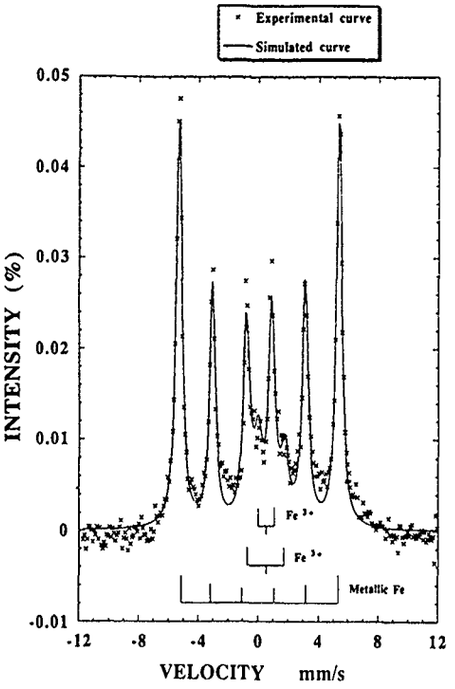

FIG. 1. Mössbauer spectra obtained on a Fe_{150} film at 300 K.

The macroscopic magnetic behavior of our films has been studied using ferromagnetic resonance (FMR) and magnetization measurements (SQUID). FMR curves roughly traduced a thin film behavior[11] but revealed several resonance magnetic fields due to anchorage of spin waves at the surface (when the applied field is perpendicular to the surface of the film). The coercive field at 300 K is about 100 Oe for cobalt, 50 Oe for iron, and lower than 10 Oe for nickel and increases at 10 K up to 1000 and 500 Oe for Co and Fe films, respectively. The value of the saturation magnetization was related to the density value and to the quantities of oxides. For iron in agreement with Mössbauer results, the classical atomic moment of 2.2 μB per magnetic iron atom is retrieved. On the contrary we found a strongly reduced value in Ni film. The atomic moment per Ni atom has been estimated to be equal to 1/4 of the bulk value (taking into account the film density). By extrapolating the magnetization curve versus temperature, the Curie temperature T_c has been found to be around 350–400 K. Thus the magnetization reduction can not be uniform, otherwise T_c would be much more reduced. This could be due to the presence of dead magnetic layers similar to that observed in Fe films and/or to antiferromagnetic coupling between Ni particles via Ni shell. Magnetoresistance measurements and magnetization under high magnetic field are in progress in view to see respectively an important negative magnetoresistance and a second transition of the saturation magnetization.

We fitted the approach to saturation of the magnetization using the Chudnovsky model.[12,13] The experimental law of approach to saturation in magnetic systems is perfectly fitted by the formalism of the random-anisotropy amorphous magnets. In the Chudnovsky's model,[12] a physical parameter is defined

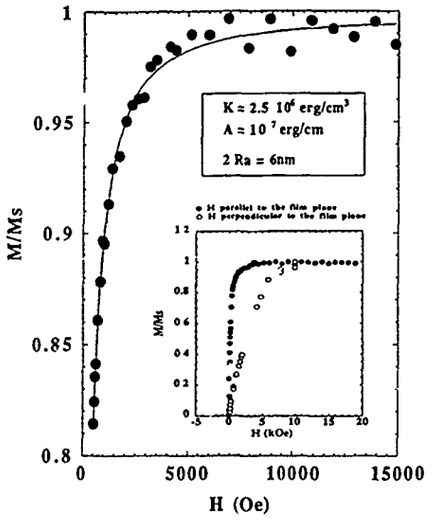

FIG. 2. Magnetization law in approaching saturation obtained on a Fe_{150} film at 300 K.

$$\lambda = \left(\frac{2}{15}\right)^{1/2} \frac{K R_a^2}{A},$$

where R_a is the distance over which the local anisotropy axes are correlated and A is the exchange constant. The parameter λ is the critical boundary between the correlated spin glass (CSG) regime ($\lambda<1$) and the speromagnetic state ($\lambda>1$). One can define the ferromagnetic correlation length $R_f=R_a/\lambda^2$. The best fit[10,13] of the curve on Fe films (Fig. 2) gives respectively, $2R_a=6$ nm, $K\sim 2.5 10^6$ erg/cm^3 (in agreement with FMR fits, to compare to 5×10^5 erg/cm^3 in the bulk), $A\sim 10^{-7}$ erg/cm, therefore $\lambda=0.66$ and $R_f=8$ nm. Let us underline that in amorphous alloys, R_a is always of the order of the inter-reticular distance (e.g., in rare earth-Fe compounds $R_a=0.5$ nm[14].) In our case we note that R_a exactly corresponds to the supported particles size and that the R_f value shows the ferromagnetic correlation limited to the first neighbors. However, if the ferromagnetic domain was strictly limited to the R_f value, the film should be superparamagnetic. That confirms the definition of R_f in the CSG model where it represents an exponential decay coupling. We thus showed that RCCS films can be described as an amorphous with an adjustable parameter R_a. In our case, R_a is great enough to reach experimental fields larger than the crossover field[11] $H_{co}=2A/M_sR_a^2$ which separates the region with and without random anisotropy fluctuations (determined around 3 kOe in Fe films). In Ni films (Fig. 3) we clearly see two regimes for the low field ($\Delta M/M_s$) variation versus temperature (maybe correlated to a $T_{Néel}$ of Ni oxide). At low temperature the random anisotropy fluctuations dominate (with a H^{-2} law) whereas at high temperature the exchanges dominate (with a $H^{-1/2}$ law), the transition occurring around 200 K.

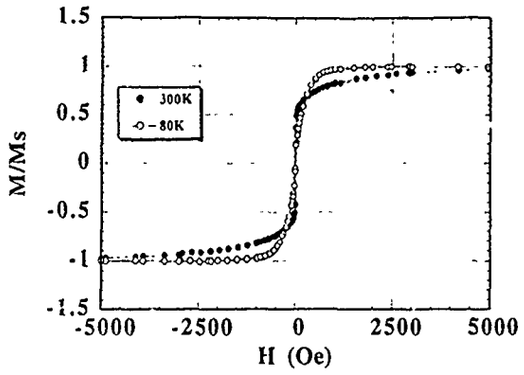

FIG. 3. Magnetization vs temperature obtained on a Ni_{300} film.

In conclusion, these first results lead us to pursue this study to elucidate some other characteristic magnetic parameters of the layers (T_c, e.g., antiferromagnetic coupling in Ni films, and complete magnetic study on promising Co films). In particular, x-ray absorption measurements will allow us to locally describe crystallographic and magnetic atomic environment in view to explain the anomalous atomic moment in Ni films. Experiments with cooled substrates are in progress to attempt to stabilize the icosahedral structure which is expected to lead to specific magnetic properties.

Size effects on switching field of isolated and interactive arrays of nanoscale single-domain Ni bars fabricated using electron-beam nanolithography

Mark S. Wei and Stephen Y. Chou
Department of Electrical Engineering, University of Minnesota, Minneapolis, Minnesota 55455

Isolated nanoscale Ni bars with a length of 1 μm, a width from 15 to 300 nm, and interactive bar arrays with a spacing from 200 to 600 nm were fabricated using electron-beam lithography and were studied using magnetic force microscopy. The study showed that the virgin magnetic state of bars with a width smaller than 150 nm was single domain and otherwise multidomain. It also showed that the switching field of isolated bars initially increases with decreasing bar width, then reaches a maximum switching field of 740 Oe at a width of 55 nm, and afterwards decreases with further bar width reduction. Furthermore, it was found that the switching field of the interactive bars decreases almost linearly with reduction of the spacing between the bars.

I. INTRODUCTION

Understanding the behavior of a single domain magnetic particle and the interaction between the particles is very important, because these particles are the basic constituents of many magnetic recording materials. However, previously most experimental studies of magnetic particles were made in an ensemble of such particles and the properties of a single particle were inferred only through extrapolation. Due to large variation in particle dimensions, randomness of magnetization and unavoidable interaction, detailed information about single particles and their interaction is smeared out.

Due to advance in nanofabrication technology, now it is possible to nanoscale magnetic particle arrays with precise sizes, shapes, and spacing. This opens up new opportunities to understand the fundamentals of micromagnetics and develop new magnetic materials. Recently, the first reported study of nanoscale permalloy bars fabricated using electron beam lithography was carried out by a joint team from the University of California at San Diego and IBM.[1,2] In that study, isolated bars had a fixed length of 1 μm and a fixed width of 133 nm and interactive bar arrays had a fixed spacing with the strongest coupling along the bars' long axis.

In this article, we present the fabrication and investigation of isolated Ni bars with a width varying from 15 to 300 nm and interactive Ni bar arrays with a spacing varying from 200 to 600 nm with the strongest coupling in the bars' short axis. Furthermore, we report and discuss the effects of bar width and spacing on the switching field of these isolated and interactive bars.

II. FABRICATION OF NANOMAGNETIC BAR ARRAYS

The isolated and interactive nanomagnetic nickel bars were fabricated using electron-beam nanolithography and a lift off process. In the fabrication, a resist, polymethyl methacralate (PMMA), was first spun onto a silicon substrate. A high resolution electron beam lithography system with a beam diameter of 4 nm was used to expose bar arrays in the PMMA. The exposed PMMA was developed in a cellosolve and methanol solution to form a resist template on the substrate. A nickel film, 35 nm thick, was evaporated onto the entire sample. In the lift off, the sample was submersed in acetone which dissolved the PMMA template and lifted off the nickel on its surface, but not the nickel on the substrate. After fabrication, bar widths were determined using a scanning electron microscope (SEM) and the bar width presented here is the measured bar width.

For isolated bars, the bar length was fixed at 1 μm, but the bar width varied from 15 to 300 nm. The spacing between isolated bars is 10 μm. Figure 1 shows a scanning electron micrograph of a Ni bar with a 15 nm width.

For interactive bar arrays, the bar width and length were fixed at 100 nm and 1 μm, respectively. The spacing between bars along the long axis is 2 μm, but the spacing between the bars along the short axis varies from 200 to 600 nm. Therefore the interaction between bars is primarily along the short axis, and the bar arrays can be regarded as isolated rows of one dimensional interactive arrays. This is very different from that in Ref. 1 where the bars were coupled primarily along the long axis. To illustrate the fabrication resolution

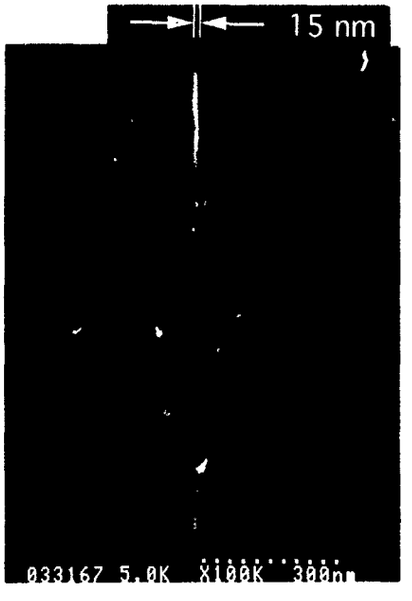

FIG. 1. SEM image of a high aspect ratio isolated Ni bar that is 1 μm long and 15 nm wide.

and uniformity, Fig. 2 shows a large array of Ni bars which are 200 nm long, 20 nm wide, and 150 nm apart along the short axis and 100 nm apart along the long axis, despite the fact that such dense bar arrays were not able to be resolved in our magnetic force microscopy (MFM) study.

III. MFM MEASUREMENTS

The nanomagnetic bars were studied using a custom built MFM that was modified from a commercial atomic force microscope (AFM). The MFM was operated in amplitude detection mode at ~200 mTorr vacuum for a high sensitivity. The MFM tips are the ordinary AFM cantilevers coated with 30 nm of cobalt and have a resonance frequency of 18 kHz. These soft tips give better sensitivity but poorer resolution than that of a harder tip.

In measuring the switching field of the isolated bars, the sample was first saturated in a fixed direction along its easy axis using a 2000 Oe magnetic field and a MFM image was taken to determine its magnetization. Then a test field was applied in the opposite direction and returned to zero. The sample was examined under MFM again to see if its magnetization flipped. If the bar flipped, a smaller test field was applied in next measuring cycle, otherwise a large field was applied. This process continued until the switching field of a nickel bar was located within 10 Oe.

IV. DATA AND ANALYSIS

A. Isolated bars

Before the isolated bars were put into any magnetic field, MFM images of the sample were taken. These images showed that for bars of a width smaller than 150 nm, the virgin magnetic state is single domain with magnetization along the direction of its easy (i.e., long) axis; and the bars of wider width are multidomain. A MFM image of a 100 nm wide isolated bar is shown in Fig. 3.

It was found that the magnetization switching field of an isolated bar is a strong function of width, as shown in Fig. 4. The switching field first increases with decreasing bar width, reaches a maximum switching field of 740 Oe at a bar width of 55 nm, then decreases with further reduction of the bar width. The initial increase in the switching field is because the bar is changing from multidomain to single domain. The later decrease is likely due to the fact that thermal energy becomes comparable to magnetization switching energy.[4]

Compared to the study in Ref. 2, where the permalloy bars of a width 133 nm had a switching field greater than 400 Oe, the Ni bar with the same width studied here has a switching field about 100 Oe less. This could be due to two reasons. First, nickel film on Si surface has significant stress, so there

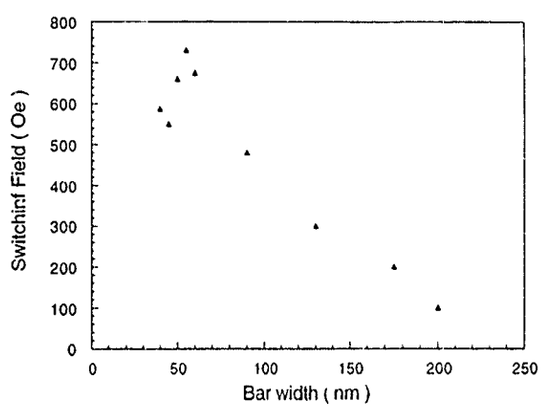

FIG. 4. Switching field of isolated bars vs bar width The maximum switching field is 740 Oe for 55 nm wide bars. The bars are 1 μm long and actual bar width was measured using SEM

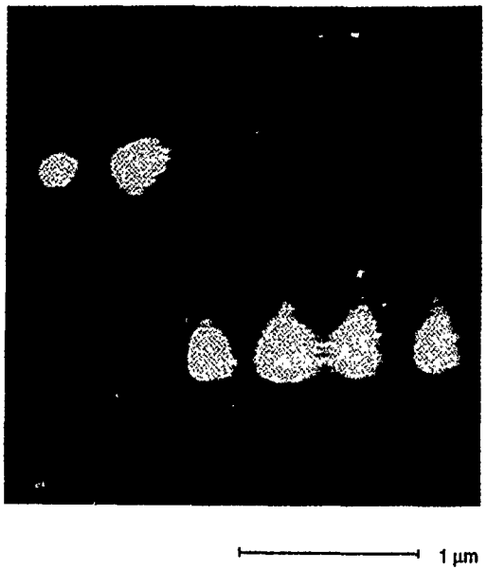

FIG. 5. MFM image of one-dimensional interactive bar arrays with 400 nm spacing.

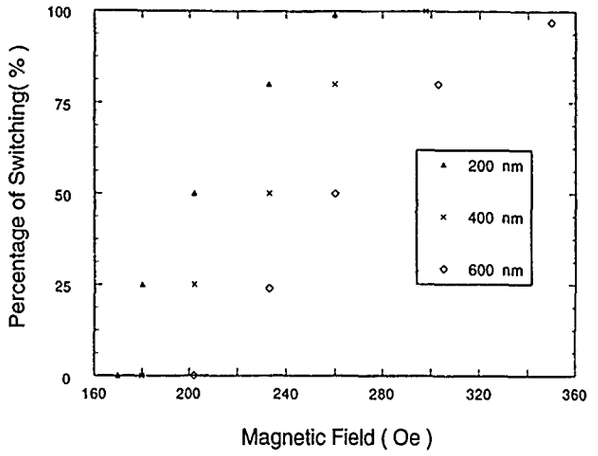

FIG. 6. Percentage of bars that switched vs the applied magnetic field for interactive bars with a spacing along the short axis of 200, 400, and 600 nm.

may be a magnetostriction effect which decreases the net anisotropy. Second, Ni has strong crystalline anisotropy but permalloy does not.

The critical width for superparamagnetism can be estimated from the switching field vs size curve. The switching field of a particle of volume V, can be described by the equation $h_{ci}=1-(V_p/V)^{0.5}$, where h_{ci} is reduced coercivity and V_p is the volume below which the particle is superparamagnetic. The equation can be rewritten in terms of the bar width W:$h_{ci}=1-(W_p/W)^{0.5}$. By fitting the switching field of the bars with a width smaller than 55 nm, W_p is found to be 18 nm.

B. Interactive nanomagnetic bars

The interactive bar arrays that were studied using MFM have a bar width of 100 nm and a spacing between bars of 0.2, 0.4, and 0.6 μm, respectively, along the short axis. Figure 5 shows a MFM image of these bar arrays. The switching field distribution was measured and is shown in Fig. 6. In this measurement, an average of about 30 bars were counted for each data point and the bars at the end of each row were not counted. Figure 6 shows three facts. First, the smaller the spacing, the smaller the switching field. The switching field for 100 nm wide isolated bar is 300 Oe. But due to interaction, the mean value of switching field (i.e., the field at which 50% of bars can flip) is 205, 232, and 260 Oe for a spacing of 0.2, 0.4, and 0.6 μm, respectively. Second, the switching field decreases with the reduction of spacing at a rate 15 Oe per 100 nm. This behavior is due to the fact that as the spacing decreases, the demagnetization field generated by neighbor bars increases and will help a bar to flip. Third, the broadness of the switching field distribution is about 100 Oe which is due to bar interaction as well as size variations.

V. CONCLUSION

We have fabricated nanoscale isolated magnetic bars with different bar widths as well as interactive bar arrays with different spacing.[5] The switching field was measured using MFM. The SEM micrographs show that these Ni bars have good uniformity and very high aspect ratio. The MFM studies show that bars with a width smaller than 150 nm were single domain and the switching field depends strongly on the width (therefore the aspect ratio) of the bar. The switching field of the isolated bars first increases with decreasing bar width, then reaches the maximum switching field of 740 Oe with 55 nm wide bars, and afterwards decreases with further reduction of bar width. The switching field of interactive bars decreases almost linearly with the reduction of spacing. The broadness of switching field distribution for interactive bar arrays is 100 Oe.

Susceptibility and high field magnetization have been measured for $Y(Co_{1-x}M_x)_2$ (M=Al, Fe, and Ni). YCo_2 exhibits a metamagnetic transition at 69 T. Ni doping in YCo_2 increases the critical field (B_c), while Fe doping decreases it. These changes can be elucidated with the band picture of metamagnetism. B_c of YCo_2 exhibits a positive shift proportional to the square of temperature. In the paramagnetic region of $Y(Co_{1-x}Al_x)_2$ with $x \leqslant 0.11$, the susceptibility is enhanced with Al and a sharp metamagnetic transition with lower B_c is observed. The susceptibility becomes maximum at a finite temperature T_{max}. B_c in the ground state is proportional to T_{max}. These experimental results are discussed with a new theory based on a spin fluctuation model. The susceptibility and the metamagnetic transition are found to be very sensitive to pressure.

I. INTRODUCTION

Ultrahigh magnetic fields over 100 T are now available for fundamental research on magnetism. One of the most interesting subjects in ultrahigh magnetic fields is itinerant electron metamagnetism, that is, a first-order field-induced transition from the paramagnetic to the ferromagnetic state in a d-electron system. Since this phenomenon was predicted to occur by Wohlfarth and Rhodes,[1] many theoretical and experimental studies have been made to elucidate it.

We have systematically studied the magnetization process of various Co-based Laves phase compounds in magnetic fields up to 120 T. We observed clear metamagnetic transitions in $Y(Co,Al)_2$ (Refs. 2 and 3), $Y(Co,Fe)_2$ (Ref. 4), $Sc(Co,Al)_2$ (Ref. 5), $Lu(Co,Al)_2$ (Refs. 6 and 7), $Lu(Co,Sn)_2$ (Ref. 8), $Lu(Co,Si)_2$ (Ref. 9), $Lu(Co,Ga)_2$ (Ref. 10), YCo_2 (Refs. 11 and 12), and $LuCo_2$.[12] Adachi *et al.* found a metamagnetic transition in the paramagnetic pyrite $Co(S,Se)_2$.[13]

All of the above compounds have characteristics of a strongly exchange-enhanced Pauli paramagnet: the electronic specific heat coefficient and the magnetic susceptibility are very large. Moreover, the temperature dependence of susceptibility $\chi(T)$ is anomalous: $\chi(T)$ increases with temperature and then decreases through a maximum at a finite temperature $T=T_{max}$. These facts suggest that the itinerant electron metamagnetism and the appearance of a maximum in $\chi(T)$ come from the same origin. Itinerant metamagnetism is considered to originate from a special shape of the density-of-states (DOS) curve for a d-electron system in the vicinity of the Fermi level.[1] On the other hand, the origin of the unusual behavior of $\chi(T)$ observed in a strongly exchange-enhanced paramagnet is not well understood. However, the above facts imply that the behavior of $\chi(T)$ also originates from the special shape of the DOS.

Thermodynamical properties of an itinerant electron magnet are dominated by the effect of spin fluctuations. In fact, magnetic properties of a weakly ferromagnetic metal at finite temperatures are successfully elucidated with the spin-fluctuation theory developed by Moriya.[14] However, the relation between the temperature dependence of susceptibility for an exchange-enhanced paramagnet with metamagnetism and its magnetization process remains unknown.

In the present study, we have studied the magnetization process and susceptibility for a typical metamagnetic compound YCo_2 and pseudobinary systems $Y(Co_{1-x}M_x)_2$ (M =Al, Fe, and Ni) to clarify the origin of the transition and the anomaly of $\chi(T)$. The metamagnetic transition is expected to be very sensitive to pressure.[15] We have also examined the effect of pressure on the magnetization process and the susceptibility of the $Lu(Co_{1-x}Ga_x)_2$ system.

II. EXPERIMENTAL PROCEDURE

The Laves phase compounds $Y(Co_{1-x}M_x)_2$ (M=Al, Fe, and Ni) and $Lu(Co_{1-x}Ga_x)_2$ were prepared by arc melting in an argon atmosphere, followed by annealing at 900–950 °C for a week. All the specimens are confined to be single phase with the cubic Laves phase structure by x-ray diffraction. The obtained ingots were powdered for magnetic measurements.

High magnetic fields up to 42 T were produced using a wire-wound pulse magnet with a duration time of about 10 ms. Ultrahigh magnetic fields up to 120 T were generated by means of a fast capacitor discharge into a single-turn coil

 0021-8979/94/76(10)/6682/6/$6.00 © 1994 American Institute of Physics

with a 100 kJ capacitor bank. Duration time of the pulse field is about 7 μs.

The magnetization in pulsed high and ultrahigh magnetic fields was measured using an induction method with a set of compensated pickup coils. For the magnetization measurement in ultrahigh magnetic fields, the powder sample was molded into a rod of 1.5 mm diameter and 5 mm length with epoxy resin (Stycast #1266) to avoid an eddy current effect. The magnetization under high pressure was measured using an extraction-type magnetometer, with a high pressure clamp cell made of Cu-Ti alloy, in steady magnetic fields up to 7 T. The specific heat was measured at low temperatures in magnetic fields of 0, 6, 10, and 14.6 T using a conventional heat pulse method with a mechanical heat switch. The temperature was measured with a carbon-glass resistor thermometer calibrated in magnetic fields.

III. RESULTS AND DISCUSSION

First we show the magnetization of YCo_2 (Refs. 11 and 12) and $LuCo_2$ (Ref. 12) at low temperatures in ultrahigh magnetic fields up to about 100 T. Sharp metamagnetic transitions can clearly be seen around 70 T with small hysteresis. In $ScCo_2$, however, we could not find a transition up to 120 T. The critical field of the transition in the ground state (B_{c0}) is determined to be 69 T for YCo_2 and 74 T for $LuCo_2$. Here, we define B_{c0} from the average of two positions at which the differential susceptibility dM/dB becomes maximum in the increasing and decreasing field scans. The values of magnetization in the paramagnetic and ferromagnetic phases at B_{c0} are 0.17 and 0.44 μ_B/Co for YCo_2, and 0.15 and 0.64 μ_B/Co for $LuCo_2$. The magnetization jump due to the transition is $\Delta M = 0.27$ μ_B/Co for YCo_2, which is apparently smaller than $\Delta M = 0.49$ μ_B/Co for $LuCo_2$. The high field susceptibility for both compounds is still large in the ferromagnetic phase. This indicates that the magnetization is not completely saturated by the metamagnetic transition.

Yamada *et al.*[16] estimated the magnetization in the ground state as a function of magnetic field for $ScCo_2$, YCo_2, and $LuCo_2$ by calculating the electronic structure of d-electrons in magnetic fields. They assumed that the volume does not change in magnetic fields. The calculated magnetization process exhibits an itinerant metamagnetic transition at 120, 89, and 94 for $ScCo_2$, YCo_2, and $LuCo_2$, respectively. A sharp peak being just below the Fermi level in DOS plays an important role in these transitions. The peak comes mainly from the d component of Co atoms. As the external field is increased, the Fermi level for the minority spin band approaches the peak of DOS and eventually a transition to a larger moment state occurs at a certain field. The estimated B_{c0} for YCo_2 and $LuCo_2$ is larger by 20 T than the observed ones. Yamada and Shimizu[15] have suggested that a magnetovolume effect reduces the value of B_{c0}. The reduction is roughly evaluated to be -13 T for YCo_2. The evaluated B_{c0} becomes very close to the observed one by considering the magnetovolume effect.

In order to get further information to support the band picture for the observed metamagnetic transition, we examined the change of B_{c0} produced by the shift of the Fermi level.[17] A small amount of 3d transition metals Fe and Ni are substituted for Co in YCo_2. Fe substitution shifts the Fermi level to the lower energy side, while the Ni substitution shifts it to the higher energy side.

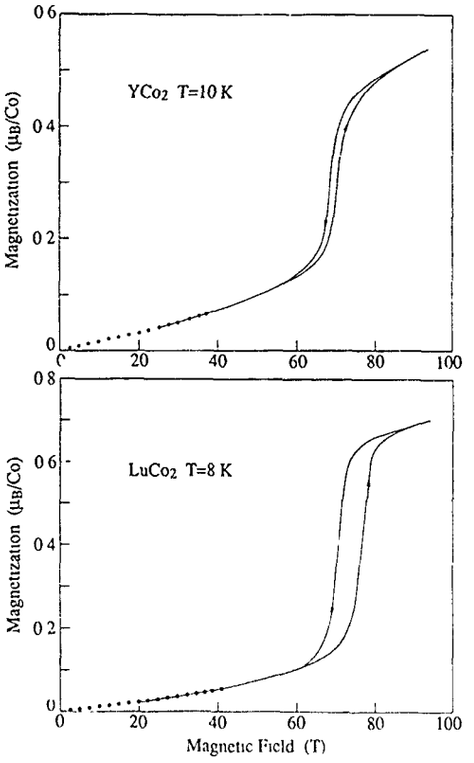

FIG. 1. Magnetization process for YCo_2 and $LuCo_2$ in ultrahigh magnetic fields up to 100 T.

As an example, we show in Fig. 2 the dM/dB curve of $Y(Co_{1-x}Ni_x)_2$ in an increasing field scan. The B_{c0} of YCo_2 obtained in this study is 72 T, which is slightly higher than that shown in Fig. 1. The position of B_{c0} rapidly moves to the higher field side with increasing Ni content. In addition to the movement of B_{c0}, significant broadening of the tran-

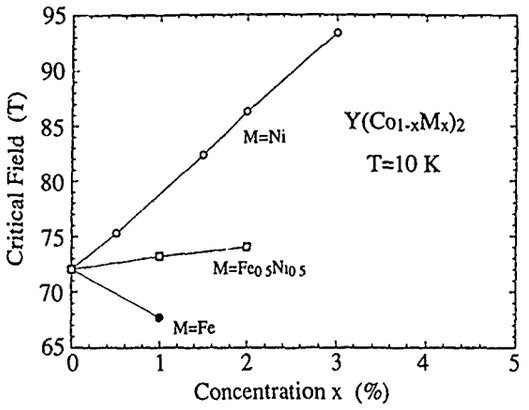

FIG. 3. Concentration dependence of the critical field for the substituted compounds $Y(Co_{1-x}M_x)_2$ (M=Fe, Ni, and $Fe_{0.5}Ni_{0.5}$).

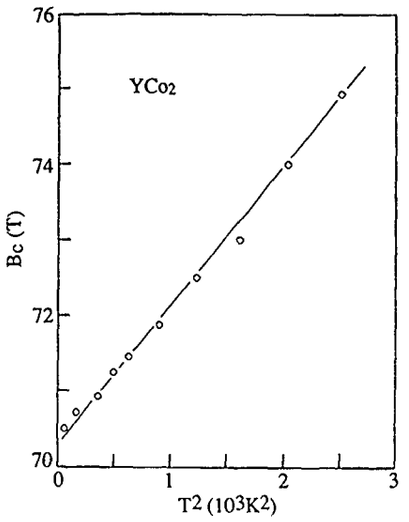

FIG. 5. Critical field of YCo^2 in an increasing field scan as a function of temperature.

sition becomes apparent in the concentration region of $x>0.015$.

The values of B_{c0} obtained for $Y(Co_{1-x}Ni_x)_2$ and $Y(Co_{1-x}Fe_x)_2$ are plotted in Fig. 3. Ni substitution results in a linear increase of B_{c0} in the investigated concentration region $x\leqslant 0.03$. In the case of Fe substitution, on the other hand, B_{c0} decreases. The observed change of B_{c0} due to Ni and Fe substitution can easily be understood with the band model of metamagnetism. Since excess d-electrons produced by Ni substitution increase the distance between the Fermi level and the peak position of DOS, the condition for the metamagnetic transition is satisfied at a higher field. On the contrary, a decrease of B_c is expected by Fe substitution. The change of B_c can qualitatively be explained with a simple rigid band model. However, the magnitude of the observed change in B_c is apparently different for these two systems. We obtain $|dB_{c0}/dx|=7.2$ T/%Ni for Ni substitution and $|dB_{c0}/dx|=4.5$ T/%Fe for Fe substitution. This fact seems to be contradictory to the rigid band model, in which symmetrical changes are expected at least for small doping. In the case of simultaneous doping with equal amounts of Fe and Ni, no change of B_{c0} is expected from the model. However, an appreciable increase of 2 T is observed for $x=2\%$ in $Y(Co_{1-x}(Fe_{0.5}Ni_{0.5})_x)_2$ as shown in Fig. 3. It should be noted that the volume change due to the substitution is negligibly small and gives no effect to B_{c0}. A theoretical study on the change of B_{c0} due to the substitution is now in progress.

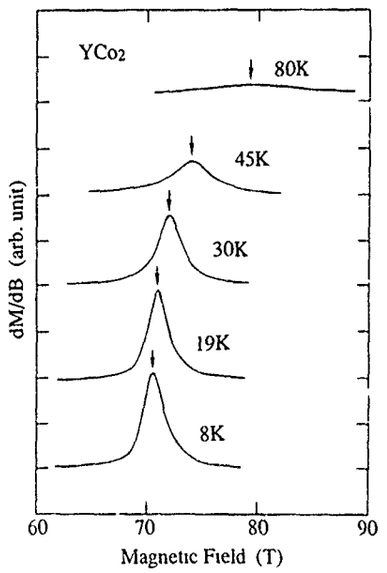

FIG. 4. Differential susceptibility dM/dB of YCo_2 for several temperatures measured in an increasing field scan.

At finite temperatures, spin fluctuations are excited in a metamagnetic compound. The metamagnetic transition is affected by the spin fluctuations. Figure 4 shows the dM/dB curve of YCo_2 at several temperatures for an increasing field scan. The metamagnetic transition is very sharp at low temperatures, but it broadens rapidly with increasing temperature. We determine the temperature, at which the first-order metamagnetic transition becomes second order (hysteresis in the magnetization curve disappears), as $T_0=100\pm10$ K. The critical field $B_c(T)$ shows a positive shift proportional to T^2 at low temperatures, as shown in Fig. 5.

In RCo_2 (R:magnetic rare-earth element) compounds, the Co site is exposed to an exchange field from the R sublattice. As the temperature decreases, ferromagnetic or ferrimagnetic ordering is realized in RCo_2 and is accompanied with a metamagnetic transition of the d-electron system (the Co sublattice). The Curie temperature T_c corresponds to the metamagnetic transition point. If T_c is lower than T_0, the magnetic transition of RCo_2 should be first order. In fact, the transitions of $ErCo_2$ ($T_c=30$ K) and $HoCo_2$ ($T_c=76$ K) are first order and those of $TbCo_2$ ($T_c=232$ K) and $GdCo_2$ ($T_c=405$ K) are second order.[18]

The positive shift of $B_c(T)$ suggests that the entropy of the d-electron system is reduced by the metamagnetic transition. The entropy reduction comes from the suppression of spin fluctuations by the transition, leading to a decrease in the coefficient γ for the electronic specific heat. Here, we evaluate the decrease of γ from the temperature dependence

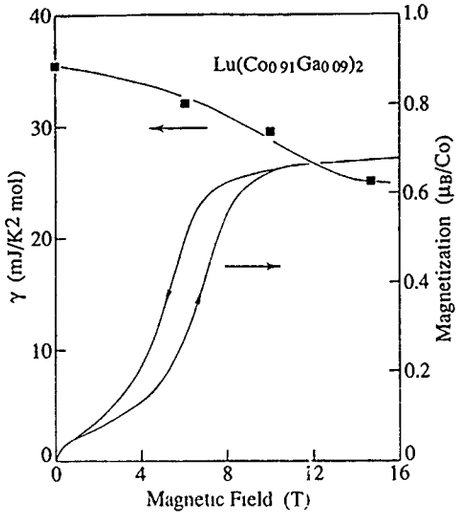

FIG. 6. Magnetization and γ value for $Lu(Co_{0.91}Ga_{0.09})_2$ as a function of field.

of the critical field. On the first-order phase boundary, the Clausius–Clapeyron relation is satisfied

$$\frac{dH_c(T)}{dT} = -\frac{\Delta S}{\Delta M}, \tag{1}$$

where ΔS and ΔM are changes in entropy and magnetization across the phase boundary. Since $H_c(T)$ $[=B_c(T)/\mu_0]$ is proportional to T^2, ΔS is proportional to T. This indicates that γ is discontinuously decreased by the metamagnetic transition. Using the experimental values of $dB_c/dT = 1.85\times10^{-3}$ T/K^2 and $\Delta M = 0.27$ μ_B/Co, we obtain the decrease of γ for YCo_2, $\Delta\gamma = -11$ mJ/K^2 mol.

In order to confirm directly the reduction of γ caused by the metamagnetic transition, we measured the specific heat of $Lu(Co_{0.91}Ga_{0.09})_2$ with low B_{c0} in steady magnetic fields.[8] Figure 6 shows the specific heat together with the magnetization as a function of magnetic field. The γ value, which is 35.5 mJ/K^2 mol in zero field, decreases during the metamagnetic transition and becomes 25 mJ/K^2 mol in the ferromagnetic state. The decrease of γ due to the transition, $\Delta\gamma = -10.5$ mJ/K^2 mol, is consistent with that estimated from $B_c(T)$ of YCo_2.

The resistivity of the metamagnetic compounds YCo_2, $LuCo_2$, and $ScCo_2$ shows a temperature dependence of $\rho(T) = \rho_0 + AT^2$ at low temperatures.[19] The coefficients A and γ for these compounds are very large compared with isostructural compounds with small susceptibility, such as $ZrCo_2$ and $HfCo_2$. Baranov *et al.*[19] have found that YCo_2, $LuCo_2$, and $ScCo_2$ satisfy the Kadowaki–Woods relation (Ref. 20), $A/\gamma^2 = 1.0\times10^{-5}$ $\mu\Omega$ cm(K mol/mJ)^2, as well as heavy fermion compounds. This relation can be explained in terms of spin fluctuation theory.[21] These results indicate that the resistivity of metamagnetic compounds is dominated by spin fluctuations. In RCo_2 the resistivity is also very large above T_c, but it is abruptly reduced at T_c.[22] The abrupt reduction mainly comes from the suppression of spin fluctuations due to the metamagnetic transition, as suggested by the decrease of γ observed in YCo_2 and $Lu(Co_{0.91}Ga_{0.09})_2$.

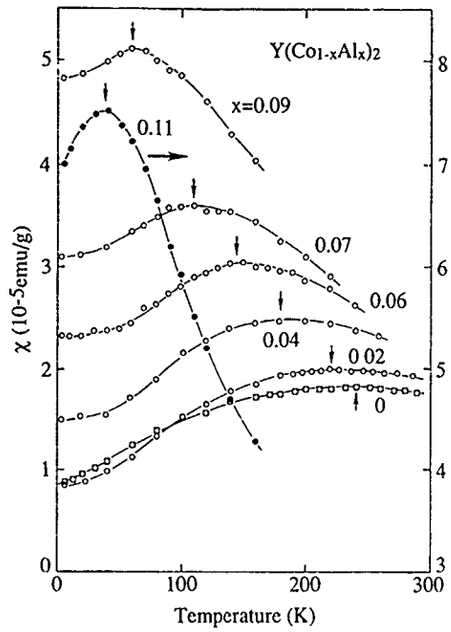

FIG. 7. Temperature dependence of susceptibility for $Y(Co_{1-x}Al_x)_2$. Small arrows indicate the position of T_{max}.

As already described in the introduction, we have found the fact that every metamagnetic compound has a maximum in $\chi(T)$. We examined the relation between the susceptibility and the magnetization process using the $Y(Co_{1-x}Al_x)_2$ system.[3] We show $\chi(T)$ for this system in Fig. 7. $\chi(T)$ of YCo_2 increases with temperature and becomes maximum around 240 K. At higher temperature it obeys a Curie–Weiss law. With increasing x, $\chi(0)$ is more enhanced. Compounds with $x \leqslant 0.11$ exhibit behavior typical of a strongly exchange-enhanced paramagnet like YCo_2. Above $x = 0.12$, the compound becomes weakly ferromagnetic.[23] The temperature at

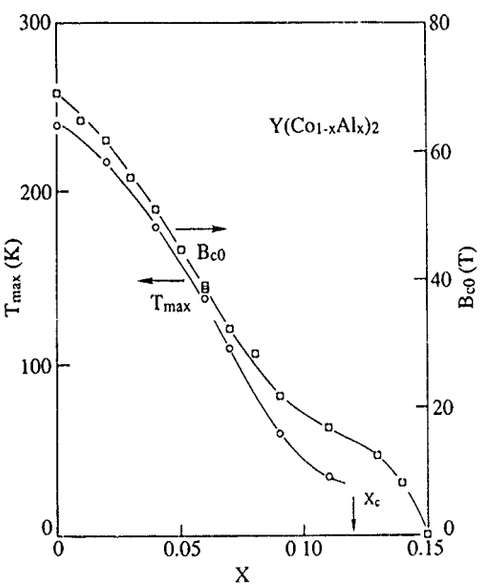

FIG. 8. Values of B_{c0} and T_{max} for $Y(Co_{1-x}Al_x)_2$ as a function of x. x_c indicates the critical concentration for the onset of ferromagnetism.

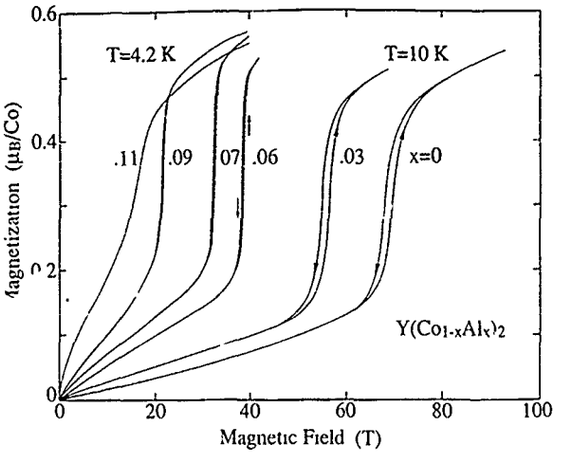

FIG. 9. Low temperature magnetization process of $Y(Co_{1-x}Al_x)_2$.

which the susceptibility becomes maximum, T_{max}, decreases rapidly in accordance with the enhancement of $\chi(0)$. The concentration dependence of T_{max} is indicated in Fig. 8. T_{max} systematically decreases as x increases.

Figure 9 shows the low temperature magnetization of the $Y(Co_{1-x}Al_x)_2$ system.[3] All the compounds with $x \leq 0.09$ exhibit sharp metamagnetic transitions. The critical field B_{c0} is plotted together with T_{max} in Fig. 8. B_{c0} decreases nearly linearly with increasing x. Above $x=0.08$, however, B_{c0} exhibits an anomalous change. In the weakly ferromagnetic phase $0.12 \leq x < 0.15$, ferromagnetism and metamagnetism coexist. This may come from heterogeneity of the system. The critical concentration, at which the critical field becomes zero, is estimated to be $x_c=0.12$ from the x dependence of B_{c0} in the concentration range $x \leq 0.08$. This x_c coincides with the onset of ferromagnetism. It should be noted that the concentration dependence of B_{c0} is very similar to that of T_{max}. We plot B_{c0} against T_{max} in Fig. 10. In the

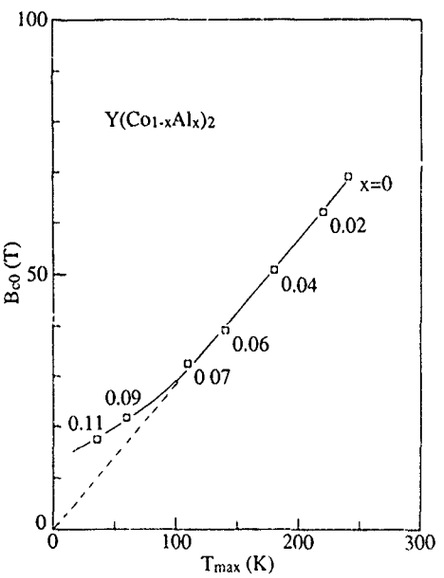

FIG. 10. Critical field B_{c0} vs T_{max} for $Y(Co_{1-x}Al_x)_2$.

$Y(Co_{1-x}Al_x)_2$ system, a simple linear relation $B_{c0}/T_{max}=0.29$ T/K is satisfied. Similar relations are found in some pseudobinary systems such as $Lu(Co_{1-x}Al_x)_2$,[7] and $Hf(Co_{1-x}Fe_x)_2$.[24] These facts suggest that the appearance of a maximum in $\chi(T)$ is strongly related to the occurrence of metamagnetism and both phenomena have the same origin: the susceptibility maximum is also associated with a special shape of the DOS curve in the vicinity of the Fermi level.

Recently, Yamada[25] developed a theory of the itinerant electron metamagnetism at finite temperatures based on the spin fluctuation model. Characteristics of the itinerant metamagnet at finite temperatures are examined by the theory. The equation of state for the itinerant system is written in the ground state as

$$H(M)=aM+bM^3+cM^5, \tag{2}$$

where a is the inverse susceptibility. The coefficients b and c are expressed in terms of the density of states and its derivatives at the Fermi level. The condition for the occurrence of a metamagnetic transition[26] is given by

$$a>0, \quad b<0, \quad c>0, \quad \text{and} \quad \frac{3}{16}<\frac{ac}{b^2}<\frac{9}{20}. \tag{3}$$

At finite temperatures, the coefficients are renormalized by thermal spin fluctuations. The coefficient a is transformed into

$$A(T)=\chi(T)^{-1}=a+\tfrac{5}{3}\,b\xi_p(T)^2+\tfrac{35}{9}\,c\xi_p(T)^4, \tag{4}$$

where $\xi_p(T)^2$ is the thermal average of the square of the fluctuating magnetic moment in the paramagnetic state. $\xi_p(T)^2$ is a monotonically increasing function and is proportional to T^2 at low temperatures. Under the condition (3), the susceptibility $\chi(T)=A(T)^{-1}$ has a maximum at a finite temperature $T=T_{max}$ due to thermal excitation of spin fluctuations. This means that both the metamagnetic transition and the maximum of $\chi(T)$ originate from the electronic structure of d electrons. The temperature dependence of the critical field is expressed as

$$B_c(T)=B_{c0}+\alpha\xi_p(T)^2, \tag{5}$$

where α is a function of b and c. This indicates that $B_c(T)$ is increased by the effect of spin fluctuations, consistent with the observed $B_c(T)$ for YCo_2. The linear relation between $B_c(T)$ and T_{max}, B_{c0}/T_{max}=const, is derived by the theory. This is also consistent with the relation between B_{c0} and T_{max} observed in the $Y(Co_{1-x}Al_x)_2$ system. Moreover, the temperature T_0, at which the first-order metamagnetic transition disappears, can be estimated using the experimental values of T_{max} and $\chi(0)/\chi(T_{max})$. The estimated T_0 is 104 K for YCo_2 with $T_{max}=240$ K and $\chi(0)/\chi(T_{max})=0.50$. This value is in good agreement with the experimental result of $T_0=100\pm10$ K. The observed characteristics of the itinerant metamagnet are successfully elucidated with this theory based on the spin fluctuation model.

Finally, we show the pressure effect on the magnetization process and the susceptibility of $Lu(Co_{1-x}Ga_x)_2$. Itinerant metamagnetism is expected to be very sensitive to high pressure since it comes from the shape of the DOS curve in the vicinity of the Fermi level. Figure 11 shows the pressure

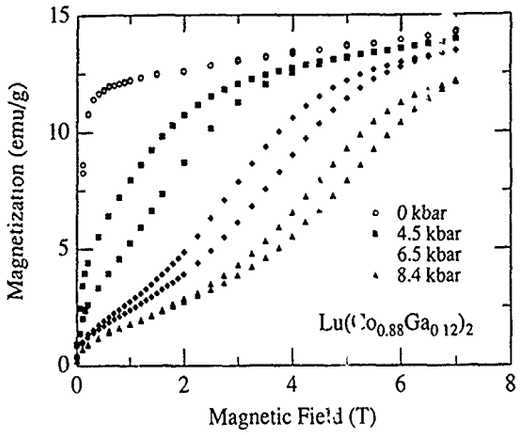

FIG. 11. Pressure effect on the magnetization process of $Lu(Co_{0.88}Ga_{0.12})_2$ at 4.2 K.

dependence of the magnetization process for $Lu(Co_{0.88}Ga_{0.12})_2$ at 4.2 K. This compound shows ferromagnetic behavior at 0 kbar. With increasing pressure, a metamagnetic transition appears and the critical field increases linearly. We obtain $dB_{c0}/dP = 1.0$ T/kbar. The DOS curve of $LuCo_2$ also has a sharp peak just below the Fermi level, which gives the metamagnetism.[16] In the $Lu(Co_{1-x}Ga_x)_2$ system, the peak becomes very broad due to hybridization between Co d and Ga p bands and the peak position approaches the Fermi level.[27] This may cause the decrease of the critical field in the Ga-substituted system. The application of high pressure increases the band width and the distance between the Fermi level and the peak position. These effects increase the critical field.

Figure 12 shows the temperature dependence of susceptibility for $Lu(Co_{0.92}Ga_{0.08})_2$ at high pressures. The application of pressure decreases the susceptibility and increases T_{max}. We obtain $dT_{max}/dP = 2.1$ K/kbar. According to Yamada's theory, T_{max}^2 is proportional to the inverse of $\chi(0)$.[25]

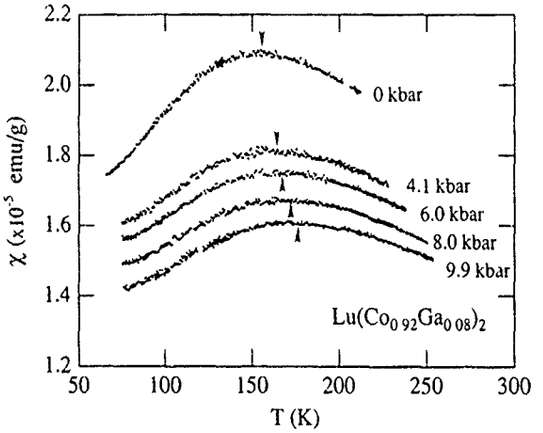

FIG. 12. Pressure effect on the susceptibility of $Lu(Co_{0.91}Ga_{0.08})_2$. Arrows indicate the position of T_{max}.

The observed increase of T_{max} indicates that the pressure effect decreases both DOS at the Fermi level and the enhancement factor. The large reduction of $\chi(T_{max})$ suggests that the spin fluctuations are much suppressed by the application of pressure. In the present study we cannot determine the relation between $B_{c0}(P)$ and $T_{max}(P)$ under high pressure with the same sample. However, the simple relation $B_{c0}(P)/T_{max}(P) = \text{const}$ may be satisfied.

In conclusion, we have successfully observed metamagnetic transitions in YCo_2 and $LuCo_2$ at $B_{c0} = 69$ and 74 T. The change of B_{c0} due to Ni and Fe doping in YCo_2 suggests that the transition originates from a special shape of the DOS curve around the Fermi level. $B_c(T)$ of YCo_2 shows a positive shift proportional to T^2 at low temperatures. In the $Y(Co_{1-x}Al_x)_2$ system, we have found the relation $B_{c0}/T_{max} = \text{const}$. These experimental results can be explained by theory based on a spin fluctuation model. We have observed the suppression of spin fluctuations due to metamagnetic transition. The metamagnetic transition and susceptibility are sensitively changed by pressure.

Local and nonlocal density functional studies of FeCr

David J. Singh
Complex Systems Theory Branch, Naval Research Laboratory, Washington, DC 20375

Local spin density approximation and generalized gradient approximation calculations are reported for ferromagnetic $B2$ FeCr. Both shear elastic constants are found to be positive, indicating metastability of the $B2$ structure. Both the moments of the Fe and Cr layers are ferromagnetically aligned, with the Fe moment being considerably depressed. This is in contrast to the behavior for thicker films. The evolution of the behavior as a function of the layer thickness is addressed using supercell calculations. It is found that Fe monolayers in bcc Cr are ferromagnetically aligned with the neighboring Cr moments, while thicker Fe layers are antiferromagnetically aligned with the adjacent Cr layers.

INTRODUCTION

Fe/Cr multilayers have become the focus of intense investigation over the past few years in part because of the discovery of oscillatory interlayer coupling and giant magnetoresistance (GMR) in this system. Although CsCl ($B2$) structure FeCr does not exist in the Fe-Cr phase diagram,[1] the system is of interest not only because of the possibility of growing it layer by layer with molecular beam epitaxy (MBE) but also because it may be viewed as alternating (001) layers of Fe and Cr, thus forming the low thickness limit in the Fe/Cr/Fe multilayer family.

This article reports local spin density approximation (LSDA) and generalized gradient approximation (GGA) calculations used to investigate the electronic, magnetic, structural, and elastic properties of this phase. The results are in general accord with an earlier LSDA linearized muffin-tin orbital (LMTO) calculation of the electronic structure, lattice parameter, and bulk modulus for this phase.[2] Enhanced bonding, reduced Fe moments, and an unexpected parallel alignment of the Fe and Cr spins is found. This alignment is opposite to that observed in multilayers. Calculations were performed for several multilayers with different Fe and Cr layer thicknesses in order to understand the parallel alignment and the regime in which it occurs.

METHOD

The present self-consistent calculations were performed using the general potential linearized augmented planewave (LAPW) method[3,4] with a local orbital extension[5] to relax the linearization of the $3d$ bands. Unlike the LMTO calculations of Ref. 2, this method imposes no shape approximations on the charge density or potential. LAPW sphere radii of 2.25 a.u. were used with well converged basis sets derived from an interstitial cutoff of 16 Ry. The Brillouin zone sampling were performed using a 16^3 special **k**-points mesh, which yielded 120 points in the irreducible 1/48 wedge of the simple cubic zone. The multilayer calculations were performed using a 12^3 mesh in the cubic zone which was folded down into the appropriate tetragonal zones. The LSDA calculations were performed using the Hedin–Lundqvist[6] functional with the von Barth–Hedin spin scaling;[7] GGA calculations used the recent Perdew–Wang functional.[8]

$B2$ FeCr: STRUCTURAL AND ELASTIC PROPERTIES

Spin polarized LSDA and GGA total energy and electronic structure calculations were performed for lattice parameters between 5.20 and 5.45 a.u. Lattice parameters and bulk moduli were obtained by fitting these to the Birch equation of state. This procedure yielded an LSDA lattice parameter of $a=5.23$ a.u. or 2.77 Å and a bulk modulus of 297 GPa. The present lattice parameter is 1.3% smaller than the 5.30 a.u. obtained by Moroni and Jarlborg using the LMTO method,[2] while the bulk modulus is 10% larger. Converged LSDA calculations for $3d$ magnets typically give lattice parameters that are 2% to 3% smaller than experiment and bulk moduli that are 25% to 40% too large, even though elastic and other properties when calculated at the experimental lattice parameter are in close agreement with experiment.[9] In contrast GGA calculations typically yield lattice parameters and bulk moduli in much better agreement with experiment for these materials. The calculated GGA lattice parameter for FeCr is $a=5.33$ a.u. which is approximately 2% larger than the LSDA value, but still 2% smaller than is obtained by applying Vegard's rule to bcc Fe and Cr; this suggests enhanced bonding in FeCr. The GGA bulk modulus is 256 GPa. Elastic constants were calculated within the LSDA but are the likely more realistic GGA lattice parameter, using the procedure of Mehl *et al.*[9] This results in fairly stiff shear elastic constants, $c_{44}=150$ GPa and $c_{11}-c_{12}=230$ GPa. These large values, which suggest strong bonding, suggest that $B2$ FeCr is a metastable phase, and therefore that this phase may be grown epitaxially to large thicknesses.

$B2$ FeCr: ELECTRONIC AND MAGNETIC PROPERTIES

The LSDA band structure and electronic density of states (DOS) are presented in Figs. 1 and 2, respectively. The Fermi energy falls in a peak in the majority spin DOS, perhaps related to the fact that the $B2$ phase is thermodynamically unstable. Both the minority and majority spin d bands are partially occupied. The similarity of the Fe and Cr projections of the DOS is remarkable. This reflects hybridization between the Fe and Cr d orbitals. This is also seen in the magnetic moments. At $a=5.33$ a.u., Fe and Cr spin moments of 1.21 μ_B and 0.61 μ_B were obtained within the LSDA. The interstitial polarization is very small as expected. Moroni and Jarlborg[2] report LSDA values at their calculated lattice parameter of 5.30 a.u. At that lattice parameter, I obtain mo-

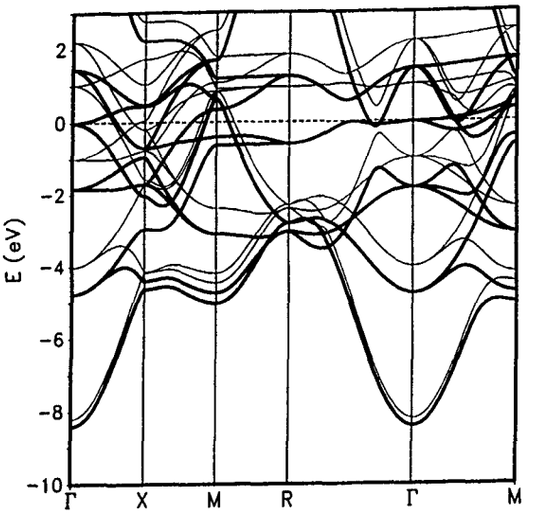

FIG. 1. LSDA band structure of $B2$ FeCr. Majority (minority) spin bands are denoted by heavy (light) lines. The dashed horizontal line denotes the Fermi energy.

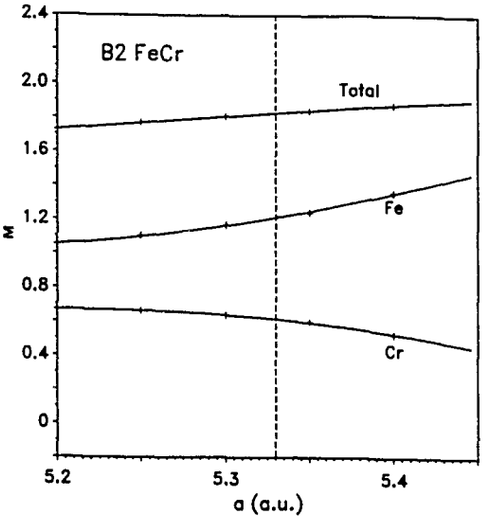

FIG. 3. Total and projected spin magnetization in μ_B per formula unit vs lattice parameter for $B2$ FeCr.

ments of 1.164 μ_B and 0.635 μ_B for Fe and Cr, respectively. These values are 0.06 μ_B larger for Fe and 0.05 μ_B smaller for Cr than for those of Ref. 2. The Cr moment is only slightly enhanced relative to bcc Cr, while the Fe moment is strongly reduced. Further, the Fe and Cr moments are aligned in FeCr (coincidentally the total spin moment of 1.82 μ_B is what would be expected if the Fe and Cr moments were antiparallel and were close to their bulk elemental values). This is in sharp contrast to what is known about the interface between thicker Fe and Cr layers where the Fe and Cr moments are antiparallel.[10,11] As shown in Fig. 3, the moments vary slowly over the entire volume range studied and in particular the parallel alignment of the Fe and Cr moments persists. This result, which is qualitatively in accord with the earlier calculations of Moroni and Jarlborg[2] and also holds in GGA calculations, can be rationalized in terms of the electronic structure. In the $B2$ structure each Fe atom is surrounded by eight Cr atoms and vice versa—a favorable environment for d bonding. As mentioned, the electronic structure shows strong Fe-Cr hybridization as reflected in the similar projected DOS for the two species. This similarity arises in three ways, a charge transfer from the Fe to the Cr atoms, parallel alignment of the spin moments, and a strong reduction in the Fe moment. Evidently, the bonding energy is sufficient to bring these things about in $B2$ FeCr.

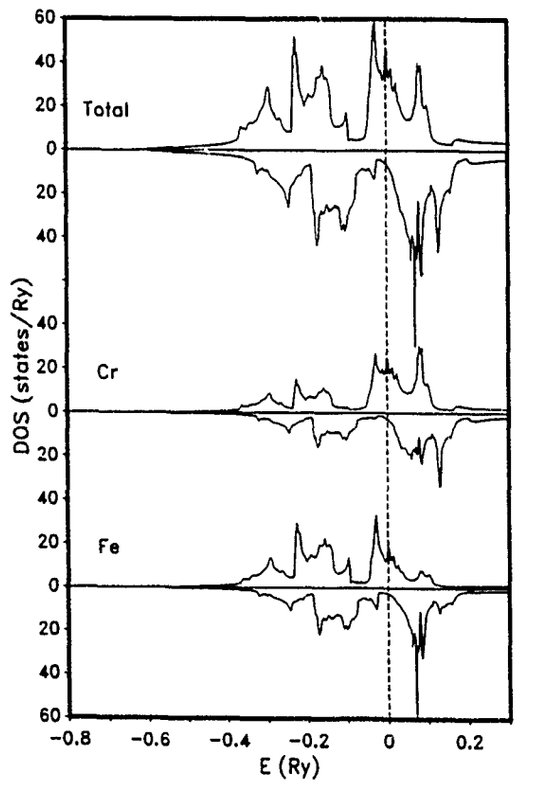

FIG. 2. Total and projected DOS of $B2$ FeCr. Majority (minority) spin contributions are shown above (below) the axis. The dashed vertical line denotes the Fermi energy.

FeCr MULTILAYERS

Regarding FeCr as a stack of single (001) Fe and Cr layers, one may consider the effects of changing the layer thicknesses. For thicker Fe layers, each interface Fe atom would be coordinated by four Cr atoms and four Fe atoms in the next layer, which depending on the layer thickness would be interior or interface Fe atoms. Similarly, one may consider changing the Cr layer thickness. In order to study these situations, LSDA supercell calculations at the bulk Fe lattice parameter were performed for several such stacks, as shown in Table I. These are denoted as Fe_nCr_m, where n is the thickness of the Fe layers and m is the thickness of the Cr layers. GGA calculations, which, were performed for the stacks containing four and fewer layers yielded similar results but with larger Cr moments consistent with previous GGA calculations for bulk Cr.[12]

The results show that thickening the Cr layer does not change the parallel interface alignment provided that the Fe

TABLE I. Projected spin moments in μ_B/atom of Fe_nCr_m (001) stacks. The projections are onto the LAPW spheres. The alignment of the spin moments is given by the sign. In cases where there are more than one inequivalent Fe or Cr atom, the moments are given in order of the distance from the interface; Fe_1 and Cr_1 are the interfacial atoms.

n	m	$M(Fe_1)$	$M(Fe_2)$	$M(Fe_3)$	$M(Cr_1)$	$M(Cr_2)$
1	1	1.36	···	···	0.52	···
1	3	1.33	···	···	0.30	−0.27
2	1	2.09	···	···	−0.41	···
3	1	1.92	2.49	···	−0.35	···
5	1	1.99	2.44	2.36	−0.42	···

remains a single atomic layer thick. In fact, the Fe spin moment changes little when additional Cr layers are added. The Cr layers are, however, antiferromagnetically aligned with neighboring Cr atoms as expected, and a reduction in the interfacial Cr moment is found when the Cr layer is thickened. On the other hand, adding even a single Fe layer leads to a reversal of the interfacial alignment and an increase in the Fe moment to near the bulk Fe value, which persists as additional Fe layers are added. Thus parallel alignment of the interfacial moments in Fe-Cr multilayers is dependent on having single atomic layer thick Fe layers so that each Fe atom is coordinated by eight Cr atoms. This prediction may perhaps be verified experimentally by growing, with MBE, a single atomic layer of Fe between two Cr layers and measuring the alignment of the Fe moment with its Cr neighbors.

CONCLUSIONS

Total energy and electronic structure calculations have been reported for $B2$ FeCr and for Fe-Cr multilayers. It is found that FeCr is elastically stable and is likely a metastable phase. A parallel alignment of the Fe and Cr moments is found; this may be understood in terms of strong hybridization apparent in the electronic structure. Calculations for Fe-Cr multilayers show that the interfacial Fe and Cr moments remain antiparallel, except in the case when the Fe is a single atomic layer thick, in which case a novel parallel alignment is found.

Temperature-dependent electronic structure and ferromagnetism of bcc iron

W. Nolting
Humboldt-Universität, Lehrstuhl Festkörpertheorie, Invalidenstrasse 110, 10115 Berlin, Germany

A. Vega
Departamento de Física Teórica, Universidad de Valladolid, 47011 Valladolid, Spain

The influence of electron correlations on the temperature dependence of the electronic structure of ferromagnetic bcc iron is investigated by the use of a many-body evaluation of a generalized model of magnetism. The one-particle part of the model Hamiltonian is taken from an LDA band-structure calculation. The model contains only two parameters, an intraband Coulomb interaction U, and an interband exchange J. With $U=1.8$ eV and $J=0.2$ eV the self-consistent model solution yields a $T=0$ moment of about 2.04 μ_B and an exact Curie temperature of 1044 K. Details of the magnetic behavior of Fe can be traced back to a striking temperature variation of the quasiparticle density of states. Typical differences in the magnetic behavior of Fe and Ni are worked out.

I. INTRODUCTION

Decisive features of band ferromagnets like Fe, Co, and Ni can be traced back to electron-correlation effects in the relatively narrow $3d$ subbands, which only weakly hybridize with the $4s$ and $4p$ bands. The Fe valence band contains eight electrons, about seven of them have predominantly d character. Current state-of-the-art band structure calculations within the "local spin density approach" (LSDA) are able to account for ground state properties of Fe quite reasonably. However, up to now a convincing theory does not exist for the temperature-dependent electronic structure, from which magnetic key quantities, such as the Curie temperature, the magnetization curve, and the exchange splittings can be derived.

II. THEORETICAL MODEL

Although prototypical magnetic materials like Fe, Co, Ni, Gd, EuO, NiO,..., belong to rather different classes of magnetism, they should be describable by one and the same theoretical model and by use of very similar approaches to the sophisticated many-body problem. Our model Hamiltonian

$$H=H_0+H_1 \tag{1}$$

has already been applied in preliminary works to some of the above-mentioned materials.[1–3] The single-particle part reads

$$H_0=\sum_{ijm\sigma} T_{ij}(m)c^+_{im\sigma}c_{jm\sigma}=\sum_{\mathbf{k}m\sigma}\varepsilon_m(\mathbf{k})c^+_{\mathbf{k}m\sigma}c_{\mathbf{k}m\sigma}. \tag{2}$$

The indices i,j mark the lattice sites and σ marks the spin projection. In the case of Fe the band index m runs over the $3d$ subbands. It is commonly accepted that the important aspects of band ferromagnetism are sufficiently well accounted for by intraatomic direct ($U_{mm'}$) and exchange ($J_{mm'}$) terms only. These terms can be rearranged in the following illustrative way:[2]

$$H_1=H_U+H_J+H_{\tilde{U}}. \tag{3}$$

H_U is an intraband Coulomb interaction of Hubbard-type ($U_{mm}+J_{mm}\rightarrow U\ \forall m$)

$$H_U=\frac{1}{2}U\sum_{im\sigma} n_{im\sigma}n_{im-\sigma}. \tag{4}$$

The second term is an interband exchange interaction ($J_{mm'}\equiv J\ \forall m\neq m'$), which has exactly the same structure as the interaction part of the $sf(sd)$ model

$$H_J=-J\sum_{i,m}\boldsymbol{\sigma}_{im}\cdot\mathbf{S}_{im}. \tag{5}$$

$\boldsymbol{\sigma}_{im}$ is the electron spin operator [$\sigma^+_{im}=c^+_{im\uparrow}c_{im\downarrow}$, $\sigma^-_{im}=c^+_{im\downarrow}c_{im\uparrow}$, $\sigma^z_{im}=0{,}5(n_{im\uparrow}-n_{im\downarrow})$]. $\mathbf{S}_{im}$ is a fictitious spin, "seen" by an electron from subband m and built up by electron spins from all the other subbands

$$\mathbf{S}_{im}=\sum_{m'}^{\neq m}\boldsymbol{\sigma}_{im'}. \tag{6}$$

The third term in Eq. (3) is a spin-independent direct Coulomb interaction between electrons from different subbands ($\tilde{U}=0{,}5(U_{mm'}-0{,}5J_{mm'})\ \forall m\neq m'$)

$$H_{\tilde{U}}=\frac{1}{2}\tilde{U}\sum_{i,m,m'}^{m\neq m'} n_{im}n_{im'};\quad n_{im}=\sum_{\sigma} n_{im\sigma}. \tag{7}$$

Since there is no direct spin dependence in $H_{\tilde{U}}$, this partial Hamiltonian will not execute a direct influence on typical magnetic phenomena. We therefore neglect it in the treatment of Fe.

We believe that H_1 contains all the interactions which are vital for the magnetic correlations and the temperature dependence of the electronic structure. For a realistic comparison to experimental data, however, we have to reintroduce the influence of all the *other* interactions by a proper renormalization of the single-particle energies. This is done by an LSDA-band-structure calculation.

$$\varepsilon_m(\mathbf{k})\rightarrow\varepsilon_m^{\mathrm{LSDA}}(\mathbf{k}). \tag{8}$$

 0021-8979/94/76(10)/6691/3/$6.00 © 1994 American Institute of Physics

We perform this LSDA calculation along the line given in Ref. 4, for *paramagnetic* Fe in order to avoid a double counting of the magnetic interactions which are already covered by the model-Hamiltonian part H_1. A more detailed justification is given in Ref. 7. Starting from an s,p,d basis we pick out the five eigenstates with highest d character and number them according to increasing single-particle energy by $m=1,2,...,5$ $[\varepsilon_1(\mathbf{k})\leq\cdots\leq\varepsilon_5(\mathbf{k})]$. The energies $\varepsilon_m(\mathbf{k})$ for all $\mathbf{k}$ from the first Brillouin zone form the mth subband. In this way the $3d$ band is decomposed into five nondegenerate subbands.

The many-body problem posed by our model Hamiltonian is not exactly solvable. However, the decomposition (3) of the interaction part can conveniently be exploited, since the partial operators H_U and H_J are well known from simpler models of magnetism. The starting point is the retarded one-electron Green function

$$\langle\langle c_{\mathbf{k}m\sigma};c^{+}_{\mathbf{k}m\sigma}\rangle\rangle_E=\frac{\hbar}{E-\varepsilon_m^{\mathrm{LDA}}(\mathbf{k})-\Sigma_{\mathbf{k}m\sigma}(E)} \tag{9}$$

the formal solution of which can be written in terms of the fundamental self-energy $\Sigma_{\mathbf{k}m\sigma}(E)$.

Via the definition

$$\langle\langle[c_{\mathbf{k}m\sigma},H_{U,J}];c^{+}_{\mathbf{k}m\sigma}\rangle\rangle(E)\equiv M^{(U,J)}_{\mathbf{k}m\sigma}(E)\langle\langle c_{\mathbf{k}m\sigma};c^{+}_{\mathbf{k}m\sigma}\rangle\rangle_E \tag{10}$$

the self-energy parts $M^{(U,J)}_{\mathbf{k}m\sigma}(E)$ of the full self-energy

$$\Sigma_{\mathbf{k}m\sigma}(E)=M^{(U)}_{\mathbf{k}m\sigma}(E)+M^{(J)}_{\mathbf{k}m\sigma}(E) \tag{11}$$

may be introduced. In the next step we define "effective" single-particle energies

$$\eta^{(x)}_{m\sigma}(\mathbf{k},E)=\varepsilon_m^{\mathrm{LDA}}(\mathbf{k})+M^{(y)}_{\mathbf{k}m\sigma}(E)\quad(x,y=U,J;\ x\neq y) \tag{12}$$

for an "effective medium" Hamiltonian

$$H^{(x)}_{\mathrm{eff}}=\sum_{\mathbf{k}m\sigma}\eta^{(x)}_{m\sigma}(\mathbf{k};E)c^{+}_{\mathbf{k}m\sigma}c_{\mathbf{k}m\sigma}+H_\lambda\,. \tag{13}$$

In general $H^{(x)}_{\mathrm{eff}}$ will be energy dependent and non-Hermitian, but the resulting Green function is the same as in Eq. (9). The advantage lies in the fact that the "effective-medium" Hamiltonian poses a formally simpler many-body problem than the "original" model Hamiltonian (1). For each $x(x=U,J)$ we try to find a reasonable approach to the corresponding "effective" Green function. This means that for $x=U$ we solve the "Hubbard problem," for which we use the self-consistent moment method from Ref. 5. For $x=J$ one meets the "sf problem," which we approximate by use of the moment-conserving decoupling procedure, developed in Ref. 4. The resulting self-energy parts

$$M^{(U,J)}_{\mathbf{k}m\sigma}(E)=F[E;\eta^{(U,J)}_{\mathbf{k}m\sigma}(E);\langle\cdots\rangle] \tag{14}$$

depend via η on the respective other self-energy part. Furthermore they will contain several thermodynamic expectation values, indicated in Eq. (13) by $\langle\cdots\rangle$. It is the main requirement of our procedure that all these averages can be represented in terms of the full self-energy, so that a closed set of equations is guaranteed, which can be solved self-consistently for the quantities of interest.

III. RESULTS

The two model parameters U and J have been fitted to get a self-consistent ferromagnetic solution with a phase transition of second order at T_C, and a $T=0$ magnetic moment as realistic as possible ($U=1.8$ eV; $J=0.2$ eV). In the same spirit we determined in Ref. 1 U and J for Ni.

It turns out that the possibility of a ferromagnetic ground state is mainly due to the intraband Coulomb interaction U, while the exchange J influences the actual values of the magnetic quantities. To realize ferromagnetism the coupling parameter U/W_m (W_m: width of the mth $3d$ subband), the electron density n_m ($0\leq n_m\leq 2$), as well as the hole density, $2-n_m$, have to exceed certain critical values, which depend on the given lattice structure. Furthermore, an upper limit for U/W_m appears, above which the magnetic phase transition is of first order.[5]

The $m=1,2$ subbands are completely filled and therefore magnetically inactive. The $m=3$ and 5 subbands $[n_3(T=0)=1.346,\ n_5(T=0)=0.704]$ have convenient occupations for a ferromagnetic ground state (Fig. 1). The $m=4$ subband, however, is for all temperatures exactly half filled ($n_4=1$, Fig. 1) and has therefore a strong tendency to antiferromagnetism, which competes with the ferromagnetic tendency of the $m=3$ and 5 subbands. According to our model solution for bcc iron the ferromagnetism of the $m=3$ and 5 subbands dominates and forces the in principle antiferromagnetic $m=4$ band by interband exchange (J) into a ferromagnetic order. So, the situation is very much more complicated than in Ni, where only the uppermost $m=5$ subband is magnetically active,[1] because the $m=1,2,3$ bands are fully occupied and the $m=4$ band contains only very few holes.

All magnetic properties of the band ferromagnet Fe can be understood as direct consequences of the temperature-dependent quasiparticle density of states (QDOS)

$$\rho_{m\sigma}(E)=-\frac{1}{\pi}\sum_{\mathbf{k}}\mathrm{Im}\langle\langle c_{\mathbf{k}m\sigma};c^{+}_{\mathbf{k}m\sigma}\rangle\rangle_E\,, \tag{15}$$

which is plotted in Fig. 1 for four different temperatures, and separately for the five $3d$ subbands. The total QDOS is of course nothing else than the sum of the five partial densities. The T dependence of the two lowest subbands ($m=1,2$) is exclusively due to interband exchange with the magnetically active $m=3,4,5$ subbands. In the latter two different correlation effects are produced by the intraband interaction U. There is a splitting into two quasiparticle subbands, which persists for all temperatures, and an additional spin splitting of each of these bands, which disappears for $T\rightarrow T_c$. The latter is still enhanced by the interband exchange. The weight ("area") of the lower σ-quasiparticle band scales with the probability for the propagating electron to find a lattice site, which is not preoccupied by a $(-\sigma)$ electron of the same subband. This probability is zero for fully occupied bands. Therefore the $m=1,2$ subbands do not split. The weight of the upper quasiparticle subband is proportional to the probability that the σ electron does meet a $(-\sigma)$ electron of the same subband. A special case is the $m=4$ subband, which is half filled and at $T=0$ fully spin polarized. So a $\uparrow$ electron has no chance to meet a $\downarrow$ electron, and a $\downarrow$ electron, brought

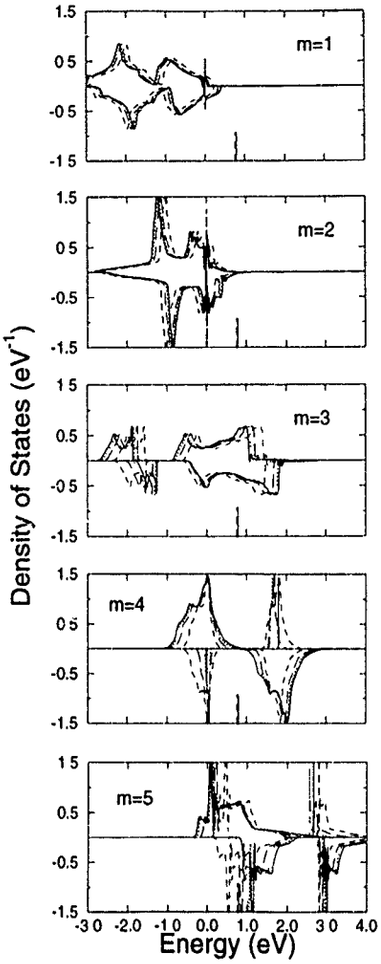

FIG. 1. Quasiparticle density of states $\rho_{m\sigma}$ of the five $3d$ subbands as a function of energy for four different temperatures [$T=0$ K: solid line; $T=900$ K: dotted line; $T=1025$ K: broken line (large bars); $T=1044$ K$=T_c$: broken line (small bars)]. Upper halves for $\sigma=\uparrow$, lower halves for $\sigma=\downarrow$. Bars on the energy axis mark the chemical potential μ.

into the system, cannot avoid a double occupancy. Consequently, the upper $\uparrow$- and the lower $\downarrow$-quasiparticle subbands disappear at $T=0$. For finite temperature collective spin excitations become dominant for this subband, introducing a spin disorder. An electron, picked out of the sample by a photoemission experiment, is then with finite probability a $\downarrow$ electron. This causes the appearance of a lower $\downarrow$-quasiparticle band. For analogous reasons there grows out an upper $\uparrow$ band for $T>0$. Above T_c the spin asymmetry disappears, but the splitting into a lower and an upper subband persists. This explains the "noncollapsing exchange splitting" in the Fe band structure, observed in spin-resolved photoemission.[6] It is interesting to compare these features to the Ni spectrum.[1] In Ni only the uppermost $m=5$ subband is partially filled, and therefore magnetically active. The first

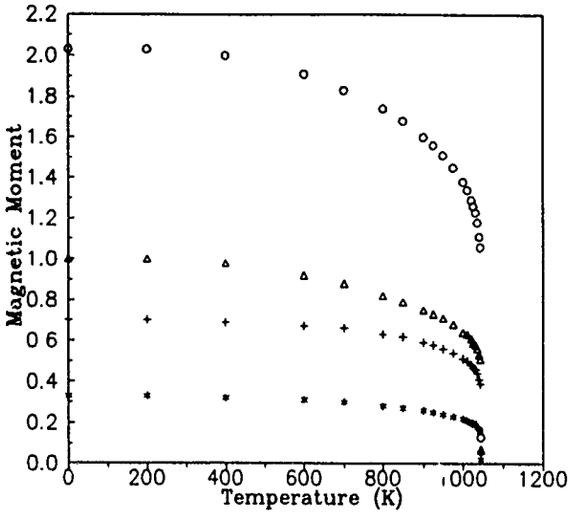

FIG. 2. Magnetic moment of ferromagnetic iron as a function of temperature (circles). Partial contributions from the subbands are also indicated ($m=3$: stars; $m=4$: triangles; $m=5$: crosses).

four subbands behave like the $m=1$ and 2 bands of Fe. They do not split, because the spectral weight of the lower quasiparticle subband is zero. Only the $m=5$ band shows the quasiparticle splitting which persists for all temperatures and is of order U. Because $U=6$ eV in Ni, the lower quasiparticle subband of the $m=5$ band lies some 6 eV below the chemical potential μ and is nothing else than the famous "Ni 6 eV satellite." In principle, the $m=3$, 4, and 5 subbands in Fe exhibit the same behavior as the Ni $m=5$ band. Because of the smaller U, however, all the quasiparticle subbands are melting together avoiding therewith a feature which could be denoted as "satellite." On the other hand, the "quasiparticle splitting" gives rise to a "noncollapsing" exchange splitting above T_c.

The T dependence of the magnetic moment, plotted in Fig. 2, follows directly from the respective T dependence of the QDOS. The model solution reproduces exactly the experimental value for the Curie temperature $T_c=1044$ K. The $T=0$ moment amounts to 2.035 μ_B, being therewith only slightly smaller than the experimental value (≈ 2.2 μ_B). The actual value of the moment depends sensitively on the total number of d electrons, which is not uniquely established. We took $n_{3d}=7.05$ from Ref. 4. Another choice can slightly alter the calculated $T=0$ moment.

Theory for itinerant electrons in noncollinear and incommensurate structured magnets (invited)

J. Kübler, L. M. Sandratskii, and M. Uhl
Institut für Festkörperphysik, Technische Hochschule, D-64289 Darmstadt, Germany

Itinerant-electron systems are described that can form a variety of magnetic-moment arrangements. These are dealt with quantitatively by using energy-band theory and the local density-functional approximation; the theoretical and computational basis is briefly reviewed and results are presented for quite general collinear and noncollinear moment arrangements and states having incommensurate helical order characterized by a wave vector **q**. Some examples presented here are Fe_3Pt-Invar, fcc-iron precipitates, and tetragonal iron. Furthermore, finite-temperature effects become tractable; the magnetovolume effect in Fe_3Pt-Invar serves as an example. Finally, the problem of biquadratic exchange in Fe-Cr multilayers will be discussed briefly.

I. INTRODUCTION

This overview is intended to demonstrate how we use the local density-functional approximation[1,2] to do *ab initio* calculations for magnetic properties of materials possessing a variety of magnetic-moment arrangements like ferromagnets, collinear and noncollinear antiferromagnets, and incommensurate spiral or helical magnets. Our treatment of the electronic and magnetic properties of these itinerant-electron systems has grown out of a long development connected with the work of Korenman and Prange, Heine, Moriya, and many others.[3-10] This is not the place to discuss the similarities and differences in our work compared with the many previous theories. Let it be said that Korenman[11] treated the vector nature of the magnetic moments formed by the itinerant electrons like we do. But unlike Korenman's, our calculations are self-consistent concerning the charge and spin densities and—if desired—the interatomic magnetic moment arrangements.

Our theory was applied previously to a number of cases some of which are the noncollinear magnetic states of Mn_3Sn (Ref. 12), the problem of fcc-Fe (γ-Fe) (Ref. 13), the case of Fe_3Pt-Invar (Ref. 14), and the problem of $ThMn_2$ (Ref. 15) which is an antiferromagnet on a frustrated lattice.

After a brief description of the theoretical background in Sec. II we will highlight the problem of Fe_3Pt-Invar in Sec. III where we point out that transverse spin fluctuations contribute in an essential way to the formation of the Invar anomaly; this leads to an understanding of the Invar effect that, though it relies on the existence of high-spin and low-spin states, does not require them to be near degenerate. Thus our results yield a magnetovolume anomaly without the somewhat artificial near degeneracy that was thought to be so essential in previous theories (for a review concerning the latter see, e.g., Refs. 16, 17). In connection with the problem of γ-Fe we will then discuss some new estimates concerning tetragonal Fe that is produced today by epitaxial growth. We will close our overview with a discussion of some new but preliminary results concerning the observed[18-20] magnetization steps and biquadratic coupling in Fe-Cr multilayers.

II. THEORETICAL BACKGROUND

The Euler–Lagrange equations that minimize the total energy as a functional of the density matrix define an effective single-particle Hamiltonian[1,2] which for spin-polarized electrons forming a noncollinear magnetic order may be written in bispinor form as[21]

$$\hat{\mathbf{H}}(\mathbf{r}) = -\nabla^2 \mathbf{1} + \sum_{j\nu} \mathbf{U}^{+}(\theta_{j\nu},\phi_{j\nu})\mathbf{V}_{\nu}(\mathbf{r}_{j\nu})\mathbf{U}(\theta_{j\nu},\phi_{j\nu}). \quad (1)$$

Here $\mathbf{U}(\theta_{j\nu},\phi_{j\nu})$ is the standard spin-$\frac{1}{2}$-rotation matrix

$$\mathbf{U}(\theta_{j\nu},\phi_{j\nu}) = \begin{pmatrix} \cos(\theta_{j\nu}/2)\exp(i\phi_{j\nu}/2) & \sin(\theta_{j\nu}/2)\exp(-i\phi_{j\nu}/2) \\ -\sin(\theta_{j\nu}/2)\exp(i\phi_{j\nu}/2) & \cos(\theta_{j\nu}/2)\exp(-i\phi_{j\nu}/2) \end{pmatrix}, \quad (2)$$

which describes the transformation between a global and a local spin coordinate system to be defined subsequently. We use the label j to designate the unit cell and the label ν the basis atom. The polar angles $\theta_{j\nu},\phi_{j\nu}$ give the direction of the local magnetization, in Cartesian coordinates

$$\mathbf{m}_{j\nu} = m_{\nu}\cdot(\cos\phi_{j\nu}\sin\theta_{j\nu},\ \sin\phi_{j\nu}\sin\theta_{j\nu},\ \cos\theta_{j\nu}), \quad (3)$$

with respect to a global coordinate system and

$$\mathbf{V}_{\nu}(\mathbf{r}_{j\nu}) = \begin{pmatrix} v_{\nu\uparrow}(\mathbf{r}_{j\nu}) & 0 \\ 0 & v_{\nu\downarrow}(\mathbf{r}_{j\nu}) \end{pmatrix} \quad (4)$$

is the spin-polarized potential of the atom at site $(j\nu)$ in the local frame of reference. The potential is unambiguously given by functional derivatives of the total energy in the local density approximation;[12,22] it is centered at $\mathbf{r}_{j\nu} = \mathbf{r} - \boldsymbol{\tau}_{\nu} - \mathbf{R}_j$ and is assumed to vanish outside its atomic sphere, $\Omega_{j\nu}$. The local frame of reference is defined as follows; designating by $\boldsymbol{\rho}_{j\nu}$ the density matrix integrated over

 0021-8979/94/76(10)/6694/6/$6.00 © 1994 American Institute of Physics

the atomic sphere $\Omega_{j\nu}$, i.e., $\rho_{j\nu} = \int_{\Omega_{j\nu}} \Sigma_{i\in occ} \psi_i(\mathbf{r})\psi_i^+(\mathbf{r})d^3r$, where the $\psi_i(\mathbf{r})$ are solutions of the Schrödinger equation with the Hamiltonian given by Eq. (1), we define the local frame of reference by those polar angles for which $\mathbf{U}(\theta_{j\nu},\phi_{j\nu})\rho_{j\nu}\mathbf{U}^+(\theta_{j\nu},\phi_{j\nu})$ is diagonal. Strictly speaking, one should make this transformation at every point in space and Korenman *et al.*[3] show what this entails. But we believe the essential physics is obtained by making an atomic-sphere approximation, thus averaging over the local directions in each sphere this way replacing a fine-grained mesh by a coarse-grained mesh given by the atomic spheres. When the polar angles are chosen to render the integrated density matrix diagonal we call the angles self-consistent.

The polar angles $\theta_{j\nu}$ and $\phi_{j\nu}$ can now be chosen to model any desired collinear or noncollinear moment arrangement. However, to guarantee translational invariance most general types of order require larger magnetic unit cells (supercells) than the crystallographic (chemical) unit cell. This can quickly lead to an insurmountable numerical problem. Fortunately there exists a type of magnetic order that does not require such large supercells. It is a helical or spiral order that was, to our knowledge, first described by Herring.[23] Here the direction of the magnetic moment of each atom in the unit cell rotates around the z axis with a particular wave vector $\mathbf{q}$ which is defined by specifying the polar angles as $\theta_{j\nu}=\theta_\nu$, $\phi_{j\nu}=\phi_\nu+\mathbf{q}\cdot\mathbf{R}_j$. Herring introduced a generalized translation operator which combines a spin rotation with a space translation; it is constructed such that it commutes with the Hamiltonian forming an Abelian group, isomorphic with the group of ordinary space translations. Therefore a generalized Bloch theorem for the eigenfunctions exists which may be labeled by a $\mathbf{k}$ vector as usual. This means that for any choice of the vector $\mathbf{q}$ it is the chemical Brillouin zone that constitutes the domain for the $\mathbf{k}$ vectors to be used for sampling the elements of the density matrix. Details can be found in Refs. 23, 24, 13, and 14.

Using the generalized Bloch theorem we expand the wave functions $\psi_k(\mathbf{r})$ in terms of the atomic bispinor functions $\phi_{k\nu L\sigma}(\mathbf{r})$ in the following form:

$$\psi_k(\mathbf{r})=\sum_{\nu L\sigma} C_{\nu L\sigma}(\mathbf{k})\mathbf{U}_\nu^+\phi_{\mathbf{k}\nu L\sigma}(\mathbf{r}). \tag{5}$$

Here the coefficients $C_{\nu L\sigma}(\mathbf{k})$ are obtained by minimizing the expectation value of the Hamiltonian using the variational method and for the basis functions, $\phi_{\mathbf{k}\nu L\sigma}(\mathbf{r})$, we employ augmented spherical waves (ASW)[25] defined in the local frame of reference; details may again be found in Refs. 13 and 14.

At this stage we can calculate the total energy as a function of the volume and a given type of magnetic order, most notably of the wave vector $\mathbf{q}$, whereas the value of the local magnetic moment normally is the result of a self-consistent calculation. However it is advantageous to know the total energy, as a function of the volume, the $\mathbf{q}$ vector, and the magnetic moment (comparable to a thermodynamic potential). For a ferromagnet this was achieved in the past by the so-called fixed-spin-moment method, see, for instance, Refs. 26–28, where the total energy, $E(m)$, of the state having a magnetic moment m per unit cell is obtained from a constrained variation.

For a general noncollinear spin structure the constrained variation must be formulated as

$$E(\{\mathbf{m}_\mu\})=\min\left\{E[\mathbf{m}(\mathbf{r})] + \sum_\nu \mathbf{b}_\nu\left(\int_{\Omega_\nu}\mathbf{m}(\mathbf{r})d^3r-\mathbf{m}_\nu\right)\right\}, \tag{6}$$

where on the left-hand side $\{\mathbf{m}_\mu\}$ is the set of desired moments at the sites (μ). On the right-hand side the vector parameters $\mathbf{b}_\nu$ can be treated as magnetic fields acting on the spin densities of the corresponding atoms. The component of $\mathbf{b}_\nu$ parallel to $\mathbf{m}_\nu$ stabilizes the magnitude of the moment and the perpendicular component counteracts the torque that is produced by the nondiagonal density matrix. In self-consistent spin arrangements the density matrix by definition is diagonal in the local frame of reference; thus in Eq. (6) the vectors $\mathbf{m}(\mathbf{r}),\mathbf{m}_\nu,\mathbf{b}_\nu$ are parallel and we may drop the vector symbols. These conditions apply to our calculations when we use planar spin spirals which are defined by $\theta_\nu=90°$ for all sites (ν).

The variation of Eq. (6) yields the Hamiltonian

$$\hat{\mathbf{H}}(\mathbf{r})=-\nabla^2 1+\sum_{j\nu}\mathbf{U}^+(\theta_{j\nu},\phi_{j\nu}) \times[\mathbf{V}_\nu(\mathbf{r}_{j\nu})+\sigma^z b_\nu(\mathbf{r}_{j\nu})]\mathbf{U}(\theta_{j\nu},\phi_{j\nu}). \tag{7}$$

Here the constraining fields $[b_\nu(\mathbf{r}_{j\nu})=b_\nu$ inside the sphere (ν) and zero outside] must be adjusted such that the resulting moments coincide with the those wanted: $\int_{\Omega_\nu} m(\mathbf{r})d^3r = m_\nu$. We emphasize that the Hamiltonian, Eq. (7), is not diagonal in the spin quantum numbers, a fact that leads to spin-hybridized energy bands.[10,13,29] Therefore the concept of two Fermi energies for bands with different spin indices cannot be applied here. Instead, to do the actual constrained calculations for noncollinear configurations one proceeds iteratively as described in detail in Ref. 14.

III. RESULTS AND DISCUSSION

We will begin with the case of Fe_3Pt-Invar stating some very basic facts first. It crystallizes in the Cu_3Au structure and is ordered such that Pt occupies the cube corners and Fe the face centers. The atomic-sphere approximation used in our calculations requires the choice of sphere radii for the constituents which were such that the atomic spheres were neutral to within about 0.2 electrons per sphere. To a good approximation this leads to a minimum in the total energy at a given volume and is found to require equal sphere radii for all volumes and states of magnetic order considered.

The ground state of Fe_3Pt is calculated to be ferromagnetic for a sphere radius, S, of $S=2.79$ a.u. possessing magnetic moments of $m_{Fe}=2.67\ \mu_B$ and $m_{Pt}=0.27\ \mu_B$. The corresponding lattice constant is $a=3.77$ Å which is somewhat larger than the experimental lattice constant of $a=3.73$ Å.[30] The calculated magnetic moment corresponds to $m=2.07\ \mu_B$

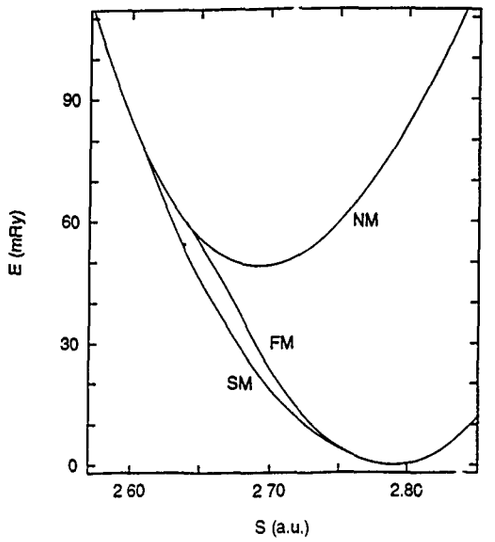

FIG. 1. Total energy per unit cell of Fe_3Pt as a function of the Wigner–Seitz radius, S. NM: nonmagnetic, FM: ferromagnetic, and SM: spiral magnetic.

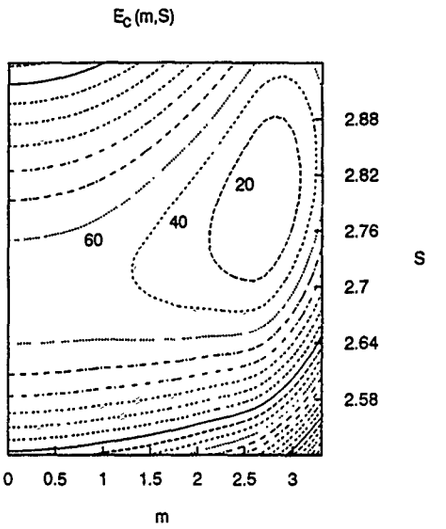

FIG. 2. Contours for Fe_3Pt of the collinear contribution to the total energy, E_c, see Eq. (8), in mRy per unit cell. S: Wigner–Seitz radius in atomic units and m: magnitude of the magnetic moment in μ_B.

per atom which is slightly smaller than the experimental value of $m=2.16\ \mu_B$ per atom quoted by Shimizu.[31] Our results differ somewhat from the results of previous calculations[32] (see also Ref. 17) in particular in the numerical values of the total energy difference between the ferromagnetic and nonmagnetic states, the values of the equilibrium lattice constant, and the equilibrium magnetic moment. This is so because our calculations are not relativistic in contrast to the older calculations where the scalar-relativistic wave equation (SRWE)[33] was used. In the earlier stages of these calculations we noticed that results for Fe_3Pt obtained without relativistic corrections were closer to experimental ground-state properties than those obtained with the SRWE. We thus purposely dropped the relativistic corrections. This is our only justification for the approach used here.

Continuing with the discussion of our results we find that spin-spiral states having $\theta_\nu=90°$ for all sites (ν) possess the lowest total energy for a wide range of volumes smaller than the calculated equilibrium volume. Furthermore, the collinear antiferromagnetic state is higher in energy than the ferromagnetic state. The total energy as a function of the atomic-sphere radius is shown in Fig. 1 for the nonmagnetic, ferromagnetic, and spin-spiral states. The lowest energy for a wide range of volumes is obtained approximately for $q=0.25$. This can be translated into the angle between the moments of two neighboring ferromagnetic planes obtaining about 90°.

Numerical experiments showed that the total energy can be written as

$$E(v,m,\mathbf{q})=E_c(v,m)+\alpha(v)E_q(m,\mathbf{q}). \tag{8}$$

Here $\alpha(v)$ is a slowly varying scaling factor which for the volume range investigated is $\alpha(v)\simeq(v_0/v)^4$, where v_0 is the equilibrium volume. The first term on the right-hand side, E_c, we may call the collinear and the second, E_q, the noncollinear contribution to the total energy. This empirical relationship greatly facilitates the discussion, so we show in Fig. 2 the collinear and in Fig. 3 the noncollinear contribution to the total energy. Here, from Fig. 3 we find for a given local moment, m, the value of q corresponding to the state with the lowest total energy and from Fig. 2 the relevant value of the volume, v. Figure 3 shows that for $m>2.6\ \mu_B$ the energy is lowest in ferromagnetic order and for $m<2.6\ \mu_B$ the energy is minimized by a spin-spiral structure with values of q lying in the interval from 0.2 to 0.3. Note that the

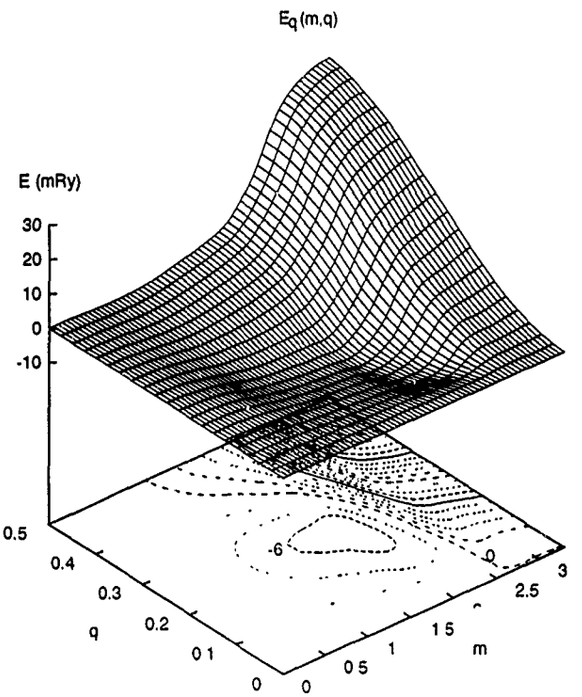

FIG. 3. Contours and surface for Fe_3Pt of the noncollinear contribution to the total energy, E_q, see Eq. (8), in mRy per unit cell. m: magnitude of the magnetic moment in μ_B and q: magnitude of the spiral vector in units of $2\pi/a$ along the (1,1,1) axis.

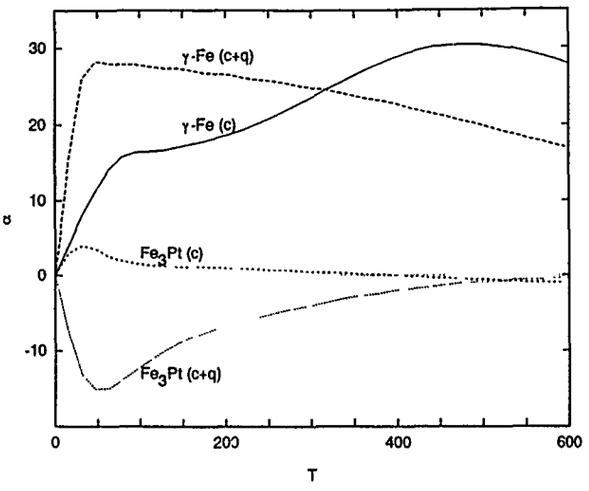

FIG. 4. Expansion coefficient α as a function of temperature T calculated for γ-Fe and Fe_3Pt; (I) using only collinear states (c) and (II) including collinear and noncollinear states ($c+q$).

noncollinear portion of the total energy $E_q(m,q)$ has a clear tendency to increase for large m, see Fig. 3. In particular the noncollinear contribution, $E_q(m,q)$, is negative for states with small moments, ($m<2.6\ \mu_B$), and positive for states with large moments, ($m>2.6\ \mu_B$). If we assume that the calculated energy surfaces are also realized at finite temperatures, this contribution upon heating leads to a preferable occupation of noncollinear states having local magnetic moments smaller than the ground-state value of $m_0=2.67\ \mu_B$.

In Ref. 14 we described a rather simple-minded scheme for statistical averages showing that the excited states modeled above give indeed important contributions to thermodynamic properties. We do not, however, claim to have a consistent scheme that enables us at the present stage to compute thermodynamic potentials and the magnetic phase transition. Still, using the computed energy surfaces we calculate the temperature dependence of the magnetic contribution to the expansion coefficient, $\alpha(T)$, from the derivative with respect to the temperature of the average value of the specific volume $\langle v(t)\rangle$. The calculations were done with and without taking into account noncollinear states and the result is shown in Fig. 4 which also contains results for γ-Fe to be discussed shortly. It is seen that with the use of only collinear magnetic states the coefficient $\alpha(T)$ is positive at very low temperatures and nearly zero for higher temperatures. Inclusion of noncollinear configurations leads to a negative sign of $\alpha(T)$ over a wide temperature range; this is one of the most prominent effects associated with Invar. The thermal expansion coefficient due to magnetic effects has been obtained experimentally.[34] Its sign and order of magnitude are in agreement with our results, although the functional form, especially an experimental peak slightly below T_C, is not brought out by our calculations.

The information on the total energy of spiral structures can also be used for a rough estimate of both the Curie temperature, T_C, and the spin-wave stiffness constant, D. The Curie temperature T_C can be estimated within the mean field approximation to the Heisenberg Hamiltonian. Neglecting the magnetic contribution of platinum, the Curie temperature is given by $T_C=J(0)(m_0+2)/3m_0$. Here the exchange parameter $J(0)$ is calculated by

$$J(0)=\Omega_{BZ}^{-1}\int_{BZ} d^3q\,\Delta E(\mathbf{q}),$$

where $\Delta E(\mathbf{q})=[E(v_0,m_0,\mathbf{q})-E(v_0,m_0,0)]/3$ is the total energy per Fe atom counted from the ground state and Ω_{BZ} is the volume of the Brillouin zone. Our calculations give $T_C=435$ K, which is in good (probably fortuitous) agreement with the experimental value of ordered Fe_3Pt, $T_C=430$ K.[17] We hasten to point out that we do not imply here that the localized-electron picture is appropriate for a description of the magnetovolume effects.

To estimate the spin-wave stiffness constant D we use the following expression (Ref. 35): $D=(4/m_0)\times\lim_{q\to 0}\Delta E(\mathbf{q})/|\mathbf{q}|^2$, with $\Delta E(\mathbf{q})$ defined above, we obtain the value of $D=135$ meV Å^2 which should be compared with the value of $D=80$ meV Å^2 for $Fe_{72}Pt_{28}$.[17,36]

Let us now briefly turn to the case of γ-Fe which was discussed in great detail in Ref. 13 and 14. Here it suffices to point out that the magnetic structures that can occur with low total energy depend sensitively on the volume. In agreement with older work[37–39] we find that there exist ferromagnetic states having high magnetic moments at volumes larger than the bcc-equilibrium volume. New in our calculations is the occurrence of spiral magnetic states at volumes larger than the equilibrium volumes but having lower total energies than the ferromagnetic states. We could show that these states are being measured by neutron diffraction experiments on γ-Fe precipitates in copper.[40] Since these states occur at large volumes (in contrast to Fe_3Pt where they occur at small volumes, see Fig. 1) they are responsible for the large positive thermal expansion coefficient that is shown in Fig. 4.

The object of these previous calculations was either iron in the bcc structure (α-Fe) or in the fcc structure (γ-Fe). Since at constant atomic volume the bcc structure can be continuously deformed to the fcc structure, the latter appearing as a body centered tetragonal with a value of $c/a=\sqrt{2}$, we now describe results of new calculations in which we focus our attention on the possible magnetic states of tetragonal iron with $1\leq c/a\leq\sqrt{2}$. These states may occur in epitaxially grown iron, but we remind the reader that our calculations are for bulk materials and not for surfaces. Thus, in view of possible effects due to lowered dimensionality, our results should be understood to describe real cases perhaps only semiquantitatively. In Fig. 5 we show the total energy counted from some suitable but arbitrary origin and the local magnetic moment for three different volumes labeled by the Wigner–Seitz radius R_{WS} as a function of the spiral $\mathbf{q}$ vector. The value of $R_{WS}=2.646$ corresponds to the equilibrium volume of bcc iron and it is seen that bcc Fe ($c/a=1$) is stable for $q=0$ which is the ferromagnetic state; up to about $c/a=1.2$ iron is ferromagnetic, but fcc Fe at this volume is nonmagnetic at $q=0$ having a metastable spiral magnetic state with a reduced magnetic moment at about $q=0.6$. At a somewhat larger volume ($R_{WS}=2.67$) the range of stable ferromagnetic states is increased, $1\leq c/a<1.3$, but fcc Fe still appears to have a spiral magnetic state. For a large volume

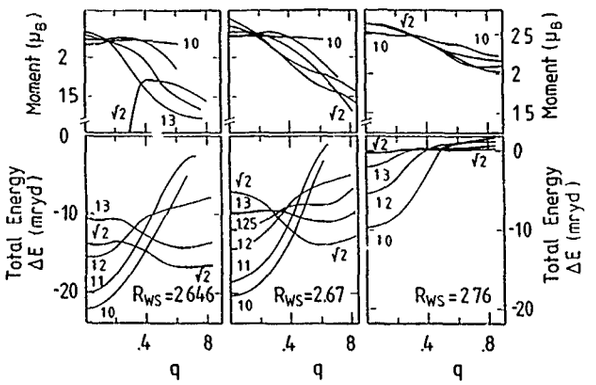

FIG. 5. Total energy and local magnetic moment of iron as a function of q, the magnitude of the spiral vector in units of $2\pi/a$, for three different volumes labeled by the Wigner–Seitz radius, R_{WS}; the parameters labeling the different curves give the values of c/a, $c/a=1$: bcc Fe, $c/a=\sqrt{2}$: fcc Fe, values in between: tetragonal iron.

corresponding to $R_{WS}=2.76$ fcc Fe is now barely stable in a ferromagnetic state, but we may speculate that its Curie temperature could be rather low because the flatness of the total energy as a function of q signals small interatomic exchange constants.

We will close this section by discussing new but preliminary results for Fe-Cr multilayers. This modern topic has received considerable attention recently by many research groups whose work, unfortunately, we have no space to cite here properly. Concentrating instead on the work of only the Jülich group[18–20] and only on a few salient facts we may state that depending on the spacer (chromium) thickness, iron layers experimentally appear to be coupled ferromagnetically, antiferromagnetically, or in a 90° configuration. One therefore postulates that the exchange coupling between Fe layers can be written as $H_c=-A_1\cdot\cos\theta-B_1\cdot\cos 2\theta$ where the second term on the right-hand side is the biquadratic coupling term. This type of coupling among other things shows up in hysteresis loops as steps in the magnetization. To our knowledge it is still not clear whether this coupling is intrinsic or extrinsic.[41]

A simple multilayer was simulated[42] by continuing periodically two closed packed (CP) layers of Fe, two CP layers of Cr, and two CP layers of Fe. The two Fe layers were found to be coupled antiferromagnetically by the chromium spacer. Next a magnetic field in the global frame of reference is turned on and increased slowly iterating the system to self-consistency at each chosen value of the magnetic field until eventually the field has aligned the Fe moments ferromagnetically. We find that the reorientation of the magnetic moments happens in steps first at about 120° then at about 30° between the Fe moments. The steps, however, are not as pronounced as in the experimental hysteresis curves. The total energy calculated was fitted to H_c above by separately taking care of the Zeeman energy. The result was $B_1/A_1\simeq 0.16$ which is in fair agreement with the value $B_1/A_1\simeq 0.13$ quoted in Ref. 18. We add, however, that the separate values of A_1 and B_1 are obtained to be about one order of magnitude larger than the experimental estimates. Furthermore we emphasize that in our calculations the spin-orbit coupling, i.e., the magnetocrystalline anisotropy, and any roughness between the layers were neglected. Therefore, even though our results are tentative at best and our simulated multilayer may not really represent reality, we conclude that the biquadratic coupling is an intrinsic property that is due to certain features in the electronic structure of the Fe-Cr layers that still need to be clarified.

IV. CONCLUSION

For itinerant-electron magnets we succeeded in describing the vector nature of the magnetic moments whose magnitude and direction are treated in noncollinear constrained moment calculation as independent variables for an *ab initio* calculation of the total energy. This supplies the energetics of spin fluctuations and enabled us to make a step—although crude—in the direction of determining finite-temperature properties. Our calculations describe the magnetovolume properties of Fe_3Pt and the results agree with experimental facts in a semiquantitative way, notably with the Invar behavior. On first sight it does not appear surprising that in Fe_3Pt with increasing temperature the magnetic moment and thus the specific volume decrease. One should bear in mind, however, that the decreasing magnetic moment is not the usual decreasing thermal average but is brought about by longitudinal spin fluctuations that are triggered by transverse fluctuations.

Furthermore, we discussed the possible states of tetragonal iron and estimated the volume at which fcc Fe is ferromagnetic by studying the total energy as a function of the spiral **q** vector. Finally we calculated the energetics of reorienting antiferromagnetically coupled Fe layers in Fe-Cr and estimated the ratio of the bilinear and biquadratic exchange constants concluding that the biquadratic coupling might be of intrinsic origin.

Verwey transition in magnetite: Mean-field solution of the three-band model

S. K. Mishra, Z. Zhang,[a] and S. Satpathy
Department of Physics and Astronomy, University of Missouri, Columbia, Missouri 65211

The nature of the Verwey transition in magnetite (Fe_3O_4) within a three-band spinless model Hamiltonian is examined. These bands, which arise from the minority-spin t_{2g} orbitals on the Fe(B) sublattice, are occupied by half an electron per Fe(B) atom. The Verwey order–disorder transition is studied as a function of the ratio of the intersite Coulomb repulsion U_1 and the bandwidth W. It is found that the electrons are ordered beyond the critical value of $U_1/W \approx 0.25$ in essential agreement with the results of the one-band Cullen–Callen model. For larger values of U_1/W, a Verwey-like order is exhibited where the electrons occupy alternate (001) planes. The model predicts a transition from the metallic to the semiconducting state with the band gap increasing linearly with U_1 beyond the transition point.

I. INTRODUCTION

The Verwey transition in magnetite[1–3] is a well-known metal–insulator transition characterized by a decrease of two orders of magnitude in conductivity as temperature is decreased below the Verwey temperature of $T_v \sim 120$ K. The transition is accompanied by an order–disorder transition, where in the simplest ionic picture, Fe^{2+} and Fe^{3+} ions order on the B sublattice of the spinel structure, interacting via Coulomb forces. Examining this picture quite early on, Anderson[4] pointed out the remarkable property of the spinel B sublattice that the short-range part of the Coulomb interaction is minimized by $\sim(3/2)^{N/2}$ different configurations of the ions where N is the number of sites on the B sublattice. The long-range part of the Coulomb interaction, on the other hand, is minimized only by a few of these configurations. The Verwey transition may therefore be interpreted as a loss of long-range order (LRO) above T_v with no abrupt change in the short-range order (SRO). This interpretation is consistent with the entropy change at the Verwey transition obtained from specific heat measurements.

This ionic picture, while providing a reasonable description of the order–disorder transition, does not provide any quantitative description of the transition from metal to insulator. Issues unaddressed include questions such as: What are the charge carriers in magnetite? Is the conductivity via motion of ions or does one has to think of itinerant electrons? In fact, subsequent to Anderson's work, a number of models have been proposed to describe the mechanism of electrical conduction and simultaneously the order–disorder transition. These include the itinerant one-band electron model of Cullen and Callen,[5] and the molecular polaron or bipolaron pictures of Yamada and Chakraverty,[6] etc.

The itinerant electron model of Cullen and Callen describes the Verwey transition in terms of motion of electrons on the B sublattice. The Hamiltonian consists of a nearest-neighbor hopping integral t and the intersite Coulomb interaction U_1 between nearest neighbors. In a seminal work,[5] Cullen and Callen studied this model and in fact found an order–disorder transition below a critical value of $U_1/t \sim 2.2$. However, there was no justification for the origin of such a model and, since there was no reliable estimate for U_1/t until our recent work,[7] the applicability of the Cullen–Callen model to magnetite remained unclear.

Recently we have examined the electronic structure of magnetite using density-functional methods with the local spin-density approximation (LSDA).[7] Based on this work, we have obtained a three-band electronic Hamiltonian for the motion of electrons on the B sublattice of magnetite. In this article, we discuss the results of a mean-field solution of the three-band model. We find that both (a) the order–disorder transition and (b) the metal–insulator transition can be described within the three-band model.

II. THE MODEL HAMILTONIAN

The crystal structure of magnetite consists of three sublattices, viz., the oxygen sublattice and the Fe(A) and the Fe(B) sublattices. The magnetic moments within each Fe sublattice are aligned in the same direction, while the two sublattices are aligned antiferromagnetically. Since there are twice as many atoms on the B sublattice as on A, there is a net magnetic moment with a magnitude of 4.1 μ_B per Fe_3O_4 formula unit.

In our earlier work,[7] we have calculated the density-functional spin-polarized electronic structure of magnetite, which is schematically shown in Fig. 1. As seen from the figure, the majority-spin bands are semiconducting, while the minority-spin bands are metallic, a picture also obtained by Yanase and Siratori from independent calculations.[8] The presence of only the minority-spin electrons at the Fermi energy is consistent with the spin-polarized photoemission experiments of Alvarado *et al.*[9]

The t_{2g} orbitals of the Fe(B) atoms form the electron bands at the Fermi energy E_f with the t_{2g} bands occupied by half an electron per Fe(B) atom. The electron count is such that the presence of these "extra" electrons makes the valency of half the B site atoms Fe^{+2} and the other half B site atoms have the valency of Fe^{+3}. The picture that emerges then is that the "extra" electrons move on the background of Fe^{+3} atoms on the B sublattice in agreement with the traditional view of charge transport in magnetite.[4]

The electronic structure provides justification for the conventional picture of conduction via Fe(B) electrons moving on the B sublattice. However, unlike the one-band pic-

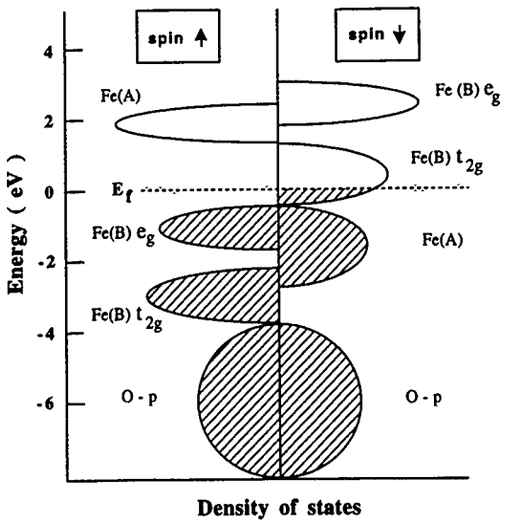

FIG. 1. Schematic picture of the electronic structure in magnetite as obtained from the density-functional band calculation (Ref. 7). The minority spin t_{2g} electrons on the Fe(B) sublattice play the key role in charge transport.

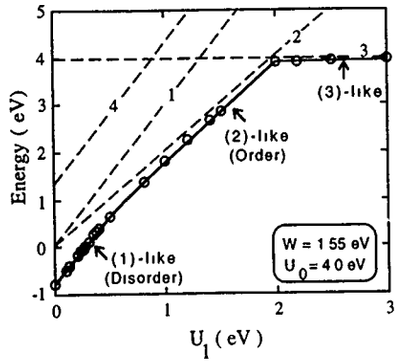

FIG. 2. Ground-state energy as a function of U_1. The dashed curves correspond to energies in the limit of zero hopping (no kinetic energy term) for various configurations. The configurations are characterized by the mean occupation of the xy,yz,zx orbitals on the four Fe(B) atoms, viz., (1) {1/2,0,0; 1/2,0,0; 1/2,0,0; 1/2,0,0}, (2) (1,0,0; 1,0,0; 6∗0}, (3) {1,1,0; 9∗0}, and (4) {12∗1/6}. The Coulomb energy of the four configurations are (1) $E=3U_1$, (2) $E=2U_1$, (3) $E=U_0$, and (4) $E=U_0/3+3U_1$. Even though the Coulomb energy of configuration (1) is relatively high, the large kinetic energy gain for this configuration makes it the ground state for lower values of U_1. Configuration (2) wins beyond the transition point of $U_1\approx0.38$ eV because of its lower Coulomb energy.

ture of Cullen and Callen, we now have the three t_{2g} bands (xy, yz, and zx), which leads to a three-band electron model on the B sublattice

$$H=\sum_{\langle ij\rangle}\sum_{\mu,\nu=1}^{3} t_{\mu,\nu}a_{i\mu}^{+}a_{j\nu}+\sum_{ij}\sum_{\mu,\nu=1}^{3} U_{i\mu,j\nu}n_{i\mu}n_{j\nu}. \quad (1)$$

Here $a_{i\mu}^{+}(a_{i\mu})$ are the creation (annihilation) operators of the electron on the B sublattice with i, μ being the site and orbital indices (xy,yz,zx), respectively, $n_{i\mu}$ is the corresponding number operator, and $\langle ij\rangle$ denotes summation over nearest neighbors (NN). The Hamiltonian (1) consists of a tight-binding NN hopping term (the band-structure term) plus the Coulomb interaction term.

The values of the electronic parameters in the Hamiltonian (1), calculated from "constrained" density-functional methods,[7] have the following values for magnetite: (a) the hopping integrals $t_{dd\sigma}=-0.41$ eV, $t_{dd\pi}=0.05$ eV, and $t_{dd\delta}=0.12$ eV, resulting in an average $t\approx-0.13$ eV and a bandwidth of $W=1.55$ eV and (b) the Coulomb parameters $U_0=4.1\pm0.5$ eV, $U_1=0.3$–0.4 eV, and $U_2\approx0.05$–0.1 eV. Here the on-site Coulomb repulsion is denoted by U_0 and the first and the second NN Coulomb terms are denoted by U_1 and U_2, respectively. Since U_0 is much larger than U_1 and $t_{\mu\nu}$, double site occupancy is prevented in view of the fact that there are half as many electrons as the B sites. Although a small value of U_2 is necessary to stabilize[10] the experimentally observed "Mizoguchi structure" at low temperatures,[11] a structure where the unit cell is doubled, U_2 is an unimportant parameter for our purpose here. In our study below, we choose the values of $U_0=4$ eV and $U_2=0$, leaving thereby the only relevant parameter U_1/W in the Hamiltonian.

III. MEAN-FIELD SOLUTION

We study the Verwey transition by solving the Hamiltonian (1) in the mean-field approximation. We retain the periodicity of the spinel structure, which means the electrons can occupy any of the twelve orbitals [four Fe(B) atoms × three orbitals/atom] in the unit cell. In the standard mean-field approximation, we have

$$n_{i\mu}n_{j\nu}\cong\langle n_{i\mu}\rangle n_{j\nu}+n_{i\mu}\langle n_{j\nu}\rangle-\langle n_{i\mu}\rangle\langle n_{j\nu}\rangle. \quad (2)$$

Incorporating the first two terms in the band-structure part of Eq. (1), the total energy may then be written as a sum over the occupied one-electron eigenvalues ε_i minus the Coulomb energy

$$E=\sum_{i}^{\varepsilon_F}\varepsilon_i-E_{\text{Coulomb}}. \quad (3)$$

The mean electron occupations $\langle n_{i\mu}\rangle$ are calculated from the eigenfunctions of the Hamiltonian (1), which in turn depends on $\langle n_{i\mu}\rangle$. These are then determined self-consistently. The procedure is thus to diagonalize the 12×12 Hamiltonian matrix for each k point in the Brillouin zone and find the $\langle n_{i\mu}\rangle$ from the eigenvectors of the occupied states. We then go back and find the eigenvalues and eigenvectors taking these new values of $\langle n_{i\mu}\rangle$ in the Hamiltonian. The process is repeated until $\langle n_{i\mu}\rangle$ values have converged, which then corresponds to the minimum energy configuration. We performed the eigenvalue summation in the expression (3) with 216 k points in the full Brillouin zone.

The calculated ground-state energy is shown in Fig. 2 as a function of the parameter U_1. The dashed curves refer to the energies of selected configurations without the band-structure term, i.e., in the limit of zero bandwidth. Without the band-structure term, the ordered phase, denoted by configuration (2) in Fig. 2, has the lowest energy for all values of $U_1\leq2$ eV. This phase has the electron configuration where two of the four sites in the unit cell have an electron each and the other two sites are empty. However, with the inclusion of

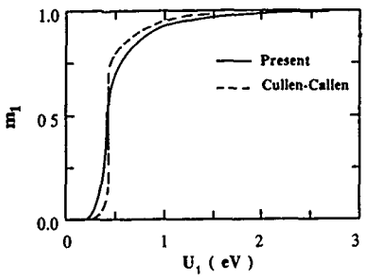

FIG. 3. The calculated Cullen–Callen order parameter m_1 as a function of the nearest-neighbor Coulomb energy U_1.

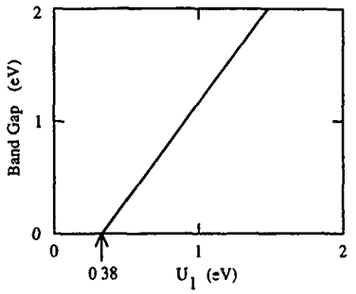

FIG. 4. Band gap as a function of the nearest-neighbor Coulomb energy U_1. A metal–insulator transition is seen at the value of U_1=0.38 eV.

the band-structure term, the disordered phase, viz., configuration (1), with half an electron on each site, has the lowest energy for the smaller values of U_1. For higher values of U_1, the Coulomb energy of configuration (1) becomes progressively larger and the ordered phase, configuration (2), wins over thereby resulting in a structural phase transition as indicated in the figure. Thus the transition is a result of the competition between the kinetic energy (band-structure energy) and the Coulomb energy.

The ordered phase is similar to the Verwey order with electrons occupying alternate (100) planes in the cubic structure. The so-called "Mizoguchi" structure,[11] inferred to be the structure of magnetite at low temperatures, where the unit cell has doubled compared to the cubic cell, is not reproduced in our calculation because we have restricted ourselves to the cubic unit cell of the spinel structure. To study the nature of the transition, we define the order parameters following earlier authors:[5]

$$m_1=(n_1+n_2-n_3-n_4)/2,$$
$$m_2=(n_1-n_2+n_3-n_4)/2, \tag{4}$$
$$m_3=(n_1-n_2-n_3+n_4)/2,$$

and

$$n=(n_1+n_2+n_3+n_4)=2.$$

Here $n_i=\Sigma_{\mu=1}^{3}\langle n_{i\mu}\rangle$. For perfect order $m_1=1$, while for perfect disorder $m_1=0$.

The calculated order parameter m_1 as a function of the Coulomb parameter U_1 is shown in Fig. 3, where we also reproduce the results of the one-band Cullen–Callen model. There is a rather sharp transition around the value of $U_1\approx0.38$ eV in both the Cullen–Callen model and the present three-band model. The order parameters m_2 and m_3 are zero everywhere except the transition region corresponding to "multiple order,"[5] an issue we have not examined yet in any detail.

We have also calculated the mean-field electronic eigenvalues (band structure). The bands are metallic until the transition point beyond which a band gap develops with the gap value increasing linearly with U_1 as shown in Fig. 4.

IV. CONCLUSION

In conclusion, we have studied the three-band model for the Verwey transition in magnetite in the mean-field approximation. The Verwey transition is described in terms of the order–disorder transition of the t_{2g} "extra" electrons on the B sublattice. Whether these electrons are ordered or not depends on the relative strengths of the Coulomb energy and the kinetic energy, characterized by the Coulomb parameter U_1 and bandwidth W, respectively. For lower values of the Coulomb parameter, a disordered state is favored, while a larger value results in an ordered state with the crossover taking place at the ratio $U_1/W\approx0.25$. The ordered state in our calculation has a Verwey-like order, where alternate (001) planes on the B sublattice are occupied by the "extra" electrons. We have shown earlier[10] that given the degree of freedom (larger unit cell) the kinetic energy term destabilizes the Verwey order into the experimentally observed Mizoguchi order. Finally, even though the Verwey transition occurs as temperature is changed, our present results pertain to zero temperature with the Verwey transition taking place as electronic parameters are varied. We are currently studying the Verwey transition within a finite-temperature mean-field theory. Preliminary results indicate that our model can explain the experimentally observed Verwey transition as a function of temperature.[12]

Wannier states in magnetite

Trao Her and Carel Boekema
Physics Department, San Jose State University, San Jose, California 95192-0106

Magnetite exhibits the well-known metal–insulator transition at the Verwey temperature (T_V) near 123 K. Neither the physical origin nor the conduction process above T_V is well understood. Using the Cullen and Callen tight-binding Hamiltonian, the "extra" fully spin-polarized $3d$ conduction electrons in the B sublattice are described. By introducing a covalency parameter Γ, the Wannier states for these conduction electrons can be characterized. Only for the lower singlet subband, does the Γ value point toward delocalization. The results reveal that the Wannier states in magnetite are a mixture of localized and delocalized electron states.

I. INTRODUCTION

The debate on the origin of the Verwey phase transition in magnetite (Fe_3O_4) and its unusual physical properties observed above this transition still continue.[1] Fe_3O_4 is a mixed-valence oxide material that undergoes a metal-to-insulator transition at the Verwey temperature (T_V) near 123 K. Several models, ranging from electron hopping to broadband conduction, have been proposed for the conduction mechanism above T_V. The local-magnetic-field anomaly[2] in Fe_3O_4 observed at twice T_V (T_W) has provided new stimulus in magnetite studies, and clearly marked the temperature interval $[T_V, T_W]$, for which precursor effects related to the Verwey transition occur.

Fifteen years ago, Mott and others[1a] suggested that above T_V Fe_3O_4 behaves like a Wigner glass, in which the "extra" $3d$ electrons ($3d^*$) randomly occupy one-half of the B sites. According to Mott,[3] the electric properties of such a glass are best described by a narrow (polaron) band. Furthermore, combined experimental evidence involving muon-spin research (μSR), Moessbauer effect spectroscopy, and neutron scattering studies strongly support this picture of phonon-assisted electron hopping above T_V.[2a] Direct experimental proof of the Mott–Wigner glass state in Fe_3O_4 has been provided by the observation of the μSR cross-relaxation effect at T_W.[2]

Despite the progress made in recent years, additional study is needed. Some questions still remain: Are these $3d^*$ electrons localized and, is the Hubbard approach as performed by Ihle and Lorentz[4] justified? A study of the Wannier states of these "hopping" $3d^*$ electrons could provide answers to these questions and shed light on the origin of the Verwey phase transition. We have used the established Cullen and Callen (CC) Hamiltonian[5] as a starting point of our Wannier study of magnetite.

II. TIGHT-BINDING METHOD

Magnetite, which can be well described by $(Fe^{3+})_A[Fe_2^{3+}e^{-1}]_BO_4$, is a ferrimagnet and has an inverse spinel structure. The Fe ions at the A sites do not play a role in the conduction mechanism. The Fe ions in the B sites are surrounded by six oxygens in an octahedral environment. The unit cell has two molecules and thus four B sites. These four B sites share two $3d^*$ conduction electrons and are half occupied. The ferrimagnetic Neel temperature of 858 K and Hunds's rules impose that these $3d^*$ electrons are fully spin polarized below RT. In the trigonally distorted octahedron, the $d_{3(z')^2-r^2}$ electron state is the lowest in energy; z' being parallel to the $\langle 111\rangle$ axis. At the corners of a cube, the four B sites form a tetrahedron, the unit of the B sublattice. For this atomic unit, the quadruplet (available for the two $3d^*$ electrons) will split into a singlet and a higher triplet electron state, when considering an attractive potential at the B sites.

Cullen and Callen (CC) introduced the following one-band Hamiltonian for these $3d^*$ electrons in the B sublattice:[5]

$$H_{\alpha\beta}=H\{1+\exp(2i\mathbf{k}\tau_{\alpha\beta})\},\quad \alpha,\beta=0,1,2,\text{ or }3 \tag{1}$$

and

$$H_{\alpha\alpha}=0,\quad \alpha=0,1,2,\text{ and }3, \tag{2}$$

where α and β are B sites in the atomic unit, H is a negative constant transfer integral and is of the order of -0.05 eV,[2a,2b] and $\tau_{\alpha\beta}$ is a vector between sites α and β. In case the obtained Wannier states show substantial *de*localization, we may need to use the three-band Hamiltonian as proposed by Zhang and Satpathy.[1b] The total Bloch function $\Phi(\mathbf{r})$ for the $3d^*$ electrons reads

$$\Phi=\sum_{\alpha=0}^{3} c_\alpha(\mathbf{k})\Psi_\alpha, \tag{3}$$

where

$$\Psi_\alpha=N^{-1/2}\sum_{j}^{N}\{\exp(i\mathbf{k}\mathbf{R}_j)\}\psi(\mathbf{r}-\mathbf{R}_j-\mathbf{t}_\alpha). \tag{4}$$

$\mathbf{R}_j$ is the B sublattice vector and $\mathbf{t}_\alpha$ is the B site vector within the atomic unit.

The Wannier function W is defined as

$$W(\mathbf{r}-\mathbf{R}_i)=N^{-1}\sum_{\mathbf{k}}\sum_{j}\sum_{\alpha}\exp\{i\mathbf{k}(\mathbf{R}_j-\mathbf{R}_i)\}c_\alpha(\mathbf{k})\psi_{\alpha,j}. \tag{5}$$

The Wannier states are then evaluated to be

 0021-8979/94/76(10)/6703/2/$6.00 © 1994 American Institute of Physics

$$W^*W=\sum_{\mathbf{k}}\sum_{\alpha}\sum_{\beta} c_\alpha^*(\mathbf{k})c_\beta(\mathbf{k})\psi_\alpha^*\psi_\beta. \quad (6)$$

The $c_\alpha(\mathbf{k})$ are determined from solving

$$\sum_{\beta=0}^{3}\{H_{\alpha\beta}-EV(\mathbf{k})\delta_{\alpha\beta}\}c_\beta=0, \quad \alpha=0,1,2, \text{ and } 3, \quad (7)$$

where the eigenvalues $EV(\mathbf{k})$ are obtained from the determinant equation

$$|H_{\alpha\beta}-E(\mathbf{k})\delta_{\alpha\beta}|=0. \quad (8)$$

In nearest neighbor (nn) approximation, we then have

$$W^*W=\sum_{\mathbf{k}}\sum_{\alpha}|c_\alpha(\mathbf{k})|^2|\psi_\alpha|^2 + \sum_{\mathbf{k}}\sum_{\alpha\alpha'}^{\text{nn}}\sum c_\alpha^*(\mathbf{k})c_{\alpha'}(\mathbf{k})\psi_\alpha^*\psi_{\alpha'}. \quad (9)$$

In order to describe electron overlap and transfer, we introduce the mixing parameter Γ for each subband

$$\Gamma=\{\sum_{\mathbf{k}}\sum_{\alpha\alpha'}^{\text{nn}}\sum c_\alpha^*(\mathbf{k})c_{\alpha'}(\mathbf{k})\}\Big/\{\sum_{k}\sum_{\alpha}|c_\alpha(\mathbf{k})|^2\}. \quad (10)$$

When the covalency parameter Γ is negative or zero, antibonding and/or localization are indicated; when positive, more covalency and delocalization are present in the Wannier states.

III. CALCULATIONS AND RESULTS

Solving for the eigenvalues $EV(\mathbf{k})$'s of the CC Hermitian matrix $H_{\alpha\beta}$ is straightforward, and can be performed analytically. An important feature is that for all $\mathbf{k}$ directions a degenerate doublet exists *in*dependent of $\mathbf{k}$; this doublet was part of the triplet (see above) at $\mathbf{k}=0$. The obtained eigenvalues fully agree with the literature values.[5] The broadening of the upper singlet (departing from the $\mathbf{k}=0$ triplet) and the lower singlet is in the order of $|3H|$ (an estimate could be between 0.1–0.2 eV). To solve for the eigenvectors $c_\alpha(\mathbf{k})$, we have transformed the 4×4 Hermitian into a real symmetric 8×8 matrix following a standard recipe. In this way, Mathematica provides the eigenvectors in a convenient and correct way.

In Table I, the results on Γ and other relevant information are given.

TABLE I. Results on Γ.

$3d^*$ bands	Γ parameter	W^*W state	Occupancy 0 K	Broadening
Doublet	-1.4_5	very localized	0	0
Upper singlet	−0.0	localized	1	$<\|2H\|$
Lower singlet	+2.9	delocalized	1	$<\|2H\|$

The estimated values for Γ have been obtained by summing over 150 $\mathbf{k}$ points; these are estimates because complete convergence for the $\mathbf{k}$ sums has not been obtained. As one can see from the table, only one state has become delocalized. When the temperature increases from 0 K, this state is being emptied. However, the available (excited) empty states, especially the doublet state, are localized in this CC description. Therefore, we see no need to use a three-band Hamiltonian (see above); for now, the CC $H_{\alpha\beta}$ appears to be sufficient, and approximately correct.

IV. DISCUSSION AND CONCLUSIVE REMARKS

As $T\to 0$ K, only the lower and upper singlet bands will be occupied. Only at X (1,0,0) in the Brillouin zone, these singlets touch; otherwise, a gap exists having an effective width of the order of $|H|$. Thus, at sufficiently high temperatures of about T_V or T_W (when thermal energies are in the order of 0.01–0.02 eV), a localized behavior of the $3d^*$ states is predicted. The upper singlet and doublet (narrow) bands are primarily responsible for the conduction process; this is consistent with the Mott–Wigner glass description. Above T_W, our Wannier picture supports the idea of (phonon-assisted) electron hopping. However, this depiction is incomplete: the strong localization indicates the necessity to take into account Hubbard-like terms, as has been done (in the extreme limit) by Ihle and Lorentz[4] to describe the Coulombic $3d^*$-electron interactions. Also, Mishra and Satpathy[1c] have used Hubbard-like terms (together with the CC $H_{\alpha\beta}$) to study the atomic charge ordering below T_V.

Our present results reveal that the Wannier states in magnetite are a mixture of localized and delocalized electron states. Evidence for such a mixture is also exhibited in the electronic properties of the high-T_c cuprates. Similarities between the electronic and geometrical structures of Fe_3O_4 and $LiTi_2O_4$ and CuO-based superconductors suggest Wannier studies may provide substantial clues on the conduction mechanisms of these transition-metal oxides. Further work is in progress.

Orbital ordering and magneto-optical effects in CeSb

V. P. Antropov and B. N. Harmon

A. I. Liechtenstein
Max-Planck-Institut für Festkörperforschung, D-70506 Stuttgart, Germany

The influence of on-site Hubbard correlations on electronic structure and magneto-optical spectra of CeSb have been studied. As the new key mechanism to produce the large magneto-optical signal is linked to the interaction between the anisotropy of the Coulomb matrix and m-dependent p-f hybridization, this effect suggests a systematic search for materials with large magneto-optical effects.

Cerium monopnictides with the NaCl-type of structure are prototypical materials belonging to strongly correlated low-carrier-density systems which have attracted attention for their unusual spectral and magnetic properties and the difficulties in explaining them. There are controversial interpretations of the double peak structure of valence-band photoemission spectra,[1] different explanations for the de Haas–van Alphen (dHvA) data,[2] and limited understanding of the nature of the structural phase transitions for these systems.[3] Among the pnictides CeSb has a special position. In addition to the anomalies inherent to all monopnictides, CeSb has a large magnetic anisotropy together with a small crystal field splitting,[4] an extremely complicated magnetic phase diagram, including a type of Devil's staircase at low temperature,[5] and the largest known Kerr angle.[6] It turns out that the widely used local spin density approximation (LSDA) fails to predict many of the ground and excited state properties: the value of the equilibrium magnetic moment, the additional orbits found in de Haas–van Alphen experiments, the small density of states at the Fermi level, and the magneto-optics.[2,7]

In this communication we have used the so-called LDA+U method in rotation-invariant form[8] to describe the ground state electronic structure and the anomalies of the magneto-optical spectra of CeSb. Some details of the method were published in Ref. 9. It turns out that the results of the self-consistent band structure of CeSb are similar to those of the empirical p-f mixing model[10,11] and leads to improvement in the description of the magneto-optical (MO) spectra.

We used the full-potential scalar-relativistic linear muffin-tin orbital (LMTO) method[12] to calculate the self-consistent band structure of ferromagnetically ordered CeSb (this corresponds to the high field state obtained in MO experiments) with the LDA+U functional (1) and the atomic sphere approximation (ASA) LMTO[10] method with spin-orbital coupling in the second-order variational step to investigate the magneto-optical spectra. The integration over the Brillouin zone has been done by the tetrahedron method with 69 **k** points for the self-consistent field (SCF) calculation and about 1000 **k** points in the $\frac{1}{16}$ BZ for optical matrix elements. The low temperature experimental crystal structure for CeSb with a 0.2% tetragonal distortion was used.[3]

Without spin-orbital coupling it was found that the Hartree–Fock-like one-electron $4f$ spin "up" states with predominantly $m=3$ and $m=-3$ character have the lowest total energy. This is in agreement with the first and second of Hund's rules, with energy differences among the $4f$ configurations arising from anisotropic Coulomb and crystal field effects. One should note that the symmetry of such orbitals is not cubic anymore, and that Jahn–Teller tetragonal distortions give a lower energy. The spin-orbital coupling (~0.5 eV) lifts the degeneracy of the $m=\pm 3$ states according to Hund's third rule and the lowest energy corresponds to the $|-3\uparrow\rangle$ one-electron state. The spin and orbital moments are equal to $-0.92\ \mu_B$ and $2.86\ \mu_B$, respectively, yielding a total magnetic moment of $1.94\ \mu_B$, which is close to the experimental value obtained for the antiferromagnetic (AFM) ground state ($2.10\pm0.04\ \mu_B$).[5]

In this article we consider only the one-determinant LDA+U singlet ground state. The ground state band structure of CeSb (with spin-orbital coupling) is shown in Fig. 1. The f bands are split by approximately 6 eV, and the singly occupied f band is located at 2.3 eV below the Fermi level. All unoccupied f bands are at approximately 3.7 eV above E_F and the broadbands which cross the Fermi level are formed by Sb p states. This picture of the CeSb electronic structure is in agreement with the phenomenological p-f mixing model.[10,11]

The density of states (DOS) is shown in Fig. 2(a) and is quite different from the LSDA DOS [Fig. 2(b)]. There is a large reduction of the density of states at the Fermi level with our LDA+U value of $N(E_F)=6.5$ st/Ry^{-1} compared to the LDA value of about 150 st/Ry^{-1}. The occupied f band with mostly $m=-3$ character interacts in a very anisotropic way with the Sb p bands (see Fig. 3) and even pushes one of the p states (mostly $m=1$ character) above the Fermi level along

the Γ-Z direction, but not in the Γ-X direction. The anisotropic p-f interaction helps explain the anomalous magnetic properties of CeSb (Ref. 13) with strong magnetic anisotropy in the ferromagnetically ordered phase {our calculated value of magnetic anisotropy as the total energy difference with the magnetic field along [001] and [110] directions is 2.4 meV (standard LSDA calculations give 0.54 meV)}. Such anisotropic p-f mixing for different m subbands near the Fermi

level, together with the large spin-orbital coupling of Sb p states (~0.6 eV) leads to particularly strong MO effects.

The nondiagonal part of the conductivity tensor (Fig. 4) is in better agreement with experimental MO spectra[6,14] than the LDA result[7] which qualitatively disagrees with experiment. A serious problem however is the small magnitude of the negative peak at 0.3 eV in comparison with the experimentally predicted MO spectra. This particular peak is of interest because the small value of the diagonal conductivity near this energy helps produce the largest measured Kerr angle of any material. The theoretical θ_k of 5° (at 0.3 eV) is large, but still smaller than the predicted value (>15°) or measured value (of about 14° at 0.5 eV).

Analysis of MO matrix elements shows that the main contribution to the peaks in $\sigma_{xy}(\omega)$ at 0.3 and 0.9 eV comes from the transitions from p to d bands near the Fermi level. Among those states the radial functions consist of an atomic-like p orbital around the Sb site and tails of states from surrounding sites which have some d-like symmetry within the Sb sphere. These are exactly the p bands which interact strongly with the occupied Ce f band and are pushed above E_F along the Γ-Z direction and stay below E_F along Γ-X. One of the interesting consequences of such anisotropy [which comes from the symmetry breaking nature of the LDA+U approach (see Fig. 3)] is that the orbital angular character (m quantum numbers) is further separated than would occur from just the spin-orbit coupling alone. Especially large contributions to $\sigma_{xy}(\omega)$ may be predicted for systems with such a big anisotropy of the f electron angular momentum density. For CeSb there is strong hybridization of one particular f orbital and one p orbital with significant energy shifts near the Fermi level where spin-orbital splitting of p states is also large. With the same mechanism it may be possible to produce strong MO effects using f-d anisotropic hybridization (with materials like CePt, CePtSb, and so on). In any case anisotropy induced contributions to MO may affect significantly the off-diagonal conductivity (but not the diagonal part), and may be another consideration for increasing the MO effect in searching for new MO materials.

Magnetic properties of $Sm_2(Fe,V)_{17}N_y$ coarse powder

Shunji Suzuki, Shinya Suzuki, and Masahito Kawasaki
Minebea Co., Ltd., R&D Center, 1743-1 Asaba, Iwata-Gun, Shizuoka-Ken 437-11, Japan

Magnetic properties and crystal structures of $Sm_2(Fe,V)_{17}N_y$ alloys were studied. Crystal structures of $Sm_2Fe_{17-x}V_x$ alloys varied from Th_2Zn_{17} ($x=0$–1) to $TbCu_7$ ($x=1.5$), and $ThMn_{12}$-type ($x=2$) as a function of vanadium content (x). The alloys were nitrogenated at 823 K for 4 h, and in all cases resulted in the expansion of the crystal lattice. The nitrogenated and annealed $Sm_2Fe_{15.5}V_{1.5}N_y$ coarse powders with 20–74 μm particles showed H_{cJ} of 342 kA/m (4.3 kOe) without fine grinding. It is supposed that one of the reasons of the high coercivity is due to the microstructures of the particles.

INTRODUCTION

Since the discovery of $Sm_2Fe_{17}N_{3-\delta}$ compounds,[1] a number of studies concerning their application for permanent magnets have been reported.[2,3] It is well known that fine grinding, nanostructures, and zinc bonding methods for those alloys improve the coercivity. High energy products around 160 MJ/m^3 (20 MGOe) for bonded magnets have been obtained by compacting an anisotropic fine powder with a resin.[4,5] However, very high compaction pressures are required to achieve the above value. Because of that reason, coarse powders are more advantageous for preparing high performance magnets.

In this study, the nitrogenation of $Sm_2Fe_{17-x}V_x$ alloys were performed and their magnetic properties were investigated in detail. It was found that $Sm_2Fe_{15.5}V_{1.5}N_y$ coarse powder showed the highest coercivity among those alloys and was suitable for bonded magnet materials.

EXPERIMENT

$Sm_2Fe_{17-x}V_x$ ($x=0,0.5,1,1.5,2$) alloys were prepared by induction melting and homogenizing at 1373 K for 12 h, and ground to 20–150 μm in particle size. These powders were nitrogenated at 773–873 K for 4 h under 0.8 MPa of N_2 atmosphere, and some were subsequently annealed at 823 K for 2–16 h. Nitrogenated $Sm_2Fe_{15.5}V_{1.5}$ alloy powders were studied in detail as these showed the highest coercivity compared to other alloy powders. Crystal structures and magnetic properties of these powders were measured by x-ray diffraction with Cu K_α radiation and vibrating sample magnetometry (VSM), respectively. The nitrogen content of alloy powders after a nitrogenation was calculated by the mass change and calibrated from a LECO analyzer (TC-436). A scanning electron microscope (SEM) and an electron probe microanalyzer (EPMA) were also used for the analysis of microstructures of alloy powders.

RESULTS AND DISCUSSION

Figure 1 shows x-ray diffraction patterns of $Sm_2Fe_{17-x}V_x$ ($x=0,0.5,1,1.5,2$) alloys. Crystal structures of the main phase for the alloys varied from Th_2Zn_{17} ($x=0$–1) to $TbCu_7$ ($x=1.5$), and $ThMn_{12}$ type ($x=2$), with the increase of vanadium content. A negligible amount of α-iron is observed in all alloys of $x=0$–2, and the $SmFe_2$ phase is observed for alloys of $x=1.5$ and 2. This is explained by the fact that iron-rich $TbCu_7$ and $ThMn_{12}$ phases compared to the Th_2Zn_{17} phase appear with accompanying samarium-rich $SmFe_2$ phase in highly vanadium substituted alloys. The composition of the $TbCu_7$-type phase for the $Sm_2Fe_{15.5}V_{1.5}$ alloy is estimated to be $Sm_{10.1}(Fe,V)_{89.9}$ from the analysis by EPMA, and is found to be nearly the same as that reported elsewhere.[6] $Sm_2Fe_{17-x}V_x$ alloys were all nitrogenated at 823 K for 4 h, resulting in the expansion of the crystal lattice without a change in structure.

Figure 2 shows the coercivity of nitrogenated $Sm_2Fe_{17-x}V_xN_y$ alloy powders as a function of x value. It is found that H_{cJ} is strongly dependent on the value of x for these alloys. The value of 120 kA/m is obtained for the powder of $x=1.5$ which is not finely ground. In particular, the nitrogenation conditions for $Sm_2Fe_{15.5}V_{1.5}$ alloys were varied in order to study their magnetic properties.

Figure 3 shows x-ray diffraction patterns of $Sm_2Fe_{15.5}V_{1.5}N_y$ alloys nitrogenated at 773–848 K for 4 h. Nitrogen contents of these alloys are also shown in the fig-

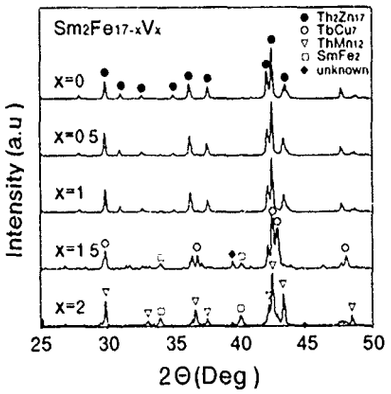

FIG. 1. X-ray diffraction patterns of $Sm_2Fe_{17-x}V_x$ ($x=0,0.5,1,1.5,2$) alloys

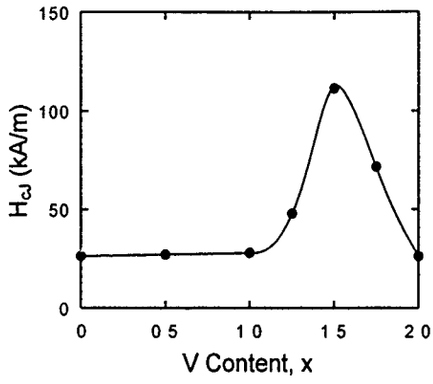

FIG. 2. Coercivity of $Sm_2Fe_{17-x}V_xN_y$ alloy powders nitrogenated at 823 K for 4 h as a function of x value.

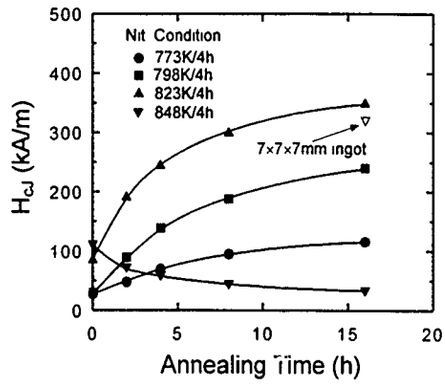

FIG. 4. Coercivity of $Sm_2Fe_{15.5}V_{1.5}N_y$ powders annealed at 823 K for 2–16 h after nitrogenation at 773–848 K for 4 h.

ure. Reflection peaks of the $TbCu_7$-type phase are shifted toward the lower angle and are broadened with increasing temperatures and the peaks of the $SmFe_2$ phase are suppressed by the nitrogenation. Nitrogen contents of these alloys are considerably higher than those of $Sm_2Fe_{17}N_{3-\delta}$ alloys nitrogenated by N_2 gas. In addition, it was found that nitrogen contents of an ingot of 7×7×7 mm in dimension were as high as those of powders prepared by similar nitrogenation conditions. Nitrogen atoms are thought to be diffused into the lattice and crystal boundaries. Heat treatment is performed in order to help diffusions of nitrogen atoms, because the distribution of nitrogen atoms in coarse powders compared to fine powders is thought to be heterogeneous.[7]

Figure 4 shows the coercivity of $Sm_2Fe_{15.5}V_{1.5}N_y$ powders annealed at 823 K for 2–16 h after nitrogenation at 773–848 K for 4 h. It is found that annealing after nitrogenation remarkably enhances the coercivity. H_{cJ} of nitrogenated powders before annealing increases with increasing nitrogenation temperatures and has a value of 116 kA/m for 848 K, where the x-ray diffraction peaks are fairly broadened and the crystal perfection is lowered as shown in Fig. 3. The annealing time also affects the coercivity which increases with time. The highest value in H_{cJ} of 330 kA/m is obtained for the powder annealed at 823 K for 16 h after nitrogenation at 823 K for 4 h. High H_{cJ} is also obtained for the 7×7×7 mm ingot as denoted by ∇ in the figure. The reason for the decrease in H_{cJ} after the annealing of the powder nitrogenated at 848 K is due to an acceleration of a decomposition of the principal $TbCu_7$ phase. The distribution of nitrogen atoms in particles by EPMA observation showed little change during annealing. The effect of annealing on the coercivity is now under study.

Figure 5 shows the hysteresis loop and magnetization curve of anisotropic $Sm_2Fe_{15.5}V_{1.5}N_y$ powder with 20–74 μm particles nitrogenated at 823 K for 4 h and annealed at 823 K for 16 h. As shown in the figure, H_{cJ} of 342 kA/m (4.3 kOe) and a remanence of 1.08 T are obtained from the coarse powder. Little change in particle size of the powder after the nitrogenation was observed, however, a few cracks on the surface of the particles were observed by SEM. A feature characteristic of pinning is observed in the magnetization curve of the present compound. This is distinct from the behavior of $Sm_2Fe_{17}N_3$ although the reason for this distinction is not yet clear.

Figure 6 shows the dependence of H_{cJ} for $Sm_2Fe_{15.5}V_{1.5}N_y$ and $Sm_2Fe_{17}N_3$ powders on particle size. $Sm_2Fe_{15.5}V_{1.5}N_y$ particles were prepared by sieving the nitrogenated and annealed powders with 20–150 μm particles, while 1–3 μm particles were prepared by grinding using a

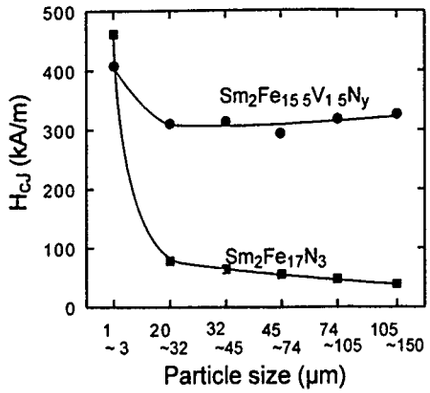

FIG. 6. Dependence of H_{cJ} of $Sm_2Fe_{15.5}V_{1.5}N_y$ and $Sm_2Fe_{17}N_3$ powders on particle size.

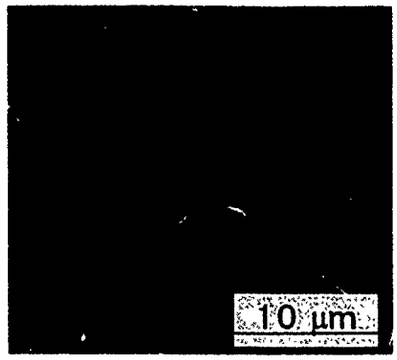

FIG. 7. SEM picture of nitrogenated and annealed $Sm_2Fe_{15.5}V_{1.5}N_y$ powder.

jet mill after annealing. The data of $Sm_2Fe_{17}N_3$ particles prepared by the authors were reproduced from Ref. 8. Both powders show high coercivity for particles of 1–3 μm. An increase in H_{cJ} for the fine particles can be explained by the behavior of single magnetic domain particles.[9] On the other hand, the values of H_{cJ} for $Sm_2Fe_{15.5}V_{1.5}N_y$ are several times higher than those for $Sm_2Fe_{17}N_3$ for the particles of 20–150 μm, and are not affected by particle size.

Figure 7 shows the microstructure of nitrogenated and annealed $Sm_2Fe_{15.5}V_{1.5}N_y$ powder as observed by SEM. The particles have polycrystalline structure with 10–30 μm grains, and show laminated structures with submicron spaces which are not observed before nitrogenation. These microstructures are one possible reason of the high coercivity.

CONCLUSION

Crystal structures of $Sm_2Fe_{17-x}V_x$ alloys changed as a function of vanadium content (x). Among nitrogenated $Sm_2Fe_{17-x}V_xN_y$ alloys, $Sm_2Fe_{15.5}V_{1.5}N_y$ alloy powder with $TbCu_7$-type structure absorbed more than 4 wt % of nitrogen, and showed H_{cJ} of 342 kA/m (4.3 kOe) without fine grinding. A feature characteristic of pinning was observed in the magnetization curve of the coarse powder, although this kind of pinning could not be observed in the behavior of $Sm_2Fe_{17}N_3$.

Mössbauer study of $R_2Fe_{17}C_x$ (R=Tb,Dy) as-quenched intermetallics compounds

Hua-Yang Gong,[a] Bao-Gen Shen, Lin-Shu Kong, Lei Cao, Wen-Shan Zhan, Zhao-Hua Cheng, and Fang-Wei Wang

State Key Laboratory for Magnetism, Institute of Physics, Chinese Academy of Science, 100080 Beijing, People's Republic of China

Intermetallics compounds $Dy_2Fe_{17}C_x$ (x=1.5,2.0,2.5,2.8) and $Tb_2Fe_{17}C_x$ (x=1.5,2.0,2.5) have been successfully prepared by the melt-spinning method. The x-ray-diffraction patterns and the thermomagnetic curves show that they are single phase with the rhombohedral Th_2Zn_{17}-type structure, except for $Dy_2Fe_{17}C_{2.8}$ and $Tb_2Fe_{17}C_{2.5}$ which have a small percentage of α-Fe. ^{57}Fe Mössbauer spectra were measured at 12 K and room temperature to study both the magnetic properties of $R_2Fe_{17}C_x$ on a local scale and the effect of the interstitial C atom on the Fe atoms. It is found that the effective hyperfine fields of the various Fe sites decrease in the order $6c>18f>18h>9d$. The average effective hyperfine fields H_{eff} at 12 and 293 K do not change much with C concentration x in agreement with the moment of the Fe atoms obtained by magnetic measurements at 1.5 K. It can be concluded that the effect of C is to enhance the exchange interaction between Fe-Fe atoms, which is sensitive to the distance of Fe-Fe atoms. The C has little influence on the moments of Fe atoms.

I. INTRODUCTION

Introduction of interstitial nitrogen or carbon atoms into R_2Fe_{17} intermetallic compounds results in a significant improvement of the magnetic properties of these compounds. The carbides $R_2Fe_{17}C_x$ ($x\approx2.5$), prepared by a gas-solid reaction, have unit-cell volumes about 6.5% larger, Curie temperatures of 760 K, and room-temperature anisotropy fields of 15±0.5 T.[1] These carbides are promising new materials for applications as permanent magnets, however, their drawback is high-temperature unstability. In our previous work we have discovered that the carbides $R_2Fe_{17}C_x$ with high carbon concentration can be prepared by melt spinning. The melt-spun $R_2Fe_{17}C_x$ compounds were found to be stable at high temperature and to retain the Th_2Zn_{17}-type or Th_2Ni_{17}-type structure up to at least 1273 K. We have successfully obtained the melt-spun $R_2Fe_{17}C_x$ (R=Y, Gd, Tb, Ho, Er, and Tm; x=0–3.0) compounds and systematically studied their structure and magnetic properties.[2–5] In this article, we report the Mössbauer effect spectra of $R_2Fe_{17}C_x$ (R=Tb, Dy, x=1.5,2.0,2.5,2.8) compounds prepared by melt spinning.

II. EXPERIMENT

Iron and carbon were first arc melted into Fe-C alloys, and then R, Fe, and Fe-C alloy were melted, by arc melting in an argon atmosphere of high purity, into homogeneous buttons with the compositions $R_2Fe_{17}C_x$ (R=Tb, Dy, $1.5\leq x\leq2.8$). For homogeneity the ingots were melted several times. The purities of the elements used were at least 99.9% After arc-melting, the ingots were melt spun under a high-purity argon atmosphere on the surface of a rotating copper wheel. The quenching rate was varied by changing the surface velocity of the copper wheel between 0 and 47 m/s. The ribbons obtained were about 1 mm wide and 20–30 μm thick.

X-ray-diffraction measurements were performed on the melt-spun ribbons using Co$K\alpha$ radiation to identify the phase components and determine the crystallographic structure. The Curie temperatures were determined from the temperature dependence of the magnetization measured in a vibrating sample magnetometer in a magnetic field of 1 kOe.

The ^{57}Fe Mössbauer spectra were recorded using a constant-acceleration spectrometer (Oxford MS-500) in transmission geometry with a ^{57}Co source. Temperature control to better than ±0.1 K was achieved by the use of a proportional temperature controller. The data were analyzed using a least-squares-fitting program.

III. EXPERIMENTAL RESULTS AND ANALYSIS

X-ray-diffraction experiments show that the cast compounds $R_2Fe_{17}C_x$ (R=Tb, Dy, $1.5\leq x\leq2.8$) are single phase with the rhombohedral Th_2Zn_{17}-type structure. Table I lists the lattice parameters, unit-cell volumes, Curie temperatures, and M_s. The addition of C to the R_2Fe_{17} leads to an expansion of the unit cell. The $Tb_2Fe_{17}C_{2.5}$ compound has a unit-cell volume about 5.6% larger than that of Tb_2Fe_{17}. For $Dy_2Fe_{17}C_{2.8}$ the unit-cell volume expansion is about 6.3% compared with the carbon-free compound. The T_c of these compounds is found to increase with increasing C concentration. It is commonly assumed that the Curie temperature of rare-earth–iron compounds is determined by the Fe-Fe, R-Fe, and R-R interactions. In general, the Fe-Fe interaction is dominant, the R-R interaction is negligible, and the influence of R-Fe interaction yields the difference in T_c among the different rare-earth compounds. The increase in Curie temperature of the carbides or nitrides is mainly due to the increase in the Fe-Fe ferromagnetic interaction which results from the increased interatomic distance produced by the carbon or nitrogen.

[a]Reference 6.
[b]Reference 7.

The ^{57}Fe Mössbauer spectra of $Dy_2Fe_{17}C_x$ (x=1.5,2.0, 2.5,2.8) and $Tb_2Fe_{17}C_x$ (x=1.5,2.0,2.5) at 12 and 293 K are shown by dots in Figs. 1 and 2. There are four crystallographically nonequivalent Fe sites, denoted in Wyckoff notation by 6c, 9d, 18f, and 18h for the Th_2Zn_{17} structure type. However, when the easy magnetization direction is perpendicular to the c axis, the spectra consist of more than four independent subspectra. Owing to differences in angle between the magnetization direction and the direction of the principal axis of the electric-field gradient tensor, the crystallographically equivalent iron atoms of a given subgroup will become magnetically nonequivalent.[8] In addition, the magnetic dipolar fields also make the situation complex. According to a calculation of the field gradients by means of a point charge model and calculations of the magnetic dipole field, the 2:17 compounds with magnetization direction perpendicular to the c axis should be analyzed in terms of seven independent subspectra. However, for $Dy_2Fe_{17}C_{2.8}$ and $Tb_2Fe_{17}C_{2.5}$ we use eight subspectra to count in the α-Fe contribution.

For $Dy_2Fe_{17}C_x$ and $Tb_2Fe_{17}C_x$ a further subdivision of the 18f, 18h, 9d sites into two groups with a relative intensity ratio of 1:2 is assumed. The relative intensity ratios for each of the spectral components were constrained to 6:6:12:6:12:3:6, corresponding to 6c, 18f_1, 18f_2, 18h_1, 18h_2, 9d_1, and 9d_2 in the crystal structure. Relative areas of the lines in each sextet were constrained in the ratio 3:2:1:1:2:3, as is required for a randomly oriented power sample. Different linewidths were used for the inner, middle, and outer pairs lines. To assign the subspectra to the various sites, we refer to our previous ^{57}Fe Mössbauer studies of $Er_2Fe_{17}C_2$. Below the spin-reorientation temperature T_{sr},[9] it was found that acceptable fits can be obtained by assuming that the hyperfine fields decrease in the order of 6c>18f >18h>9d. Therefore, we analyzed the spectra of $Dy_2Fe_{17}C_x$ and $Tb_2Fe_{17}C_x$ in the same way.

The results of the fitting procedure are shown by the solid curves in Figs. 1 and 2. The average hyperfine fields are weighted by the contribution of the various sites. The average hyperfine fields of $Dy_2Fe_{17}C_x$ and $Tb_2Fe_{17}C_x$ at 12 and 293 K are plotted as a function of C content in Fig. 3 which illustrates that the hyperfine fields are almost independent of C content. For $Dy_2Fe_{17}C_x$, H_{eff} even shows a small decrease as the C concentration increases. It has been found that the

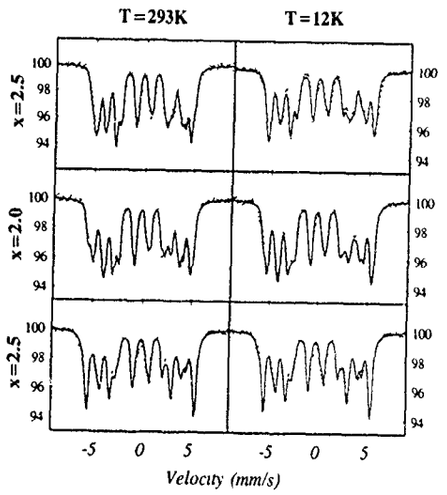

FIG. 2. ^{57}Fe Mossbauer spectra of $Tb_2Fe_{17}C_x$ at 12 and 293 K. The solid curves are fits to the spectra.

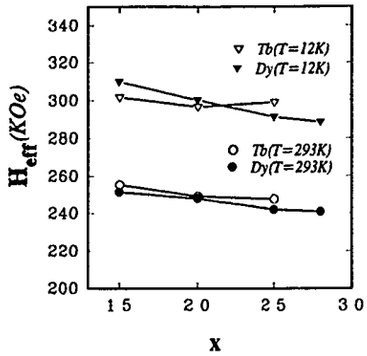

FIG. 3. Dependence on C content x of the average hyperfine field for $Dy_2Fe_{17}C_x$ and $Tb_2Fe_{17}C_x$.

average hyperfine fields are nearly proportional to the average iron moment.[10] This indicates that the interstitial C atom has little influence on the iron moment. This conclusion agrees with our previous magnetic studies on the $R_2Fe_{17}C_x$ compounds, which showed that the saturation magnetization M_s, at 1.5 K does not change much with increasing C concentration. This situation is different for $R_2Fe_{17}N_x$ obtained by gas-solid interaction, in which interband electron transfer is believed to occur,[11] the iron moments increase with the nitrogen, and the average hyperfine fields are approximately 4 T larger in the parent alloy. This indicates that the influence of interstitial C atoms on the Fe sublattice is different from that of N atoms due to their different electronic configuration. Nitrogen has a larger electronegativity than that of carbon.

Magnetic properties of $Tm_2Fe_{17}C_x$ ($0 \leq x \leq 2.8$) compounds prepared by melt spinning

Bao-Gen Shen, Lin-Shu Kong, Lei Cao, Hua-Yang Gong, Fang-Wei Wang, Zhao-Hua Cheng, and Jian-Gao Zhao
State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, P.O. Box 603, Beijing 100080, People's Republic of China

The formation, structure, and magnetic properties of $Tm_2Fe_{17}C_x$ compounds with $x=0$, 0.5, 1.0, 1.5, 2.0, 2.5, and 2.8 were studied. The samples with $x \leq 1.0$ were arc melted and heat treated at 1370 K for 14 h. The carbides were prepared by melt spinning at appropriate quenching rates of $v_s=10$–20 m/s for $1.5 \leq x \leq 2.5$ and by the crystallization from corresponding amorphous for $x=2.8$. X-ray diffraction and thermomagnetic measurements show that all samples studied are single phase with the hexagonal Th_2Ni_{17}-type structure except for $Tm_2Fe_{17}C_{2.8}$, which contains a few percent of α-Fe. The lattice parameters a,c and the unit-cell volumes v increase as the carbon concentration x increases. The Curie temperature is found to rise with x from 260 K for $x=0$ to 669 K for $x=2.8$. The saturation magnetization M_s at 1.5 K is found to be 92.2–97.1 emu/g as x varies from 0 to 2.8, and the carbon concentration dependence of the Fe moment is approximately constant ($2.12 \pm 0.04 \mu_B$). The spin-reorientation transitions are observed. The spin-reorientation temperature is found to increase with the carbon concentration for $x \leq 1.5$, and then has a slight decrease with x for $x > 1.5$.

I. INTRODUCTION

In previous works[1–3] we have shown that the interstitial carbides $R_2Fe_{17}C_x$ with higher carbon concentration can be prepared by the melt-spinning method. These carbides are found to be single phase up to carbon concentration $x=2$ for R=Y and Gd and $x=2.8$ for R=Dy, Ho, and Er. As compared with the carbon-free parent compounds, the unit-cell volume expansion in the carbide with $x=2.8$ is about 6%–7% and the Curie temperature increase is about 400 K, which are comparable to those of corresponding nitrides or carbides produced by solid-gas reaction. It is notable that the $R_2Fe_{17}C_x$ compounds obtained by melt spinning are stable at high temperatures at least up to 1000 °C.[1–3] We have reported the formation, structure, and magnetic properties of $R_2Fe_{17}C_x$ (R=Y, Gd, Tb, Dy, Ho, and Er) compounds.[1–5] For $Tm_2Fe_{17}C_x$ with $x \leq 1.4$, a number of investigations have been made, however, when the carbon concentration x is higher than 1.5, the carbides have not been investigated in detail because the interstitial carbon concentration is limited to about $x=1.5$ by arc melting and is not well controlled by a gas-solid-phase interstitial modification. In this article, the structure, intrinsic magnetic properties and spin reorientation are reported for melt-spun $Tm_2Fe_{17}C_x$ compounds with the higher carbon concentration of up to $x=2.8$.

II. EXPERIMENT

Iron (99.9% in purity), thulium (99.9%), and Fe-C alloy (99.8%) were melted by arc melting in an argon atmosphere of high purity into homogeneous buttons with composition $Tm_2Fe_{17}C_x$ ($x=0$, 0.5, 1.0, 1.5, 2.0, 2.5, and 2.8). The alloys were melted several times to ensure homogeneity. After melting, the ingots with $x \leq 1.0$ were then annealed in a steel tube in a highly purified argon atmosphere at 1370 K for 14 h, resulting in the formation of single-phase compounds of the 2:17-type structure, while for $x \geq 1.5$ the ingots of about 3 g were melt spun on the outside of a copper wheel rotating with the surface speeds of 0–47 m/s. Ribbons about 1 mm wide and 20–30 μm thick were produced. X-ray-diffraction measurements were made to determine the single-phase and crystallographic structure. The magnetizations at 1.5 and 300 K were measured by using an extracting sample magnetometer with a field up to 65 kOe. The Curie temperatures were determined from the temperature dependence of the magnetization measured by using a vibrating sample magnetometer under a field of 1 kOe. The spin-reorientation temperatures were determined from the ac susceptibility versus temperature curves measured at an ac magnetic field of less than 1 Oe.

III. RESULTS AND DISCUSSION

X-ray-diffraction measurements show that the arc-melted ingots $Tm_2Fe_{17}C_x$ with $x \leq 1$ are single phase with a hexagonal Th_2Ni_{17}-type structure. When the carbon concentration x is greater than 1.5, the $Tm_2Fe_{17}C_x$ ingots show a multiphase structure with α-Fe coexisting with the rare-earth carbides and the 2:17 phases. The amounts of α-Fe phase increase with increasing carbon concentration and become a majority for $x \geq 2.0$; however, the single phase of $Tm_2Fe_{17}C_x$ with $1.5 \leq x \leq 2.5$ can be obtained by melt spinning. The as-quenched samples revealed a hexagonal Th_2Ni_{17} structure. It is found that the formation of the single-phase $Tm_2Fe_{17}C_x$ is sensitive to the quenching rates. The optimal quenching rates are only a relatively narrow range of 10–20 m/s. For $x=2.8$, the preparation of single-phase compound is difficult by direct quenching; however, the sample of almost single phase can be obtained by the crystallization from a corresponding amorphous $Tm_2Fe_{17}C_{2.8}$ alloy prepared at a speed of 47 m/s. Figure 1 shows the example of the x-ray-diffraction patterns with Co$K\alpha$ radiation for the $Tm_2Fe_{17}C_x$ compounds with $x=0.5$, 1.5, and 2.8.

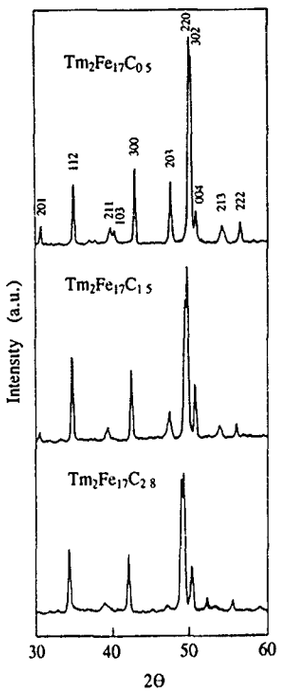

FIG. 1. X-ray-diffraction patterns of $Tm_2Fe_{17}C_x$ with $x=0.5$, 1.5, and 2.8.

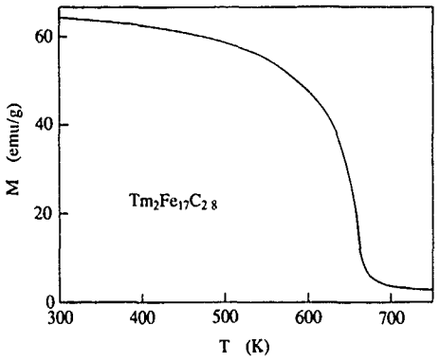

FIG. 2. Temperature dependence of the magnetization measured in a field of 1 kOe for $Tm_2Fe_{17}C_{2.8}$.

The lattice constants and unit-cell volumes of $Tm_2Fe_{17}C_x$ compounds are listed in Table I. Both lattice parameters a and c, and the volumes v dilate upon carbonation and rise monotonically with increasing carbon concentration, which is consistent with the reported results for the melt-spun $R_2Fe_{17}C_x$ with R=Dy, Ho, and Er.[1–3] The relative cell volume increase $\Delta v/v$ is 1.0%–6.8% as x increases from 0.5 to 2.8, also shown in Table I. For $x=2.8$ the value of $\Delta v/v$ is comparable to that of the corresponding nitrides or carbides produced by gas-solid reaction.[6]

Curie temperature T_c of $Tm_2Fe_{17}C_x$ were determined from the temperature dependence of magnetization measured at a field of 1 kOe. As an example, the magnetization versus temperature curve for $x=2.8$ is shown in Fig. 2. Values of T_c are listed in Table I. T_c is found to rise remarkably with increasing carbon concentrations. When $x=2.8$, T_c is about 400 K higher than that of the parent compound Tm_2Fe_{17}. In rare-earth Fe-rich compounds, the Curie temperature depends mainly on the exchange interactions between Fe-Fe atoms, which is sensitive to the distance between Fe-Fe atoms. The increase of Curie temperature with x demonstrates that the introduction of interstitial carbon atoms results in the increase of Fe-Fe interactions in $Tm_2Fe_{17}C_x$. It seems reasonable to suggest that the volume expansion has an essential effect on the Curie temperature.[4]

The saturation magnetizations M_s(1.5 K) and M_s(300 K) measured by using an extracting sample magnetometer in a field of 65 kOe at 1.5 and 300 K, respectively, are also summarized in Table I. The M_s(1.5 K) of $Tm_2Fe_{17}C_x$ is found to be 92.2–97.1 emu/g, as x varies from 0 to 2.8. A small effect of the interstitial carbon atoms on the M_s(1.5 K) is observed. The antiparallel coupling between the rare-earth spin moment and the Fe moment for heavy-rare-earth compounds leads to ferrimagnetism. For $Tm_2Fe_{17}C_x$, the saturation moment μ_s can be expressed as

$$\mu_s = 17\mu_{Fe} - 2\mu_{Tm}, \tag{1}$$

where μ_{Fe} and μ_{Tm} are the Fe and Tm magnetic moments, respectively. The μ_{Tm} can be assumed to be $7\mu_B$, which is the moment of a free Tm^{3+}. According to Eq. (1), the Fe magnetic moment is obtained, as shown in Table I. The μ_{Fe} is found to be $2.12\pm0.04\mu_B$, being almost independent of carbon concentration.

The room-temperature saturation magnetization M_s(300 K) is found to increase with increasing carbon concentration for $x\leqslant1.5$, then has an approximately constant value of 123.4 emu/g for $x\geqslant1.5$. The increase of the M_s(300 K) at lower carbon concentration is due to the enhancement of the Curie temperature which shifts the thermomagnetization curve to higher temperature.

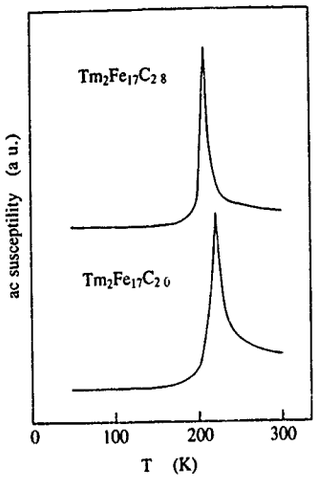

FIG. 3. Temperature dependence of the ac susceptibility of $Tm_2Fe_{17}C_x$ with $x=2.0$ and 2.8.

The spin reorientation in $Tm_2Fe_{17}C_x$ is observed from the measurements on ac susceptibility versus temperature curves. Examples of these measurements are shown in Fig. 3. The spin-reorientation temperatures T_{sr} are summarized in Table I and Fig. 4. Figure 4 also presents the experimental data reported by Zhao *et al.*[7] and Gubbens *et al.*[8] for comparison. It is known that the spin reorientation in the rare-earth–iron compounds generally results from the competing anisotropies with different temperature dependence for the rare-earth and iron sublattices. The introduction of carbon atoms ($x \leq 1.5$) into Tm_2Fe_{17} leads to the enhancement of spin-reorientation temperature. This demonstrates that the Tm sublattice anisotropy has a strong enhancement for $x \leq 1.5$. When the carbon concentration x is richer than 1.5, the T_{sr} is found to decrease slightly, indicating that the Tm sublattice anisotropy has a little change at higher carbon concentration.

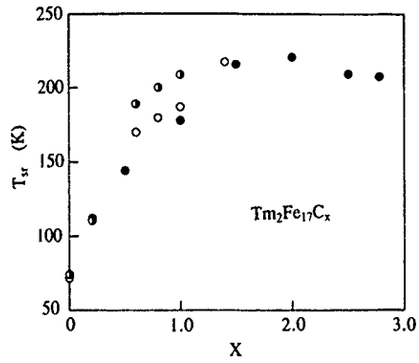

FIG. 4. The spin-reorientation temperature of $Tm_2Fe_{17}C_x$ as a function of carbon concentration x: (●) present results; other data are taken from (○) Zhao *et al.* (Ref. 7) and (◑) Gubbens *et al.* (Ref. 8).

Kerr microscopy observation of carbon diffusion profiles in $Sm_2Fe_{17}C_x$

J. Zawadzki,[a] P. A. P. Wendhausen, B. Gebel, A. Handstein, D. Eckert, and K.-H. Müller
Institut für Festkörper und Werkstofforschung Dresden, D-01171 Dresden, Germany

The effect of carbon diffusion from CH_4 gas into coarse Sm_2Fe_{17} powder on the magnetic domain structure (MDS) was studied at room temperature by means of the magneto-optical polar Kerr effect. The diffusion occurs initially along preferential paths and then through the bulk. A gradual variation in the MDS through incompletely carburized grains was observed, which reflects local changes in spontaneous magnetization and magnetic anisotropy. This suggests the existence of smooth "bathtublike" carbon concentration profiles. An acceleration of the carburization process caused by cracking of grains during the diffusion was observed. The diffusivity R of carbon in Sm_2Fe_{17} at 450 °C was estimated to be 2.5×10^{-16} m^2/s. For $Sm_2Fe_{17}C_{2.2}$ the domain-wall energy density is $\gamma=3.1\times10^{-2}$ J/m^2, the domain-wall thickness $\delta=3.3$ nm, the single-domain particle size $D_c\approx0.3$ μm, and the exchange constant $A=8.1\times10^{-12}$ J/m.

I. INTRODUCTION

Recently much attention has been focused on the ternary interstitial $Sm_2Fe_{17}Z_x$ (Z=N,C) phases with rhombohedral Th_2Zn_{17}-type crystallographic structure. $Sm_2Fe_{17}Z_x$ compounds can be formed, e.g., by melting processes in the case of carbon[1] or by heating Sm_2Fe_{17} powder in nitrogen- or carbon-containing gases at elevated temperatures. They have excellent intrinsic magnetic properties, which can exceed those of $Nd_2Fe_{14}B$.[2–5] For instance, by absorbing carbon the Sm_2Fe_{17} compound changes its magnetic anisotropy from planar to uniaxial, connected with an anisotropy field up to about 16 T.[4] Simultaneously, a substantial increase of the Curie temperature from 389 K up to about 700 K is observed. Nitrogen has a similar or even more pronounced effect on the magnetic properties of Sm_2Fe_{17}. Understanding of the coercivity mechanism in $Sm_2Fe_{17}C_x$ materials requires the knowledge of their microstructure as well as their magnetic domain structure (MDS). Fundamental parameters controlling the nucleation as well as the pinning mechanism are the domain-wall width δ, the wall energy density γ, and the single-domain particle size D_c. Until now, however, no information on the MDS of $Sm_2Fe_{17}C_x$ has been available.

This article focuses on the MDS in the $Sm_2Fe_{17}C_x$ series and its evolution during the carburization process.

II. EXPERIMENTAL DETAILS

The Sm_2Fe_{17} alloy was prepared by melting elemental Fe with Fe-50 wt % Sm master alloy under argon in an induction furnace. The cast ingots were homogenized at 1000 °C for one week in a sealed glass ampoule filled with argon. The structure and phase composition were examined by x-ray diffraction (XRD) using Co $K\alpha$ radiation as well as by metallographic techniques. The homogenized ingots were coarsely crushed. Powder fractions with particle sizes from 160 to 500 μm and 30 to 60 μm were used. The powder was then exposed to CH_4 gas at a pressure of 0.6 bar. The coarse powder was carburized at 450 °C for 40, 160, and 200 h. For comparison finer powder was carburized at 500 °C for 96 h to get a high carbon content. After these heat treatments the following nominal carbon contents were obtained: $x\approx0.8$, 1.2, 1.3, and $x\approx2.2$ (x being the number of carbon atoms per formula unit). The amount of absorbed carbon was checked by the combustion method with CO_2 determination. After carburization the powders were examined by XRD. An additional phase analysis of the carburized powders was also performed by thermomagnetic measurements. For magneto-optic investigations powders were embedded in epoxy resin. These specimens were polished using emery papers and diamond pastes. The MDS observations were performed at room temperature with polarized light in a Jenapol microscope equipped with a high-resolution camera and an image analyzer. The domain contrast was provided mainly by the magneto-optical polar Kerr effect, which depends on the component of magnetization normal to the surface.

III. RESULTS AND DISCUSSION

Figure 1 shows the typical temperature dependence of magnetic polarization (measured at a small magnetic field) for $Sm_2Fe_{17}C_x$ samples with different carbon contents x. For medium values of x the sharp magnetic transition of Sm_2Fe_{17} at 120 °C is diminished and a small step appears near 400 °C. For $Sm_2Fe_{17}C_{2.2}$ only one sharp transition is observed at 415 °C. Therefore, it can be assumed that in par-

FIG. 2. Development of carbon diffusion layers in Sm_2Fe_{17} after carburization for 40 h (nominal composition of the sample is $Sm_2Fe_{17}C_{0.8}$). The laminar magnetic domains with strong Kerr contrast show the distribution of the uniaxial phase.

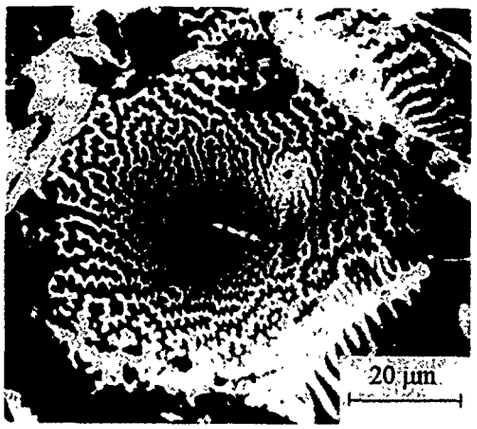

FIG. 4. Gradual change of the domain structure in a partially carburized grain (nominal composition of the sample is $Sm_2Fe_{17}C_{1.2}$).

tially carburized powders thin surface layers of the grains have a composition near to that of $Sm_2Fe_{17}C_{2.2}$.

The photographs show typical MDS for $Sm_2Fe_{17}C_x$ with nominal carbon contents $x \approx 0.8$ (Fig. 2), $x \approx 1.2$ (Figs. 3 and 4), $x \approx 1.3$ (Fig. 5), and $x \approx 2.2$ (Fig. 6). Obviously the carbon absorption has a strong influence on the MDS. In carburized regions the MDS is that of a magnetically uniaxial compound with a large anisotropy field. Simple wavy or complex starlike MDS with spikelike closure domains (see, for instance, Figs. 3 and 5) were observed in some grains. This indicates that the c axis (magnetically easy direction in the carburized phase) is oriented nearly perpendicularly to the polished surface in these grains. Laminar or wedge domains appear in the carburized regions of grains with the c axis parallel or nearly parallel to their surface (upper-left-hand-side part of Fig. 3). The pure Sm_2Fe_{17} phase reveals sometimes a coarse irregular domain pattern typical for basal plane anisotropy magnets. The characteristic feature of the MDS in $Sm_2Fe_{17}C_x$ series is that the carburized regions show a very strong Kerr contrast in opposition to the noncarburized ones, where only a relatively weak contrast was observed.

The distribution of domains characteristic for the uniaxial phase suggests that the carburization process is initially controlled by grain-boundary diffusion and then by diffusion into the bulk of the grains. In the sample of nominal composition $Sm_2Fe_{17}C_{0.8}$ carburized regions were observed mainly along cracks and grain boundaries (see Fig. 2). At this stage, the grains consist of a carburized outer shell and a noncarburized core. Because of the higher diffusion rate close to sharp edges of the grains compared to round ones, the internal rim of the carburized shell became oval after some time. It shrinks then to the center, gradually decreasing the Sm_2Fe_{17} core and finally results in carburization of the whole grain (see Fig. 4). The inhomogeneous carbon diffusion can induce mechanical stress and strain resulting in cracks or even in decrepitation (see Figs. 2 and 3). This increases the surface area of the powder and makes the diffusion process more effective. For instance, Fig. 5 shows often-observed circular microcracks arising from inhomogeneous stress profiles.

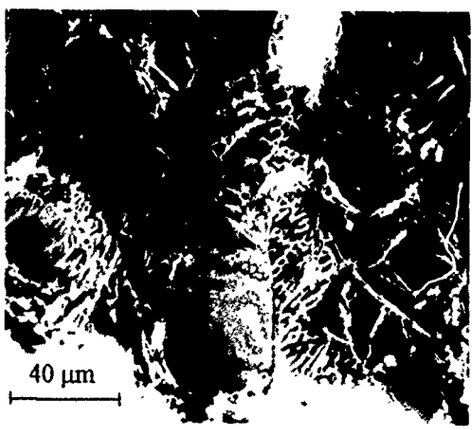

FIG. 3. Typical domain patterns observed for the nominal composition $Sm_2Fe_{17}C_{1.2}$ showing fully and partially carburized grain regions (carburization time 160 h).

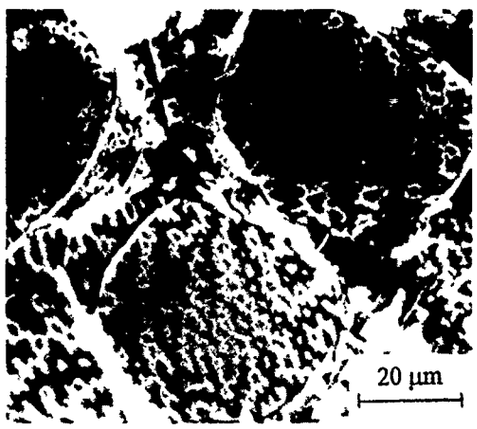

FIG. 5. Circular cracks caused by inhomogeneous stress profiles during carburization (nominal composition of the sample is $Sm_2Fe_{17}C_{1.3}$).

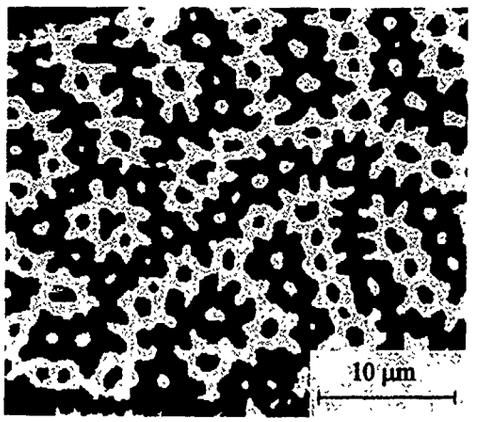

FIG. 6. Starlike domain structure in a large grain with the magnetically easy direction perpendicular to the polished surface (nominal composition is $Sm_2Fe_{17}C_{2.2}$).

Our observations of the MDS in $Sm_2Fe_{17}C_x$ series suggest also that the carbide is rather a single gas-solid solution with a continuous range of carbon contents than a two-phase mixture of carbon-poor and carbon-rich phases. A gradual change of the MDS across the grains was observed in the Sm_2Fe_{17} powders heated under CH_4 atmosphere for 160 and 200 h. For instance, Fig. 4 shows the domain pattern in a grain with the c axis perpendicular to its polished surface. As can be seen the MDS becomes finer as the distance from the grain boundary increases. According to models of the MDS, developed for uniaxial materials,[6] assuming a constant crystallite thickness, the main domain width is approximately proportional to $\gamma^{1/3}J_s^{-2/3}$, where J_s is the saturation polarization. The domain-wall energy can be expressed as $\gamma=4(AK_1)^{1/2}$,[7] where A and K_1 are exchange and anisotropy constants, respectively. Therefore, the decrease of the main domain width can be attributed to a diminution of A or K_1 in the regions with smaller carbon content.

By determination of the carburized layer thickness d at initial stages of carburization the estimation of the diffusion rate is possible. The diffusivity R of carbon atoms of 450 °C was calculated according to the equation for the average displacement x of diffusing particles with the Brownian movement: $R=x^2/2t$,[8] where t is the carburization time. In our estimation we assumed $x\cong d$. In order to avoid the influence of geometrical effects of the grain size on the $Sm_2Fe_{17}C_x$ layer thickness, we considered only very big grains with flat edges. The value obtained is $R=(2.5\pm0.5)\times10^{-16}$ m^2/s, which is of the same order of magnitude as that reported in Ref. 2 for nitrogen.

The wall energy density γ was determined for a $Sm_2Fe_{17}C_{2.2}$ sample, in which all the grains were homogeneously carburized. For this purpose the MDS in large grains with the easy axis normal (or almost normal) to the polished grain surface was analyzed. The Bodenberger–Hubert approach[9] was used for the analysis of the characteristic starlike surface domain patterns like those in Fig. 6. It can be shown that the average surface domain width w in the basal plane (perpendicular to the easy axis) for large grains in polycrystalline material is independent of the grain size and is given by $w=\mu_0\beta\gamma/J_s^2$, where β is a geometrical factor depending on the type of surface domain structure. We adopted the value of β as determined for uniaxial highly anisotropic materials in Ref. 9. We obtained an average surface domain width w of (0.93 ± 0.09) μm. Using a value of 1.43 T for the saturation polarization J_s^5, this yields a wall energy γ of $(3.1\pm0.3)\times10^{-2}$ J/m^2. From this, the single-domain particle size, $D_c=5.6\pi\mu_0\gamma/J_s^2$, is $D_c\approx0.3$ μm. The standard continuum model for a domain wall[7] gives in a first approximation the relations $A=\gamma/16K_1$ for the exchange constant and $\delta=\pi\gamma/4K_1$ for the domain-wall thickness. Using the anisotropy constant $K_1=7.4$ MJ/m^3 calculated from demagnetization curves[10] we obtained $A=8.1\times10^{-12}$ J/m and $\delta=3.3$ nm.

The preference of nitrogen atoms in $Nd(FeTi)_{12}N_x$ and $Nd(FeTiCo)_{12}N_y$ alloys have been studied by neutron diffraction. The results show that Ti atoms are preferentially to occupy the 8*i* sites, but Co atoms enter the 8*f* rather than the 8*i* site. Nitrogen atoms occupy the 2*b* sites in $Nd(FeTi)_{12}N_x$ and $Nd(FeTiCo)_{12}N_y$.

I. INTRODUCTION

A ternary Fe-rich $R(MFe)_{12}$ (M=stabilizing elements) alloy with tetragonal $ThMn_{12}$ structure has been studied extensively.[1,2] The Curie temperature of $SmTiFe_{11}$ is lower than that of $Nd_2Fe_{14}B$ and its lower saturation magnetization leads to the theoretical $(BH)_{max}$ of $SmTiFe_{11}$ only half that of $Nd_2Fe_{14}B$.[3] It is shown that Curie temperature, iron moment, and magnetocrystalline anisotropy increase drastically with the addition of nitrogen atoms.[4,5] $RTiFe_{12}N_x$ compounds have been observed to possess different intrinsic magnetic properties from their original counterparts $RTiFe_{11}$.[6] It has been shown that the Curie temperature of $RTiFe_{11}N_x$ increases by about 150–170 K and the Fe moment increases by 17%. In particular, $RTiFe_{11}N_x$ has an easy axis with a strong anisotropy field at room temperature for R=Nd, Tb, and Dy. Owing to the fact that the easy uniaxial anisotropy is a prerequisite for a magnetic material with high coercive force, to understand the effects produced by nitriding it is necessary to investigate the crystallographic structures of these nitrides. The determination of the site occupation of nitrogen atoms is a key prerequisite to the calculation of the electronic structure or crystal-field interactions in the nitrides. For this reason, we have carried out a neutron-diffraction and Mössbauer spectra study on the $Nd(FeTi)_{12}N_x$ and $Nd(FeTiCo)_{12}N_y$ alloys.

II. EXPERIMENTAL DETAILS

The samples used were prepared by arc melting of the high-purity (99.9%) primary materials under purified argon atmosphere. The buttons were melted at least three times to achieve homogeneity. Then the alloy buttons were smashed into powders. Nitrides were prepared by passing puried nitrogen gas at atmospheric pressure over finely ground powder samples at 500 °C for 3 h and at sufficiently high rates of flow to ensure enough absorption of nitrogen, followed by rapidly cooling to room temperature. X-ray diffraction analysis was used to detect phase structure. Neutron-diffraction data were collected at room temperature.

III. RESULTS AND DISCUSSION

All the samples are of single phase except for a very little amount of α-Fe coexistence found by x-ray diffraction analysis. The nitrides of $RTiFe_{11}$ were found to maintain their original tetragonal structure, space group $I4/mmm$, but with slight increases in cell volumes. This increase in lattice parameters is highly anisotropic (mainly in the basal plane).

Neutron-diffraction measurements were performed on $Nd(FeTi)_{12}N_x$ and $Nd(FeTiCo)_{12}N_y$ alloys to determine the site occupation of nitrogen atoms. The results obtained from neutron diffraction data fit are listed in Tables I and II. It can be seen from Tables I and II that Ti atoms still prefer to occupy the 8*i* sites in agreement with Ref. 6, but Co atoms enter the 8*f* site rather than the 8*i* site. The occupation of nitrogen atoms in $NdTi_{1.12}Co_{0.94}N_y$ is the same as that in $Y(TiFe)_{12}N_x$, in which nitrogen atoms enter the 2*b* site. The quantities of nitrogen atoms entering interstitial position are $x=0.43$ and $y=0.395$ for $Nd(FeTi)_{12}N_x$ and $Nd(FeTiCo)_{12}N_y$ alloys, respectively. The position of the N atom was found to correspond to the 2*b* site of the tetragonal space group, which gives rise to noticeable displacements of the 8*j* metal

TABLE I. The structural parameters of $Nd(FeTi)_{12}N_x$ from neutron-diffraction data The atomic coordinate parameters (in units of the cell constants *a* and *c*) are *x*, *y*, *z*, *n* is the number of atoms on different sites; K_z is the moment value (μ_B) in the *z* direction; *R* is the consistent factor; R_N and R_M are quality-of-fit indices for the nuclear and magnetic scattering, respectively; X^2 is the residual value.

positions. The increase in T_c and cell volume are in good agreement with the values reported in Refs. 2 and 7–9. The short metal-metal distances (between the 8f sites) remain almost unchanged after N insertion and can be derived directly from cell parameters.

IV. CONCLUSION

Neutron-diffraction analysis of Nd-(FeTi)-N and Nd-(FeTiCo)-N alloys has been performed. It was found that Ti atoms still prefer to occupy the 8i site, but Co atoms enter the 8f rather than the 8i site. The nitrogen atoms prefer to occupy the 2b site.

Synthesis and magnetic properties of $PrFe_{12-x}Mo_x$ and $PrFe_{12-x}Mo_xN_y$ ($0.5 \leq x \leq 1.0$, $y \approx 1$)

O. Kalogirou, V. Psycharis, L. Saettas, and D. Niarchos
National Center for Scientific Research "Demokritos," Institute of Materials Science, 153 10 Ag. Paraskevi, Attiki, Greece

A series of iron-rich ternary intermetallics $PrFe_{12-x}Mo_x$ ($x=0.5$, 0.75, 1.0) and their nitrides have been prepared by arc melting, annealing at 1273–1393 K and water quenching. A single-phase structure of the $ThMn_{12}$ type has been obtained for $x=1.0$ when annealed at 1345 K (with α-Fe<5%). The lattice constants are $a=8.5978(2)$ Å, $c=4.7795(3)$ Å. The alloys exhibit planar anisotropy, a Curie temperature of 498 K, and a room-temperature magnetization of 120.4 A m^2/kg prior to the nitrogenation. After nitrogenation the anisotropy changes to uniaxial, the Curie temperature increases to 681 K, and the room-temperature magnetization becomes 136 A m^2/kg. A lattice expansion corresponding to 2.4% of the cell volume is observed. In the $x=0.5$ and $x=0.75$ alloys, a secondary 2:17 phase is also present, besides the 1:12-type structure. The peritectic decomposition temperature is 1393 K for all samples.

I. INTRODUCTION

The ternary Fe-rich R-Fe-M alloys related to the tetragonal $ThMn_{12}$-type structure, and especially their nitrides, have been extensively studied during the past few years as potential candidates for permanent magnet applications due to their relatively high Curie temperature, saturation magnetization, and favorable magnetocrystalline anisotropy.[1] The tetragonal phase can be stabilized only by replacing iron with a small amount of a third element such as M=Ti, Mo, V, Cr, etc.[1]

One significant result of introducing nitrogen into the 1:12 phase is the observed change in the magnetocrystalline anisotropy from planar for non-nitrided compounds to uniaxial for nitrided ones[2] due to the change of the second-order crystal-field parameter A_{20} from negative to positive as in the case of Nd.[3] Among the light-rare-earth elements Pr has a negative a_J like Nd. Thus the magnetic properties of $Pr(Fe,Mo)_{12}$ and $Nd(Fe,Mo)_{12}$ nitrides are expected to be similar; however, since it has been reported that Pr does not form the 1:12 phase[4] no attention has been paid to the synthesis of this compound. Recently Yang *et al.*[5] have reported the preparation of $PrFe_{10.5}Mo_{1.5}$ and its nitride. Sun *et al.*[6] have reported that the solubility range in the $YFe_{12-x}Mo_x$ system is $0.5 \leq x \leq 4.0$. On the other hand, it has been shown that the intrinsic magnetic properties of $RFe_{12-x}Mo_xN_y$ improve with decreasing Mo concentration.[6,7] Thus, we examined the existence range of $PrFe_{12-x}Mo_x$ between $0.5 \leq x \leq 1.0$ and have succeeded in synthesizing at least the $x=1.0$ member of the series in the form of the $ThMn_{12}$-type structure. The structural and magnetic properties of the parent $PrFe_{11}Mo$ compound and the related nitride have also been studied.

II. EXPERIMENT

The $PrFe_{12-x}Mo_x$ ($x=0.5$, 0.75, 1.0) samples were synthesized by arc melting, with ≥99.9% pure constituents, in an argon atmosphere. The ingots were wrapped in tantalum foil, annealed in vacuum at various temperatures between 1273 and 1393 K for 3 days and then water quenched. Nitrides were formed by heat treating fine powders (<37 μm) of the alloys in purified N_2 gas at 723 K for 12 h. The samples were characterized by x-ray powder diffraction (XRD) (Siemens D500, Cu$K\alpha$ radiation with a diffracted-beam monochromator), Rietveld analysis, and thermomagnetic analysis (TGM). The magnetocrystalline anisotropy was studied by means of x-ray powder diffraction on magnetically aligned powder samples. Magnetization curves were measured using a Quantum Design superconducting quantum interference device (SQUID) magnetometer with a maximum field of 5 T at room temperature.

III. RESULTS AND DISCUSSION

Alloys with the composition $PrFe_{11}Mo$ ($x=1.0$) can be prepared by arc melting and annealing at 1273, 1348, or 1373 K. All annealed alloys present the $ThMn_{12}$-type structure with some α-Fe impurity (less than 10%). At 1393 K the 1:12 phase almost disappeared due to α-Fe precipitation indicating that 1393 K exceeds the peritectic decomposition temperature of $PrFe_{11}Mo$. The lowest α-Fe content was obtained after annealing at 1348 K for 3 days and was calculated to be 5% by the Rietveld analysis. For this sample a complete crystallographic analysis was performed. The crystal structure parameters (unit-cell dimensions, atom positions) for the sample with nominal composition $PrFe_{11}Mo$ were determined by applying the Rietveld refinement method[8] and using as starting structural parameters the ones given in Refs. 9 and 10. Following the procedure described in Ref. 9, it was concluded that the Mo atoms occupy the 8*i* site. The Mo atoms per formula unit were calculated as 0.92(7), very close to the nominal value of $x=1.0$. The isotropic thermal parameters B were kept constant during the refinement and equal to the values given in Ref. 10. The calculated α-Fe content is 5% wt. The lattice constants, atomic positions, and bond distances are listed in Table I. The Rietveld diffraction patterns (observed, calculated, and difference patterns) are shown in Fig. 1.

The Curie temperature of $PrFe_{11}Mo$ as determined by TGM was 498 K. No other ordering temperature was observed, except that of α-Fe. The room-temperature magneti-

zation at 5 T of $PrFe_{11}Mo$ is 120.4 A m^2/kg. This value was deduced taking into account the α-Fe content, 5%, as calculated from the Rietveld analysis. After nitrogenation the Curie temperature increased by about 180 K reaching 681 K. The room-temperature magnetization of the nitride at 5 T reached a value of 136 A m^2/kg (Fig. 2). Nitrogenation resulted in an increase of α-Fe content. The given magnetization value was calculated considering the α-Fe content, 15%, as found from preliminary Mössbauer spectroscopy. The unit-cell dimensions for the nitrided compound are a=8.649(2) Å, c=4.835(3) Å, and V=361.70 Å^3. The unit-cell expansion is 2.4% comparable to the other 1:12 nitrides leading to a value of $y \approx 1$. The magnetization values confirm recent experimental observations that a lower Mo concentration improves the magnetic properties of $RFe_{12-x}Mo_x$ and their nitrides.[6,7] The Curie temperatures of $PrFe_{11}Mo$ and $PrFe_{11}MoN_y$ are 43 and 41 K higher than those of $PrFe_{10.5}Mo_{1.5}$ and $PrFe_{10.5}Mo_{1.5}N_y$, respectively.[5] A similar improvement is observed in the saturation magnetization, i.e., 8.4 and 15.1 A m^2/kg higher than those of $PrFe_{10.5}Mo_{1.5}$ and $PrFe_{10.5}Mo_{1.5}N_y$, respectively.[5]

In Fig. 3 the XRD spectra of the non-nitrided and nitrided $PrFe_{11}Mo$ compounds and the corresponding spectra of magnetically aligned powders, bounded on double-side tape with a magnetic field normal to the plane of the sample holder are shown. As shown in Fig. 3(b) the intensity of the (0 0 2) reflection of the aligned non-nitrided sample decreases and the intensities of the (2 4 0), (0 3 1), (2 3 1), and (1 4 1) increase indicating planar anisotropy. The opposite behavior of the corresponding reflections was observed in the nitrided sample indicating uniaxial anisotropy [Fig. 3(d)]. Such a change from planar anisotropy for the parent compound to uniaxial for the nitrided one has been observed in the case of the x=1.5 compound as well.[5] This is probably due to the sign change of the second-order crystal-field coefficient in the Pr site by analogy to Nd.[3,4]

The $PrFe_{12-x}Mo_x$ alloys with x=0.5 and x=0.75 were annealed at 1273, 1348, 1368, and 1393 K. As found by both

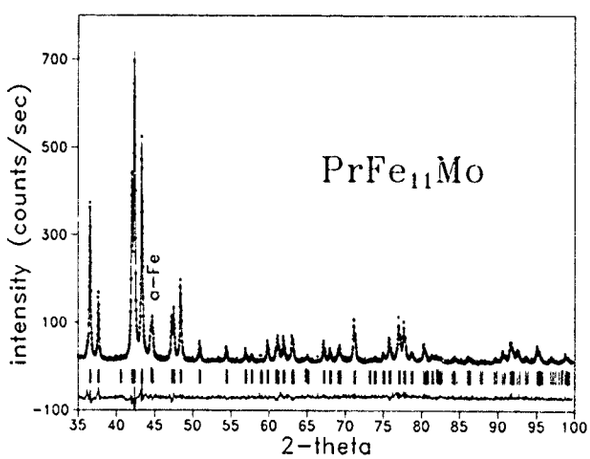

FIG 1. Rietveld refinement patterns for the $PrFe_{11}Mo$ compound. The observed intensities are shown by dots and the calculated ones by the solid line. The position of the Bragg reflections are shown by small vertical lines below the pattern The line at the bottom indicates the intensity difference between the experimental and the refined patterns.

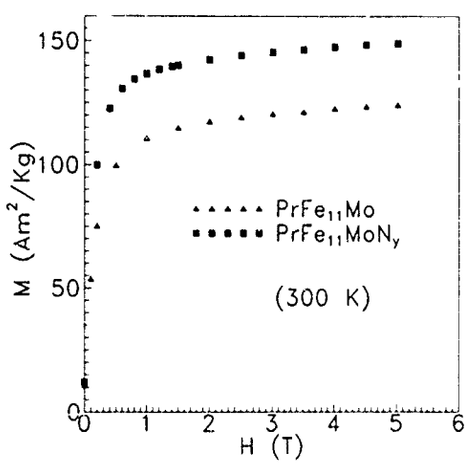

FIG. 2. Room-temperature magnetization curves of randomly aligned powders of $PrFe_{11}Mo$ before and after nitrogenation

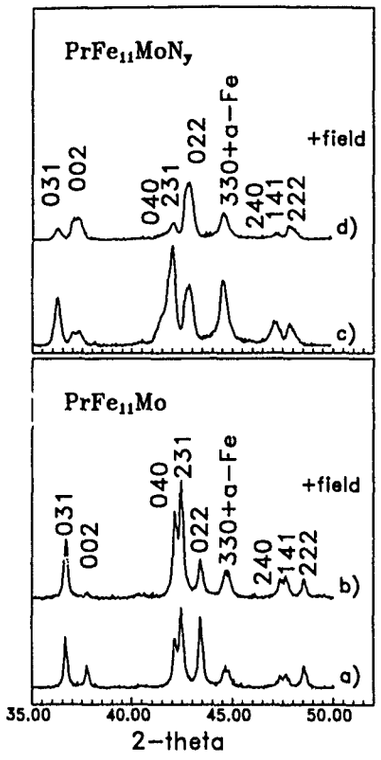

FIG. 3. XRD spectra for (a) parent non-nitrided compound ($PrFe_{11}Mo$), (b) magnetically aligned compound (field normal to the plane), (c) nitrided compound ($PrFe_{11}MoN_y$), and (d) magnetically aligned nitrided compound (field normal to the plane).

XRD and TGM all annealed samples presented a mixture of the 1:12, 2:17, and α-Fe phases. Best results, i.e., minimum 2:17 and α-Fe content, were observed at 1348 K and at 1368 K for the $x=0.5$ and $x=0.75$ samples, respectively. After nitrogenation a mixture of 1:12 and 2:17 nitrides and α-Fe was observed. As in the case of the $x=1.0$ samples, annealing at 1393 K of the $x=0.5$ and $x=0.75$ samples resulted in the precipitation of α-Fe. It was concluded that the peritectic decomposition temperature of $PrFe_{12-x}Mo_x$ is around 1390 K.

IV. CONCLUSION

This work has demonstrated that useful properties of the derivatives of the $ThMn_{12}$-type structure alloys such as $PrFe_{11}Mo$ studied in this work can be obtained by proper heat treatment and second transition-metal concentration. As in other $ThMn_{12}$-type alloys nitrogenation enhances further the magnetization, Curie temperature, and anisotropy. To our knowledge this is the first time that the $PrFe_{11}Mo$ ($x=1.0$) and the related nitride have been synthesized and characterized. It is expected that further improvement can be obtained concerning the system $PrFe_{12-x}Mo_xN_y$ ($0.5 \leqslant x \leqslant 1.0$, $y=0,1$) by proper heat treatment and is part of our current work.

The permanent magnetic properties of isotropic and anisotropic powders of $R(Fe,Mo)_{12}N_x$ compounds, where R=Pr and Nd, were investigated by using mechanical alloying and a conventional milling process. For the isotropic magnetic powders, a coercive force of up to 9 kOe and a maximum energy product of 6.6 MGOe were obtained in Nd compounds, while with the anisotropic powders a maximum energy product of 12 MGOe was achieved. In the isotropic $Pr(Fe,Mo)_{12}N_x$ compounds the best result were 4.5 MGOe for $(BH)_{max}$ and 6.0 kOe for ${}_iH_c$. The temperature dependence of coercive force has been investigated in a temperature range between 300 and 500 K, and the results are reported in a comparison with that of Nd-Fe-B magnets.

I. INTRODUCTION

Findings of the nitrogenation effect on the magnetic properties of rare-earth intermetallic compounds have recently made a great progress in the field of hard magnetic materials. These important developments in magnetism and magnetic materials have shown that great improvements in the magnetic properties can be achieved by introducing interstitial nitrogen or/and carbon atoms. This is particularly important for permanent magnet materials, which require large values of magnetization, uniaxial anisotropy, high Curie temperature T_c, and coercivity at or above room temperature. In 1990 the nitrides $Sm_2Fe_{17}N_x$ and $Nd(Fe,M)_{12}N_x$, where M=Ti, V, Mo, W, etc., were discovered,[1,2] and the studies of the new hard magnetic materials based on RE-Fe nitrides spread worldwide. We have reported that for the RE-Fe nitrides having the $ThMn_{12}$-type structure the interstitial nitrogen atoms not only have a crucial effect of increasing Curie temperature and saturation magnetization, but also give rise to a profound change in magnetocrystalline anisotropy. Due to these effects, $Nd(Fe,M)_{12}N_x$ and $Pr(Fe,M)_{12}N_x$ became well-known candidates for permanent magnet applications.[3–6] Compared to the case of 2-17 nitrides, because of the difficulty in stabilizing the 1-12 phase with a light rare earth, more problems have been encountered in developing high-performance magnets based on the 1-12 nitrides. However, from an economic point of view, the 1-12 compounds present special interest due to the lower price of Nd than Sm. In addition, the 1-12 nitrides have a lower ratio of rare earth to transition metal than the 2-17 nitrides. Accordingly, it is worth studying the 1-12 nitrides concerning the formation conditions of good single phase, improvement on the intrinsic magnetic properties, and creation of high coercivity. As we know, a strong easy-axial anisotropy is the origin of a large coercive force, however, the coercivity is a very sensitive property and depends on microstructure formed by the processing treatment. In this work we have succeeded in preparing the single phase of $NdFe_{10.5}Mo_{1.5}$ and $PrFe_{10.5}Mo_{1.5}$, as well as their nitrides. The key problems dealing with magnet manufacture and the prospect of the 1-12 nitrides in the permanent magnet development are discussed.

II. EXPERIMENTS

Alloys were prepared by arc melting of 99.9% pure materials in an argon atmosphere, followed by a heat treatment around 1000 °C for 1 week. The nitrogenation was carried out at 400–600 °C for 2–4 h in high-purity N_2 gas at atmospheric pressure. The nitrogenated powder was then further pulverized into fine powder by a ball mill. The hysteresis loops of the samples were measured by vibrating sample magnetometer (VSM) with a field of up to 20 kOe in a temperature range from room temperature to 600 K. Some samples were magnetized with a pulse field of up to 40 and 100 kOe.

Mechanically alloyed powders were produced in a high-energy ball mill, starting with Pr-Mo-Fe and Nd-Fe-Mo alloy powders. Magnetic amorphous powders were made by milling process for 1–10 h under argon atmosphere. The powders were then heat-treated in the temperature 750–950 °C for 40 min to form the crystallized 1-12 phase, in a vacuum of 10^{-3} Pa. Nitrides were prepared by passing purified nitrogen gas over the crystallized 1-12 phase at atmospheric pressure at 500 °C for 1–4 h.

Anisotropic magnets based on $Nd(Fe,Mo)_{12}N_x$ nitrides were prepared by a conventional milling process. The powder samples of cylindrical shape ($\Phi 3\times 4$ mm) were aligned with a magnetic field of 10 kOe and fixed in epoxy resin.

III. RESULTS AND DISCUSSIONS

All the samples were found to crystallize in the $ThMn_{12}$-type structure, and, no second phase was observed before and after nitrogenation. As an example, the x-ray-diffraction patterns of $PrFe_{10.5}Mo_{1.5}$ and their nitrides are shown in Fig. 1.

A. Isotropic powders

Isotropic magnetic powders based on $Pr(Mo,Fe)_{12}N_x$ and $Nd(Mo,Fe)_{12}N_x$ were prepared by using a mechanical milling process. In both cases of $Nd(Mo,Fe)_{12}$ and $Pr(Mo,Fe)_{12}$, the x-ray-diffraction patterns and thermomagnetic curves show that there are no other magnetic phases (such as α-Fe). It is important to mention that in order to obtain a desirable co-

FIC 1. X-ray-diffraction patterns of (a) $PrFe_{10.5}Mo_{1.5}$ and (b) $PrFe_{10.5}Mo_{1.5}N_x$.

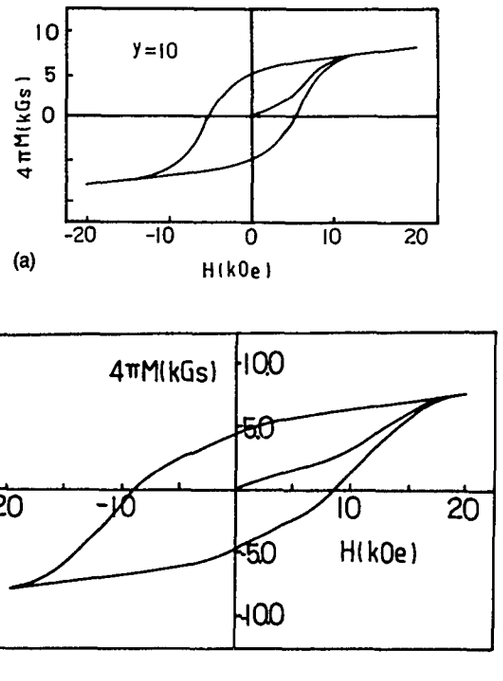

FIG. 3. The magnetic hysteresis loops of different composition powders (a) $Pr(Mo_{0.13}Fe_{0.87})_{10}N_x$, (b) $Nd(Fe,Mo)_{12}N_x$, which were obtained at an annealing temperature of 770 °C for 40 min, measured at room temperature.

ercivity, no α-Fe second phase associated with the starting alloys is required. Figure 2 shows the variations of coercive force, saturation magnetization, and remanence as a function of crystallized temperature of $Pr(Mo_{0.13}Fe_{0.87})_{10}N_x$. From the figure it can be seen that intrinsic coercive force depends sensitively on crystallization temperature with the optimum crystallization temperature 770 °C.

A coercive force of 6.0 kOe is obtained for the Pr nitrides with a crystallization temperature of 770 °C for 40 min and a nitrogenation treatment at 500 °C for 2 h. Figure 3(a) indicates the magnetic hysteresis loop which was obtained at an annealing temperature of 770 °C for 40 min and followed by a heat treatment at 500 °C under N_2 atmosphere for 2 h.

The best results were obtained in $Pr(Mo_{0.13}Fe_{0.87})_{10}N_x$, which has a large coercive force combined with a high remanent magnetization. A higher coercive force, e.g., $_iH_c$=8.9 kOe, is achieved for $Nd(Fe,Mo)_{12}N_x$ with the same process and is seen in Fig. 3(b). As in the case of the mechanically allowed powders, no sensitive orientation effect is observed. Thus, the mechanically alloyed powders are isotropic. From the virgin magnetization curves an obvious jump is observed, which is characteristic of a pinning mechanism for the coercive force. The critical field at which the jump occurs corresponds to the value of the coercive force. This behavior suggests that the coercive force in the case of mechanical alloying is determined by a domain-wall pinning. For the

Mill time (h)	19	49	59	64	107
$_iH_c$ (kOe)[a]	2 558	3.880	4.133	4.326	5.171
$_iH_c$ (kOe)[b]	3 894	5.168	5.209	5.561	6.305

[a]Samples were magnetized and measured at H=20 kOe
[b]Samples were magnetized at H=100 kOe and measured at H=40 kOe.

isotropic samples, the theoretical values of square ratio should be 0.5; our results are larger than this value indicating that the samples are far from saturation at the applied field of 20 kOe.

B. Anisotropic powders

Figure 4 indicates the variation of coercive force as a function of milling time for $Nd(Fe,Mo)_{12}N_x$. It is clear that the coercive force depends sensitively on particle size of the powders, i.e., it increases with grinding time, reaching a maximum, then decreases after prolonged milling. The intrinsic coercive force $_iH_c$ of the powders prepared by the milling process exhibits a large dependence of the magnitude of the magnetic field H_m applied before the coercive force measurements. Table I shows $_iH_c$ for the same sample under different magnetizing field. For the powders with the optimum milling time, a coercive force of 5.2 and 6.3 kOe was obtained by using a magnetizing field of 20 and 100 kOe, respectively. The magnetizing-field dependence of $_iH_c$ is characteristic of domain nucleation. This behavior is different from that of mechanical alloying powders mentioned above. Anisotropic magnets can be made by using the powders prepared by milling methods; however, the saturation magnetization and remanence were found to degrade with milling. Thus, the optimum values of coercive force and remanence cannot be obtained simultaneously. Figure 5 is related with a larger remanence, but a smaller coercive force for $Nd(Fe,Mo)_{12}N_x$. Their permanent magnetic properties are summarized below, respectively: $_iH_c$=2.6 kOe, B_r=9.1 KG, $(BH)_{max}$=12.0 MGOe. All these measurements were made with a magnetizing field of 20 kOe. The coercive force is larger when using a higher applied field as indicated in Table I. Figure 6 plots the temperature dependence of coercive force for three kinds of samples: One was prepared by milling process, the other two by using mechanical alloying. In a temperature range from room temperature to 100 °C the temperature coefficient of coercive force for both samples is −0.5%/K. For a comparison, the temperature dependence of coercive force of $Nd_2Fe_{14}B$ magnets is presented also in Fig. 6. The temperature coefficient of $_iH_c$ for the latter is −0.6%/K. Among the 1-12 nitrides the Curie temperature of $Nd(Fe,Mo)_{12}N_x$ and $Pr(Fe,Mo)_{12}N_x$ is lower. Thus, it may be expected to improve the temperature stability of the magnets based on the 1-12 nitrides by a substitution of Mo with another element, such as Ti, V, etc.

Structural and magnetic properties of $Ce(Fe,M)_{12}N_x$ interstitial compounds, M=Ti, V, Cr, and Mo

Qi Pan, Zun-Xiao Liu, and Ying-Chang Yang
Department of Physics, Peking University, Beijing 100871, People's Republic of China

Stabilizing the 1-12 phase with cerium was possible using a special heat treatment. The structural and magnetic properties of $Ce(Fe,M)_{12}$ and their nitrides, for M=Ti, V, Cr, Mo, etc., were investigated using x-ray-diffraction and magnetic measurements. The effects of interstitial nitrogen atoms on lattice parameters, Curie temperature, saturation magnetization, and magnetocrystalline anisotropy are reported. A profound change was found on the magnetocrystalline anisotropy. As an example, in the case of $CeMo_2Fe_{10}N_x$, the easy magnetization direction changes from c axis to the basal plane depending on the nitrogen content x.

I. INTRODUCTION

During the last few years, a lot of work dealing with the rare-earth (RE)–Fe nitrides having the $ThMn_{12}$-type structure has been conducted for the purpose of permanent magnet development.[1,2] Because of the difficulties in forming the 1-12 phase with cerium, few reports were concerned with cerium compounds. The cerium ion often possesses a relatively higher valence (Ce^{4+}) in the RE-iron intermetallics.[3] Generally, the Ce-Fe compounds have smaller lattice parameters, lower Curie temperatures T_c and less spontaneous magnetization than other rare-earth compounds; thus, it is expected that the interstitial nitrogen atoms may have more significant effects on magnetic properties of the Ce compounds. In addition, Ce^{4+} is nonmagnetic, and it is hoped to obtain useful information associated with the iron sublattice behavior. A study on the Ce nitrides is not only of significance for basic research, but there is also a potential technical application. Since there is a lot of cerium in inexpensive mischmetal, an investigation on the formation and magnetic properties of Ce nitrides might be useful for developing low-cost magnetic materials.

In this work we succeeded in stabilizing the $Ce(FeM)_{12}$ compounds and their nitrides, where M=Ti, V, Cr, and Mo. The effects of interstitial nitrogen atoms on lattice parameters, Curie temperature, saturation magnetization, and magnetocrystalline anisotropy are reported.

II. EXPERIMENT

The samples were prepared by arc melting 99.5% pure materials in a purified argon atmosphere, followed by a heat treatment at 600–1000 °C for 1 week. Nitrides were prepared by passing purified nitrogen gas at atmospheric pressure over finely ground powder samples at 400–600 °C for 1–5 h, followed by rapidly cooling to room temperature. X-ray diffraction and chemical analysis were made to determine the structure and the weight percentage of nitrogen. The powder samples of cylindrical shape were aligned in a 10 kOe field and fixed in epoxy resin. Magnetization curves were measured on aligned powder samples with a field of up to 70 kOe K by using an extracting sample magnetometer. The Curie temperature was determined from σ-T curves which were measured by a vibrating sample magnetometer in the temperature range from 300 to 1000 K.

III. RESULTS AND DISCUSSIONS

A. Crystallographic structure

The samples before nitrogenation were found to be crystallized in single $ThMn_{12}$-type phase for M=Ti, V, Mo. The only exception is Cr, which contained a little 2-17 phase. After nitrogenation, the $Ce(M,Fe)_{12}N_x$ maintains the same structure, but with an increase in the lattice parameters. The lattice parameters a and c, unit-cell volume V, and relative change in unit-cell volume upon nitrogenation $\Delta V/V$ of $Ce(M,Fe)_{12}N_x$, in comparison with $Ce(M,Fe)_{12}$, are all listed in Table I. As an example, x-ray-diffraction patterns of $CeTiFe_{11}$ are illustrated in Fig. 1(a). The unit-cell volumes increase from 2.7% to 3.5% compared with their original counterparts.

B. Curie temperature and saturation magnetization

The Curie temperature T_c, saturation magnetization σ_s, anisotropy field H_A, and easy magnetization direction (EMD) of $Ce(M,Fe)_{12}$ and their nitrides are summarized in Table II. The interstitial nitrogen atoms have an effect of increasing the Curie temperature. The T_c of $CeTiFe_{11}N_x$ is raised from 485 to 710 K by introducing the nitrogen atoms into the $CeTiFe_{11}$ compounds. This effect may be due to the expansion of the unit-cell volume after nitrogenation.

The effect of the interstitial nitrogen atoms on the enhancement of saturation magnetization is significant. The molecule moment is increased from 17.4 μ_B to 21.88 μ_B with M=Ti, or from 13.6 μ_B to 18.6 μ_B with M=V in the $Ce(M,Fe)_{12}$, etc. Since Ce^{4+} is nonmagnetic, the increase of

the saturation magnetization represents an increase in the iron atomic moment.[4] So far, the increases of T_c and the magnetic moments have been regarded as being attributed mainly to the volume expansion (about 3% in average), as a magnetovolume effect, but, that is not enough. The nitrogen atoms enhance the Fe moments not only through lattice expansion but also by changing the electronic bonding nature, which was calculated by Sakuma.[5]

C. Magnetocrystalline anisotropy

In the most rare-earth compounds, 4 f electrons are expected to be well localized compared with the d and s electrons in the transition-metal compounds. So the single-ion model is used effectively dealing with the magnetocrystalline anisotropy in the rare-earth-ion sublattice. In the case of iron sublattice, owing to the itinerant properties of 3d electrons, the situation becomes more complicated. It is not easy to calculate the changes in magnetocrystalline anisotropy theoretically before or after nitrogenation. So the experimental results are even more important in obtaining information about the iron sublattice behavior.

On the basis of the x-ray-diffraction patterns on aligned samples, we can obtain the magnetocrystalline anisotropy of $Ce(M,Fe)_{12}$ and their nitrides. The x-ray-diffraction patterns of magnetically aligned powder samples of $CeTiFe_{11}$ are shown in Fig. 1(b): a drastic increase in (002) reflections and diminution of ($hk0$) lines reveals that it has an easy axial. Figures 2 and 3 are the comparison of magnetization curves along, and perpendicular to, the origination direction at 1.5 K and room temperature between $CeMo_{1.5}Fe_{10.5}$ and $CeMo_{1.5}Fe_{10.5}N_x$, $CeTiFe_{11}$, and $CeTiFe_{11}N_x$. It can been seen that after nitrogenation the anisotropy is decreased. In

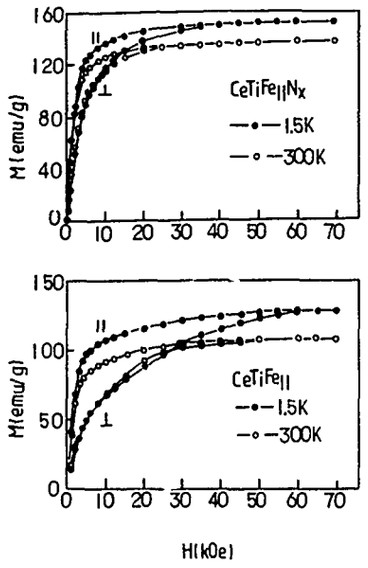

FIG. 3. Magnetization curves along and perpendicular to the origination direction at 1.5 K and room temperature between $CeTiFe_{11}$ and $CeTiFe_{11}N_x$

the compounds with Ce, iron is the only magnetic atom, so the behavior of $CeMo_{1.5}Fe_{10.5}N_x$ anisotropy represents changes in the anisotropy on the iron sublattice.

In order to determine the effect of interstitial nitrogen atoms on the magnetocrystalline anisotropy of the iron sublattice we made samples of $CeMo_2Fe_{10}N_x$ where $x=0$, 0.2, 0.5, 0.8. The x-ray diffraction patterns of $CeMo_2Fe_{10}N_x$ are plotted in Fig. 4: (a) $x=0$ nonaligned samples; (b) $x=0$ aligned samples; (c) $x=0.2$ aligned samples; (d) $x=0.5$ aligned samples; (e) $x=0.8$ aligned samples. The x-ray-diffraction pattern on aligned samples of $CeMo_2Fe_{10}$ in Fig. 4(b) shows that the EMD is along the c axis due to the drastic increase in (002) reflection and diminution of ($hk0$) lines. After the absorption of a certain quantity of nitrogen, the EMD deviates from the c axis, as indicated in Fig. 4(c) for $CeMo_2Fe_{10}N_{0.2}$ because the relative intensity of the (202) line is larger rather than the (002) line. As expected, a profound change was found on the magnetocrystalline anisotropy upon nitrogenation. With the increases of nitrogen content, the drastic increases in ($hk0$) reflections and decreases in (001) lines reveal that when almost all the 2b sites are occupied by nitrogen atoms, the EMD changes to basal plane for $CeMo_2Fe_{10}N_{0.8}$, which is shown in x-ray-diffraction pattern Fig. 4(e). It is clear that the changes in the magnetocrystalline anisotropy of the iron sublattice is observed from the c axis to basal plane with increasing the nitrogen content x.

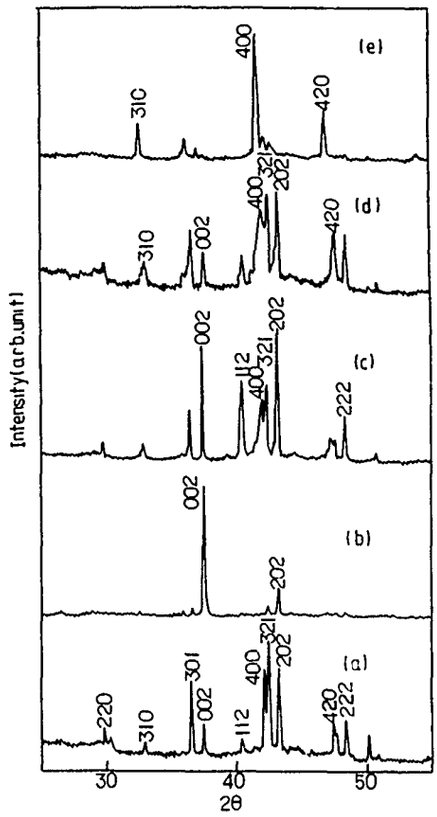

FIG. 4. The x-ray-diffraction patterns of $CeMo_2Fe_{10}N_x$: (a) $x=0$ nonaligned samples; (b) $x=0$ aligned samples; (c) $x=0$ 2 aligned samples; (d) $x=0.5$ aligned samples; (e) $x=0.8$ aligned samples.

IV. CONCLUSION

We have succeeded in forming $Ce(M,Fe)_{12}$ compounds and their nitrides with $ThMn_{12}$-type structure. The nitrides increases both the Curie temperature and spontaneous magnetization, and makes significant changes in magnetocrystalline anisotropy which depends on the nitrogen content x. The experimental results indicate that at room temperature the easy magnetization direction for $CeMo_2Fe_{10}N_{0.8}$ is in the basal plane, contrary to the $CeMo_2Fe_{10}$ compounds.

The magnetic properties of a series of $Tb_2Fe_{17-x}Al_x$ solid solutions, with nominal x compositions of 0, 2, 3, 4, 5, 6, 7, and 8, have been studied by neutron diffraction and Mössbauer spectroscopy. Neutron-diffraction data indicate that the compounds all crystallize with the Th_2Zn_{17} structure and that the aluminum atoms are excluded from the $9d$ site and show a distinct preference for the $6c$ site only for an aluminum content greater than 6. The unit-cell volume increases by approximately 1% per aluminum atom substituted in the formula unit. The magnetic moment per formula unit, measured at 295 K, shows very little change for x less than or equal to 4, but decreases rapidly with increasing aluminum content for higher values of x. Mössbauer spectral results indicate that all the samples are ferromagnetically ordered at 85 K. However, at 295 K $Tb_2Fe_9Al_8$ is paramagnetic and $Tb_2Fe_{10}Al_7$ is either paramagnetic or has at most very small ferromagnetic moments. An analysis of the magnetic spectra with a basal magnetic model is successful for x values of 5 or less; however, at higher x values an axial model for the magnetization is required, indicating the presence of a spin reorientation with increasing aluminum content and decreasing temperature. The weighted average hyperfine field decreases approximately linearly by 21 kOe per substituted aluminum atom at 85 K and more rapidly at 295 K. As expected, the isomer shifts increase with increasing aluminum content as a result of interatomic charge transfer and intraatomic iron $4s$-$3d$ electronic redistribution.

The discovery[1] that the addition of interstitial nitrogen could dramatically increase the Curie temperature of R_2Fe_{17} and, in some cases, change the magnetic anisotropy from basal to axial has led to a renewed interest in these compounds. The primary reason for the increased T_C is the expansion of the lattice caused by the interstitial nitrogen.[2] The lattice may also be expanded by partially substituting the iron by other elements,[3] and an investigation of such partially substituted compounds may lead to a better understanding of the magnetization process and consequently to solid solutions possessing better magnetic properties. In the $R_2Fe_{14-x}Al_xB$ solid solutions,[4,5] aluminum causes both the coercive and the anisotropic fields to increase with only slight decreases in the magnetization and T_C. Partial substitution of iron atoms by aluminum in Ce_2Fe_{17}, Y_2Fe_{17}, Nd_2Fe_{17}, Dy_2Fe_{17}, and Ho_2Fe_{17} causes the unit cell to expand and the T_C to increase with aluminum content at lower aluminum concentrations.[3,6-8] In $Tb_2Fe_{14}B$ the terbium magnetic moments are aligned antiparallel[9] with the iron moments and a similar antiparallel magnetic structure is expected in $Tb_2Fe_{17-x}Al_x$. It has been reported[10,11] that $Tb_2Fe_{17-x}Al_x$ crystallizes in the hexagonal Th_2Ni_{17} structure at aluminum concentrations up to an x of 3.8 and in the rhombohedral Th_2Zn_{17} structure at higher concentrations. Furthermore, its T_C increases with increasing aluminum content at low aluminum concentrations.[10]

The $Tb_2Fe_{17-x}Al_x$ samples were prepared from 99.9% pure elements by arc melting followed by annealing at 900 °C for more than 3 weeks. The phase purity of the samples was checked by x-ray diffraction which indicated that the $Tb_2Fe_{17-x}Al_x$ samples with nominal x values of 2 and higher crystallized with the rhombohedral Th_2Zn_{17} structure. This limiting composition for the rhombohedral phase is considerably lower than that reported by Oesterreicher and Boller[10-12] and may be due to the higher annealing temperature used for the samples in our study.

The neutron-diffraction patterns were measured[6] and refined[13,14] by the same methods as reported earlier. The Mössbauer spectra were measured[6] and fit[15-17] as reported earlier. The spectra that indicated ferromagnetic ordering were fit with four or seven magnetic sextets corresponding to the four or seven magnetically inequivalent iron sites expected for an axial or basal orientation of the magnetization and the site point symmetry.

The Curie temperature of the $Tb_2Fe_{17-x}Al_x$ solid solutions increases with increasing aluminum content at lower aluminum concentrations and reaches a maximum at an x ~3.[18] The results of the refinement of the 295 K neutron-diffraction patterns of these solid solutions are given in Table

I. The lattice parameters increase approximately linearly with x as was found[19] to be the case for the related $Nd_2Fe_{17-x}Al_x$ solid solutions, but the increase differs from the behavior found for the c lattice parameter in $Tb_2Fe_{17-x}Ga_x$, which increases up to an x of 6 and then remains constant at higher values. The unit-cell volume of $Tb_2Fe_{17-x}Al_x$ increases linearly by 8.9 Å^3 per aluminum, a value which is similar to that of the gallium solid solutions.[20]

As is shown in Fig. 1, the aluminum completely avoids the 9d crystallographic site, the site expected to have the smallest Wigner–Seitz cell volume.[19] In contrast, at [illegible]t up to an x of 6, the aluminum somewhat favors the 18h site and occupies the 6c and 18f sites almost randomly. At x values above 6 these trends change and aluminum highly favors the 6c and 18f sites. A rather similar occupation has been observed[19] in the $Nd_2Fe_{17-x}Al_x$ solid solutions and explained on the basis of the differing near-neighbor environments of the different sites.

The compositional dependence of the magnetic moments derived from the neutron-diffraction[9] scattering is given in Table I, and shown in Fig. 2. As expected on the basis of the terbium crystal field,[20] the terbium magnetic moments are antiferromagnetically exchange coupled to the iron moments which are in the basal plane of the unit cell for x values of 5 and less. At larger x values a spin reorientation occurs such that, in $Tb_2Fe_{10}Al_7$, the magnetization is axial. Unfortunately, $Tb_2Fe_9Al_8$ is paramagnetic, at least at 295 K. The iron moment on the 6c site increases gradually for x values up to 6, whereas the other iron moments remain approximately constant for x between 0 and 6.

The Mössbauer spectra of the $Tb_2Fe_{17-x}Al_x$ solid solutions have been measured at 85 and 295 K. The spectra were initially fit with either four or seven broadened magnetic sextets which represent the expected number of magnetic

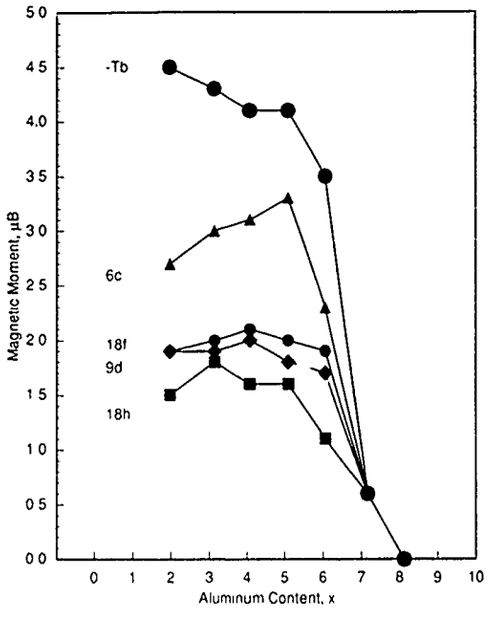

FIG. 2. The iron and terbium magnetic moments at 295 K in the $Tb_2Fe_{17-x}Al_x$ solid solutions. The terbium moments are aligned antiparallel to the iron moments.

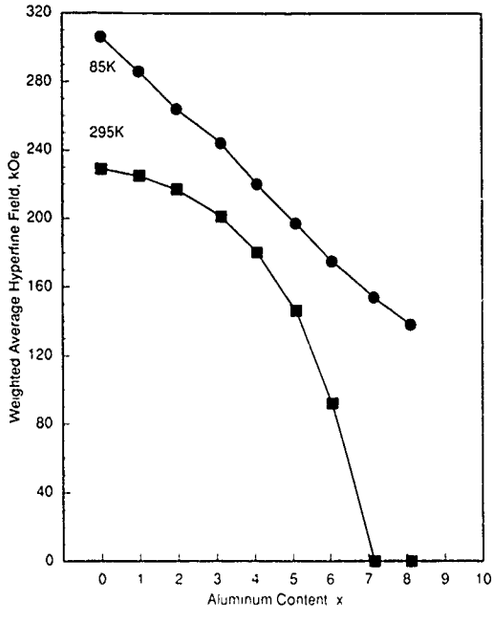

FIG. 3. The area weighted average hyperfine fields in the $Tb_2Fe_{17-x}Al_x$ solid solutions.

sextets in the axially or basally magnetized R_2Fe_{17} materials.[15,21] In agreement with the neutron-diffraction results, it was found that all the 295 K magnetic Mössbauer spectra could only be fit with the basal magnetization model, except for $Tb_2Fe_{11}Al_6$, for which a better fit with the simpler axial model was obtained. The low-temperature spectra for the samples with x values of 6, 7, and 8 were successfully fit with an axial model. This spin reorientation is also apparent in the quadrupole shift changes with increasing x and decreasing temperature. The fitting model, which does not take into account the near-neighbor environment of each iron site, is quite successful in reproducing the observed spectral absorption, but some problems with intensity do occur. A more detailed analysis of these spectra in terms of a binomial distribution of the near-neighbor aluminum environments will be reported elsewhere.[22] Because of the approximations involved in the spectral fits, only the weighted average hyperfine parameters are discussed herein.

The weighted average isomer shifts increase linearly with increasing aluminum content with variations of 0.0257 and 0.0185 mm/s per aluminum at 295 and 85 K, respectively. These increases are typical of those found upon the substitution of either aluminum[19] or gallium[20] for iron to form R_2Fe_{17} solid solutions. The increase may be attributed to an interatomic charge transfer between the iron and aluminum and a subsequent $3d$-$4s$ intraatomic iron electronic redistribution.[23–25] The weighted average hyperfine fields at 295 and 85 K, as a function of aluminum content, are shown in Fig. 4. As expected the hyperfine field at 85 K decreases almost linearly by 21 kOe per aluminum atom with the increasing replacement of magnetic iron with diamagnetic aluminum and the decrease is even more rapid at 295 K; however, the observed hyperfine fields are higher than those observed in the $Nd_2Fe_{17-x}Al_x$ solid solutions, even though the unit-cell volumes of the former are smaller.

Structure and magnetic anisotropy of $Sm_2Fe_{17-x}Al_xC$ (x=2–8) compounds prepared by arc melting

Zhao-Hua Cheng, Bao-Gen Shen, Jun-Xian Zhang, Fang-Wei Wang, Hua-Yang Gong, Wen-Shan Zhan, and Jian-Gao Zhao
State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, P.O. Box 603, Beijing 100080, People's Republic of China

In previous work it was discovered that the 2:17-type rare-earth–iron compounds with high carbon concentration could be formed by the substitution of Ga, Si, or Al, etc., for Fe in $R_2Fe_{17}C_x$. The effect of Al substitution for Fe on the structure and magnetic anisotropy of $Sm_2Fe_{17}C$ has been investigated. Alloys with the composition of $Sm_2Fe_{17-x}Al_xC$ (x=2, 3, 4, 5, 6, 7, and 8) were prepared by arc melting. The carbides are single phase with rhombohedral Th_2Zn_{17}-type structure except for $Sm_2Fe_{17}C$ which contains a small amount of α-Fe. The addition of Al results in an approximately linear increase in the lattice constants and the unit-cell volumes. The Curie temperature T_c is found to increase slightly when $x \leqslant 3$, then decrease rapidly with increasing Al concentration, while the room-temperature saturation magnetization decreases monotonically with the addition of aluminum. X-ray-diffraction and magnetization measurement studies of magnetic-field-oriented powders demonstrate that the samples with $x \leqslant 6$ exhibit an easy c-axis anisotropy at room temperature and the room-temperature anisotropy field increases from 5.3 T for x=0 to about 11 T for x=2. Further substitution decreases the anisotropy field. For the sample with x=2, the room-temperature anisotropy field is higher than that of $Nd_2Fe_{14}B$, and the saturation magnetization is about 110 emu/g. In this alloy, the substitution of a small amount of other elements, such as Co, Ni, etc., may yield a further improvement in its magnetic properties. Thus, it is possible that these carbides can be used as the starting materials for producing high-performance 2:17-type sintered permanent magnets.

I. INTRODUCTION

The interstitial rare-earth–iron compounds based on the rhombohedral Th_2Zn_{17}-type or hexagonal Th_2Ni_{17}-type structure are found to have an excellent intrinsic magnetic properties;[1] however, the poor high-temperature stability of $Sm_2Fe_{17}C_x$ and $Sm_2Fe_{17}N_x$ compounds prepared by gas-solid reaction methods restricts the possible application of these materials as permanent magnets. Our previous studies have shown that the heavy-rare-earth–iron compounds $R_2Fe_{17}C_x$ with high carbon concentration ($x \approx 3.0$) could be obtained from melt spinning.[2–4] Their intrinsic magnetic properties are comparable to those of the corresponding carbides prepared by gas-solid reaction. It was noteworthy that they could be stabilized at high temperature (above 1000 °C). It was, however, still difficult to synthesize $Sm_2Fe_{17}C_x$ with $x \geqslant 1.5$. Recently, it was discovered that highly stable $Sm_2Fe_{17}C_x$ with $x \leqslant 3.0$ can be formed by the substitution of Al, Ga, or Si.[5–7] In this work, the effect of the substitution of Al on the structure and magnetic anisotropy of $Sm_2Fe_{17}C$ is reported.

II. EXPERIMENT

Iron and carbon were first melted together in an induction furnace to form Fe-C alloy with a lower melting temperature. Then Fe, Sm, Al, and Fe-C alloys were melted by arc melting in a high-purity argon atmosphere. Elements used were at least 99.9% pure. An excess of 10%–20% Sm was added to compensate the evaporation during melting. The ingot alloys were melted at least four times to ensure homogeneity, then annealed under an argon atmosphere at 1400 K for 5 days followed by quenching into water. Ingots were then ground to yield powders and oriented in an applied field of 2 T in an epoxy resin. X-ray-diffraction (XRD) experiments were performed on powder samples using Co$K\alpha$ radiation to determine the phase structure as well as lattice constants and unit-cell volume. The Curie temperature T_c was derived from the temperature dependence of magnetization $\sigma(T)$ curves measured by a vibrating sample magnetometer in a field of 700 Oe. The anisotropy fields H_A were obtained from the magnetization curves measured along and perpendicular to the aligned direction by using the magnetometer with a magnetic field up to 7 T. The saturation magnetization at 300 K was obtained from fitting the experimental data for $M(H)$ vs H using the law of approach to saturation.

III. RESULTS AND DISCUSSIONS

The XRD study demonstrates that all Al-containing alloys are single-phase compounds with the rhombohedral Th_2Zn_{17}-type structure and no significant diffraction from impurity phases, especially bcc α-Fe, is observed. For example, Fig. 1(a) shows the typical XRD pattern of $Sm_2Fe_{11}Al_6C$; however, $Sm_2Fe_{17}C$ contains a few percent α-Fe of impurity phase. This fact implies that the addition of Al can help the formation of the 2:17-type carbides with high carbon concentration.

The lattice constants a,c and the unit-cell volume v of $Sm_2Fe_{17-x}Al_xC$ compounds are summarized in Table I. It can be seen that these both show a linear dependence on Al concentration as we would excepted on the basis of a simple model involving atomic volumes. To a good approximation,

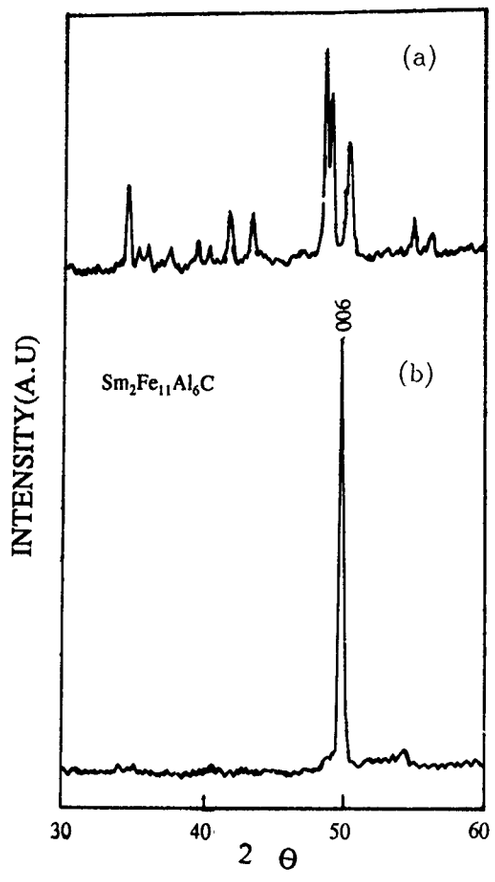

FIG. 1. Co$K\alpha$ radiation x-ray-diffraction patterns of $Sm_2Fe_{11}Al_6C$ prepared by arc melting: (a) unoriented powders, and (b) oriented powders.

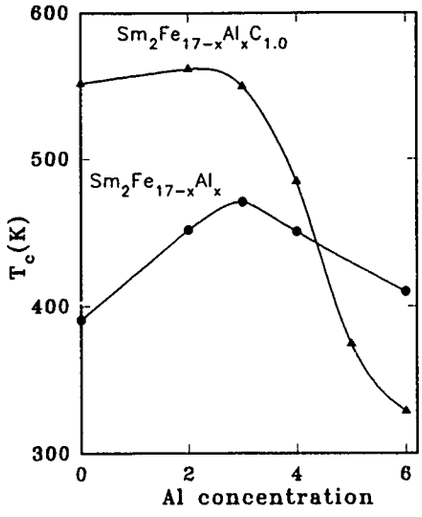

FIG. 2. The Curie temperature of $Sm_2Fe_{17-x}Al_xC$ and $Sm_2Fe_{17-x}Al_x$ as a function of Al concentration.

therefore, the substitution of larger Al atoms for Fe merely produces an expansion of the lattice. This result is consistent with that of $R_2Fe_{17-x}Al_x$ with R=Y, Ho,[8] and Sm.[9] The fact that the ratio c/a is, within experimental uncertainty, independent of the Al content of these carbides indicates that the expansion of the lattice caused by the substitution of larger Al atoms for smaller Fe atoms is essentially an isotropic process.

The Curie temperature T_c of $Sm_2Fe_{17-x}Al_xC$ versus Al concentration is shown in Fig. 2. For comparison, the T_c of $Sm_2Fe_{17-x}Al_x$ is also presented in this figure.[9] For the carbides, T_c is found to increase slightly when $x\leqslant 3$, then decrease rapidly with increasing Al concentration, while the T_c of $Sm_2Fe_{17-x}Al_x$ increases more sharply when $x\leqslant 3$. It is commonly assumed that the magnetic ordering temperature in rare-earth–iron compounds is determined by the Fe-Fe exchange interactions. The generally low values of T_c in R_2Fe_{17} compounds result from the relatively small Fe-Fe distance in these materials. The increase in Curie temperature corresponds to an increase in the positive Fe-Fe exchange coupling as a result of increased interatomic distance. Jacobs *et al.* have shown that this coupling increases with increasing Al content up to about $x=3$ in $R_2Fe_{17-x}Al_x$ with R=Y, and Ho;[8] however, for the carbides, the interstitial carbon atoms have already enlarged the interatomic distance. Both C and Al atoms will influence the Curie temperature and the effect of Al atoms on the Curie temperature is not significant.

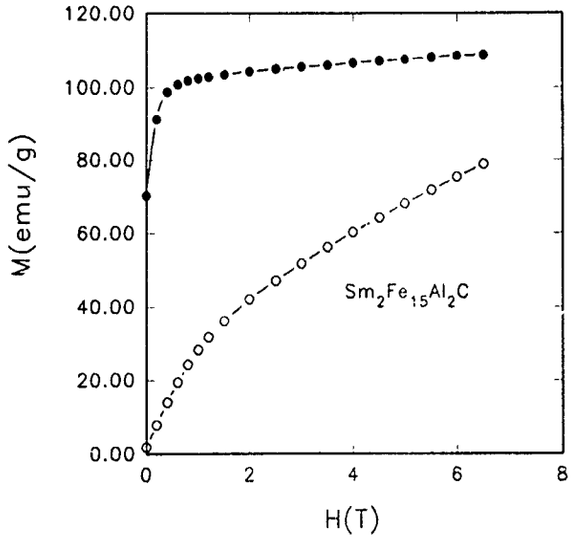

FIG. 3. Magnetization curves of $Sm_2Fe_{15}Al_2C$ at 300 K along and perpendicular to aligned direction, solid and open circles are for parallel and perpendicular to the aligned direction, respectively.

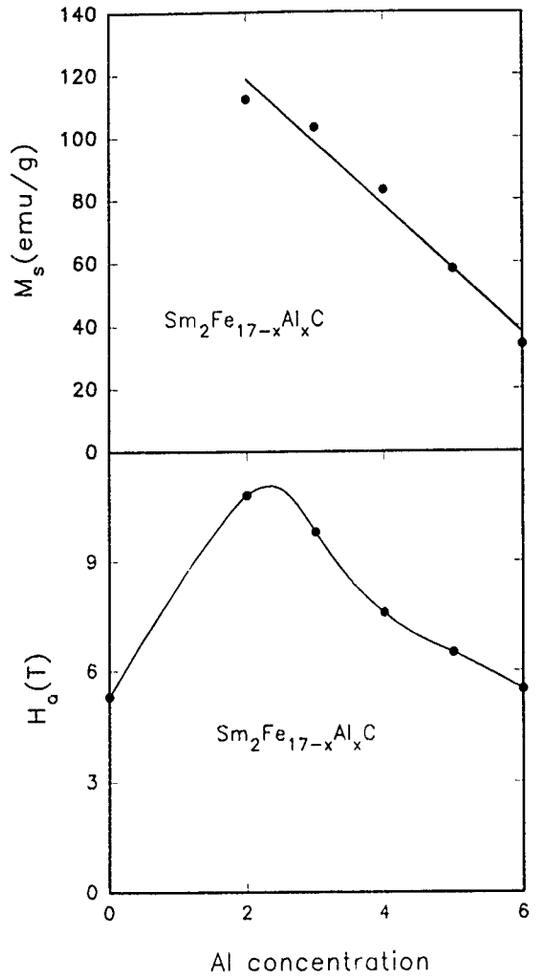

FIG. 4. The saturation magnetization M_s and anisotropy field at room temperature as a function of the Al concentration.

In order to study the effect of Al on the magnetocrystalline anisotropy in $Sm_2Fe_{17}C$ compounds, XRD and magnetization measurements have been carried out on the magnetic-field-aligned powder samples. XRD studies of magnetic-field-oriented powders can provide information concerning the magnetocrystalline anisotropy on the basis of the diffraction peaks present in each of the patterns. Figure 1(b) presents the room-temperature diffraction patterns of oriented $Sm_2Fe_{17-x}Al_xC$ powders with $x=6$. A uniaxial anisotropy occurs for all compounds as evidenced the fact of a drastic increase in the (0,0,6) reflection and the disappearance of $(h,k,0)$.

Figure 3 shows an example of the magnetization curves measured parallel and perpendicular to the aligned direction at room temperature for the sample with $x=2$. The anisotropy field H_A estimated from the measurement curves and the saturation magnetization M_s of $Sm_2Fe_{17-x}Al_xC$ as a function of the Al concentration is plotted in Fig. 4. The room-temperature saturation magnetization decreases monotonically with increasing Al content, while the room-temperature anisotropy field of $Sm_2Fe_{17-x}Al_xC$ is found to increase from 5.3 T,[10] for $x=0$, to 10.8 T for $x=2$. Further substitution decreases the anisotropy field. This means that the addition of Al in $Sm_2Fe_{17-x}Al_xC$ has a very significant influence on the magnetocrystalline anisotropy. Earlier reports indicated that the addition of Al in Sm_2Fe_{17} compounds can develop a room-temperature uniaxial anisotropy when $x\geq 2$,[6,9] without the need to introduce interstitial nitrogen or carbon atoms. For the sample with $x=2$, the Curie temperature is about 560 K, the room-temperature saturation magnetization is about 110 emu/g, and the anisotropy field at room temperature is 10.8 T. The value of H_A is much higher than that of $Sm_2Fe_{17}C$ and $Nd_2Fe_{14}B$ (8 T), but the saturation magnetization is somewhat lower than that of the Al-free compound. In this alloy, the substitution of a small amount of other elements, such as Co, Ni, etc., or the reduction of the Al concentration may yield a further improvement in the hard magnetic properties. Thus, it is possible that these carbides can be used as the starting materials for producing high-performance 2:17-type sintered permanent magnets.

In summary, single-phase $Sm_2Fe_{17-x}Al_xC$ compounds with $2\leq x\leq 8$ have been prepared by arc melting. The addition of Al in these materials can not only help the formation of the 2:17-type rare-earth–iron compounds with high carbon concentration, but also improve the hard magnetic properties. For the samples with $x=2$, the Curie temperature is about 180 K higher than that of Sm_2Fe_{17} and comparable with that of $Nd_2Fe_{14}B$, and the anisotropy field is much higher than that of $Nd_2Fe_{14}B$ and $Sm_2Fe_{17}C$. The present work suggests that $Sm_2(Fe,Al)_{17}C_x$ magnets with appropriate carbon concentration can be a starting material for sintered permanent magnets.

The magnetic properties of single-phase 2:17 compounds of the composition $Sm_2Fe_{17-x-y}Co_yM_x$ with M=Al and Ga and x and y in the range 0–5 are reported. The Curie temperature is found to increase for the $y=0$ samples with increasing x up to a maximum at $x=3$ for M=Al and $x=4$ for M=Ga and a monotonic increase with increasing y for all x and M. Samples with $x<2$ showed an easy-plane magnetic anisotropy at room temperature while samples with $x>2$ showed a single-phase uniaxial anisotropy. The addition of Co is seen to increase the saturation magnetization and the anisotropy field.

I. INTRODUCTION

The rare-earth–iron compounds of the composition R_2Fe_{17} are of potential commercial interest as they possess good thermal stability and the large Fe content yields high saturation magnetization; however, two severe drawbacks have limited the practical application of these compounds as hard magnetic materials; (1) the relatively low values of the Curie temperature[1,2] and (2) the lack of a room-temperature uniaxial anisotropy. While many rare-earth–cobalt compounds do not suffer from these drawbacks, they are certainly not as attractive for commercial applications from an economic standpoint.

Recent studies concerning methods by which the technical magnetic properties may be improved have been concerned with the preparation of materials with either substitutional or interstitial impurities. Results have shown that the substitution of Co, Ni, Al, and Si, for Fe, at least up to a certain point, increases the Curie temperature (see, e.g., Refs. 1–3) and recent evidence has indicated that the substitution of sufficient quantities of Al or Ga for Fe can induce a room-temperature anisotropy in these materials.[4,5] Interstitial hydrogen, carbon, and nitrogen can yield substantial increases in the Curie temperature (see, e.g., Refs. 6 and 7). Although C and N interstitials favor the formation of a uniaxial anisotropy,[7,8] the presence of interstitial H has been shown to be detrimental in this respect.[8] In the present work an investigation of the effects of *sp* (i.e., Al and Ga) substitutions on Sm-based compounds is reported.

II. EXPERIMENTAL METHODS

Samples of $Sm_2Fe_{17-x-y}Co_yM_x$, with M=Al and Ga and x and y in the range of 0–5 were prepared by arc melting components followed by grinding to a powder with an average particle size of about 20 μm. Powders were annealed under argon at 1273 K for 72–100 h and water quenched. Structural properties were investigated using a Siemens D500 scanning x-ray diffractometer. Room-temperature magnetic anisotropy was determined from x-ray-diffraction patterns of powder samples which were mixed with epoxy resin and aligned in a magnetic field of 1.0 T. Curie temperatures were obtained by calorimetric techniques. Magnetization curves were obtained at 10 K with a standard induction magnetometer in applied fields up to 3.0 T.

III. RESULTS

X-ray-diffraction studies indicate that all compounds are of the rhombohedral Th_2Zn_{17} structure. A typical pattern is illustrated in Fig. 1(a) and cell volumes are given in Table I. The measured magnetic anisotropies and Curie temperatures are also given in the table. The presence of a uniaxial anisotropy observed in some of the samples is illustrated in Fig. 1(b). The unit-cell-volume dependence of the Curie temperature is illustrated in Fig. 2 for the Sm-Fe-Al and SM-Fe-Ga compounds. The magnetic properties of the Sm-Fe-Co-Al compounds are summarized in Fig. 3. ΔM_0 is defined as the difference between the easy- and hard-axis magnetization extrapolated to zero applied field and is a measure of the strength of the magnetic anisotropy field.

IV. DISCUSSION AND CONCLUSIONS

The value of the Curie temperature in these materials[2] is primarily dependent on the magnitude of the exchange coupling between transition-metal (TM) atoms J_{TT}. This becomes more positive and increases T_c as larger nonmagnetic atoms are substituted for Fe. Beyond a certain point, however, a decrease in J_{TT} and T_c results from either the further dilution of the magnetic species or the further increase in Fe-Fe neighbor distances or both. The rare-earth–transition-metal (RE-TM) coupling[3] J_{RT} and the RE-RE coupling J_{RR} are substantially smaller than J_{TT} and are relatively independent of interatomic distances. As illustrated in Fig. 2, the changes in T_c as a function of atomic volume which result from the substitution of Al are substantially less than those which result from the substitution of Ga. As this difference is not expected on the basis of atomic volume, it is presumably due to the $3d$ coupling between Ga and Fe, which is not a factor for the Al-containing compounds. The substantial increase in Curie temperature with the substitution of Co for Fe is indicative of a strong Ferromagnetic Fe-Co coupling.

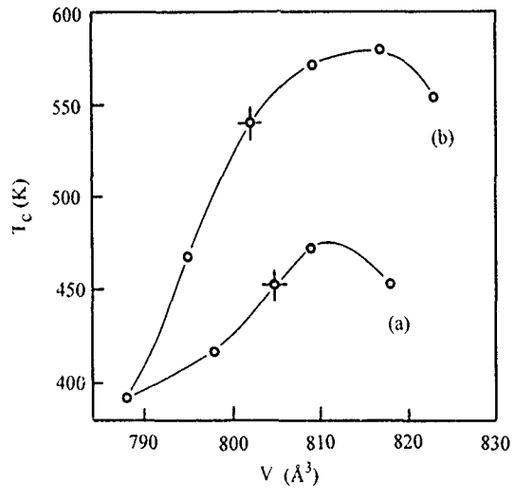

FIG 2 Measured cell volume dependence of the Curie temperature for $Sm_2Fe_{17-x}M_x$ compounds for (a) M=Al and (b) M=Ga.

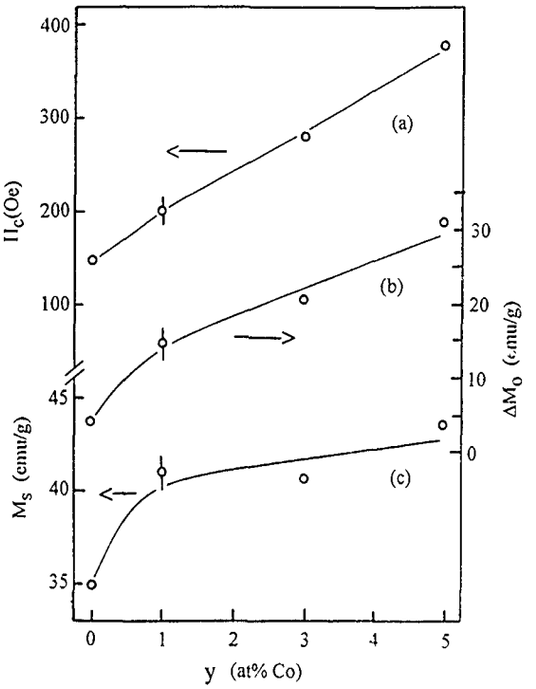

FIG. 3. Composition dependence of the magnetic properties of $Sm_2Fe_{14-y}Co_yAl_3$ compounds: (a) coercivity at 10 K, (b) ΔM_0=difference between easy- and hard-axis magnetization at 10 K, and (c) M_s (saturation magnetization) at 10 K and 1.0 T.

In contrast to earlier reports[2] that the substitution of Al or Ga for Fe in Sm_2Fe_{17} does not alter the planar anisotropy, the present results clearly show that in compounds with $x>2$, a uniaxial anisotropy is observed. The net magnetic anisotropy is determined from the sum of the Fe and the rare-earth sublattice anisotropies. The rare-earth sublattice anisotropy is determined by the product of the second-order Stevens coefficient α_J, which reflects the form of the $4f$ charge distribution and the second-order crystal-field parameter. A_2^0 is negative in the 2:17 compounds,[6,9,10] and a negative product $\alpha_J A_2^0$ gives a uniaxial contribution, it is in cases where α_J is positive, as for Sm, that an easy-axis anisotropy is favored. The present studies indicate that increasing the sp content (at least up to $x=5$) increases the uniaxial contribution from the Sm sublattice as a result of an increase in the magnitude of the negative A_2^0.[4] These changes can be understood in terms of the electronic structure of the RE environment.[11] The principal contribution to the electric-field gradient experienced by the Sm $4f$ shell results from the details of the RE $5d$ and $6p$ electron charge density which must match that of the neighboring atoms on the Wigner–Seitz (WS) boundary. These are the $18f$ TM sites which lie in the basal plane of the Th_2Zn_{17} structure as illustrated in Fig. 4. The existence of sp atoms in those sites in Al- and Ga-substituted compounds has been demonstrated by Weitzer *et al.*[12,13] The large electron density at the WS boundary of the $18f$ sp atoms is analogous to the case of N or C interstitials in the basal plane and yields a large negative A_2^0.

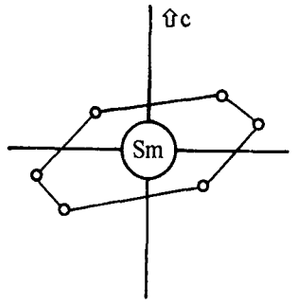

FIG. 4. 18*f* site configuration around the Sm atoms in the rhombohedral Th_2Zn_{17} structure.

The hysteretic properties of the uniaxial materials studied here show several characteristic features: (1) large distinction between the magnetization measured along the easy axis and along the hard axis; (2) large values of the saturation magnetization; and (3) moderate values of the coercivity. These properties are illustrated in Fig. 3 for $Sm_2Fe_{14-y}Co_yAl_3$. Even very small concentrations of Co are beneficial in improving the technical magnetic properties, including an increase in the saturation magnetization and Curie temperature as given in Table I.

Numerous RE-TM compounds have been studied with the idea of utilizing their hard magnetic properties for permanent magnet applications. The RE_2Fe_{17} compounds are attractive because of their low cost. The present work shows that a room-temperature uniaxial anisotropy and an increase in Curie temperature can be achieved by *sp* substitution for Fe. As well, the saturation magnetization in these materials is high and can be further improved by the substitution of a small quantity of Co for Fe. Further investigation of sample preparation methods such as e.g., ball milling is required in order to achieve improvement in coercivity. The properties for the materials prepared in the present work are consistent with the requirements for perpendicular recording materials and are comparable to commercially viable materials such as CoCr films. The present compounds also have the advantage of allowing for the design of materials with specific characteristics which are tailored to particular recording applications. Further investigation of these materials for this application is warranted and will enable compositions and processing techniques to be refined.

Structural and magnetic properties of the $R_2Fe_{17-x}Ga_x$ compounds (R=Y, Ho, $0 \leqslant x \leqslant 6$) have been investigated. All investigated $Ho_2Fe_{17-x}Ga_x$ compounds with $x>2.5$ crystallize in the Th_2Zn_{17}-type structure and the others in the Th_2Ni_{17}-type structure. The substitution of Ga for Fe leads to an increase in lattice constants a, c, and unit-cell volume, a decrease of the average Fe moment, and a maximum of the Curie temperature as a function of the Ga concentration at $x=3$, for both $Y_2Fe_{17-x}Ga_x$ and $Ho_2Fe_{17-x}Ga_x$ compounds. The high magnetic field leads to a spin phase transition from the ferromagnetic to the canted phase. The critical field B_c of the transition decreases with increasing Ga concentration. The exchange interaction constants J_{TT} between Fe–Fe spins and J_{RT} between R–T spins have been derived from a mean field analysis of Curie temperature. It has been found that J_{TT} increases at first, going through a maximum at $x=3$, then decreases with increasing x, whereas J_{RT} is almost independent of the Ga content, which is consistent with the result obtained from a mean field analysis of the high field magnetization curves of the $Ho_2Fe_{17-x}Ga_x$.

I. INTRODUCTION

Since Coey and Sun reported that the introduction of nitrogen leads to a remarkable improvement in the magnetic properties of R_2Fe_{17} compounds,[1] which makes these compounds interesting materials for permanent magnets, the structural and magnetic properties of the interstitial nitrides have attracted much attention. In order to fully understand the interaction in these nitrides, it is necessary to first understand the exchange interaction of the R–T and T–T spins in their parent compounds. Previous studies of these interactions have shown improvement in the properties of these compounds by substituting other atoms for Fe or R.[2,3] In this paper, the influence of the substitution of Ga for Fe on the magnetic properties of $R_2Fe_{17-x}Ga_x$ (R=Ho, Y) compounds has been studied. The exchange interaction of the R–T and T–T spins in these compounds has been calculated based on a mean field analysis of the Curie temperature of $R_2Fe_{17-x}Ga_x$ (R=Y, Ho), which are then compared with the results obtained by the mean field analysis of the high field magnetization curves of $Ho_2Fe_{17-x}Ga_x$.

II. EXPERIMENT

The $Ho_2Fe_{17-x}Ga_x$ (x=0, 0.25, 1.0, 2.5, 4.0, and 6.0) and $Y_2(Fe_{1-x}Ga_x)_{17}$ (x=0, 0.06, 0.12, 0.20, 0.30, and 0.40) compounds were prepared by arc melting the constituent elements of 99.9 wt % purity or better, and followed by annealing in an argon atmosphere at 1473 K for 4 h. X-ray diffraction was performed on powdered samples using Cu-$K\alpha$ radiation. Magnetization measurements at 4.2 K have been performed in the High Magnetic Field Installation at the University of Amsterdam.[4] The measurements were done on powder particles about 30 μm, which are sufficiently small to regard them as monocrystalline. During the magnetization measurement, the particles are free to rotate in the sample holder, so that they can orient their magnetic moments into the direction of the applied field. Magnetization versus temperature curves were measured in a field of 500 Oe by means of the vibrating sample magnetometer (VSM) between temperatures from 300 K to 800 K. The Curie temperature were derived by σ^2 vs T plot.

III. RESULT AND DISCUSSION

X-ray diffraction patterns showed that the $Ho_2Fe_{17-x}Ga_x$ compounds for $x \leqslant 2.5$ crystallize in Th_2Ni_{17}, and for $x>2.5$ crystallize in Th_2Zn_{17}, as shown in Fig. 1. The substitution of a larger radius Ga atom for the Fe atom makes the Th_2Ni_{17}-type structure unstable. The values of lattice parameters a and c are given in Table I. The substitution of Ga for Fe results in a linear increase of the lattice constants in $Ho_2Fe_{17-x}Ga_x$ compounds, reflecting the larger radius of the Ga atom.

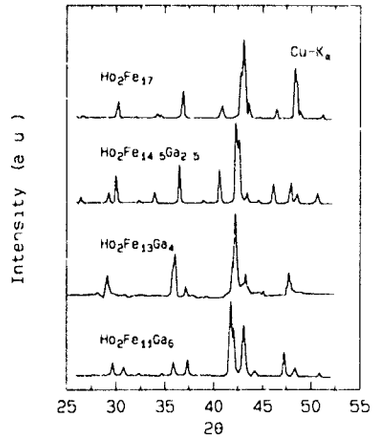

FIG. 1. The x-ray diffraction patterns of $Ho_2Fe_{17-x}Ga_x$, x=0, 2.5, 4.0, and 6.0

$Ho_2Fe_{13.0}Ga_{4.0}$	8.584	8.392	518	20.4	1.91
$Ho_2Fe_{11.0}Ga_{6.0}$	8.639	8.434	450	0.4	1.83

The Curie temperature T_c of the $Ho_2Fe_{17-x}Ga_x$ and $Y_2Fe_{17-x}Ga_x$ rises rapidly at first with x, going through a maximum at about $x=3$, and falls quickly with x, as shown in Fig. 2. The values of Tc for these compounds are also listed in Table I. The Curie temperature is mainly determined by the Fe–Fe exchange interaction, which is sensitive to the Fe–Fe distance. Therefore the increase of Tc for the compounds with $x<2$ with x may be partially associated with the lattice expansion upon the substitution of Ga for Fe. On the other hand, it has previously been found that Ga, like Al in $Y_2Fe_{17-x}Al_x$ compounds, preferentially occupies the 6c sites.[5–7] Therefore the substitution of Ga for Fe may decrease the negative exchange interaction between Fe–Fe at 6c sites and increase the Curie temperature of these compounds. The decrease of the Curie temperature for the compounds with $x>3$ increasing with the Ga concentration is due to the decrease of the average iron magnetic moment and the reduced iron concentration.

The saturation moment of $Ho_2Fe_{17-x}Ga_x$ and $Y_2Fe_{17-x}Ga_x$ decreases with increasing Ga concentration. The average iron magnetic moment μ_{Fe} was derived on the basis of the saturation magnetization σ_s measured at 4.2 K. The σ_s values have been corrected for the contribution of α-Fe impurity phase to the magnetization, which could be deduced from the high temperature magnetization measurements. In the evaluation of the magnetic moment per iron, it was assumed that the moment of Ho is independent of the Ga content, and the value is the same as that of the free Ho ion ($10\mu_B$). It can be found that the average Fe ion moment decreases with increasing Ga content, as shown in Table I.

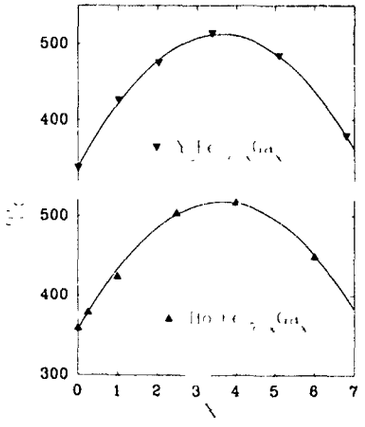

FIG. 2. Ga content dependence of the Curie temperature T_c of $Y_2Fe_{17-x}Ga_x$ and $Ho_2Fe_{17-x}Ga_x$.

In the rare earth-transition metal intermetallics, there are three types of the interactions, namely the R–R interactions between the magnetic moments within the R sublattice, the T–T interactions between the magnetic moments of T sublattice, and the R–T intersublattice interactions. Among them, the T–T interaction is the strongest and the R–R interaction is the weakest, and is usually neglected.[8] According to the mean field analysis of Curie temperature,[8] J_{RT} and J_{FeFe} can be expressed by

$$J_{RT}=g_R g_T \mu_B{}^2 N_T n_{RT}/2Z_{RT}(g_R-1)(g_T-1), \tag{1}$$

$$3kT_c=a_{FeFe}+(a_{FeFe}{}^2+4a_{RFe}a_{FeR})^{1/2}, \tag{2}$$

where

$$a_{FeFe}=Z_{FeFe}J_{FeFe}s_{Fe}(s_{Fe}+1), \tag{3}$$

$$a_{RFe}a_{FeR}=Z_{RFe}Z_{FeR}s_{Fe}(s_{Fe}+1)(g-1)^2J(J+1)J_{RFe}{}^2, \tag{4}$$

$$J_{FeFe}=a_{FeFe}/Z_{FeFe}s_{Fe}(s_{Fe}+1), \tag{5}$$

where a_{ij} is the microscopic exchange coupling parameters, J_{ij} is $i-j$ exchange constants, n_{RT} expresses the macroscopic molecular field coefficients, $g_R=8$ and $j=\frac{5}{4}$ for Ho, the orbital moment of the Fe atom is assumed to be quenched, so one takes $g_T=2$, $J_T=s_T$, and $s_T=\mu_{Fe}/2$. Z_{ij} is the number of the nearest j neighbors of the i ion, N_i is the numbers of the i atom per formula unit. The J_{FeFe} and J_{RFe} were calculated using Eqs. (1)–(5). The values of J_{FeFe} and J_{RFe} as a function of Ga content are shown in Fig. 4. It can be seen that J_{RFe} is almost unchanged with x; however, J_{TT} increases with the Ga content for $x<3$, going through a maximum at about $x=3$, and then decreases for $x>3$, as shown in Fig. 4. The J_{RT} can also be calculated from a mean field analysis of the high field magnetization curves.[9] For ferrimagnetic R–T in-

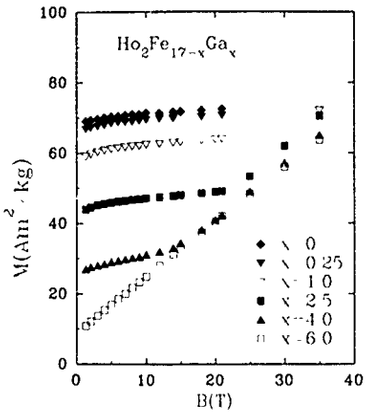

FIG. 3. The high field magnetization curves of $Ho_2Fe_{17-x}Ga_x$.

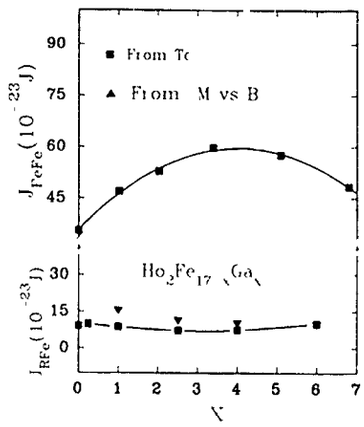

FIG. 4. Ga content dependence of the exchange interaction constants J_{FeFe} and J_{RFe} in $Ho_2Fe_{17-x}Ga_x$.

termetallics, in the fields beyond a critical field strength $B_{cr,1}=n_{RT}|M_T-M_R|$ (M_T and M_R are the magnetization of the R and T sublattice, respectively), the exactly antiparallel R and T moments start to bend toward each other. The total magnetization is described by $M=B/n_{RT}$ and thus

$$\frac{dM}{dB}=[n_{RT}]^{-1}, \tag{6}$$

where $M=[M_R{}^2+M_R{}^2+2M_RM_T\cos(\alpha)]^{1/2}$.

The parameter n_{RT} can be derived from the high field slopes for $B>B_{cr,1}$. We can see in Fig. 3 that the critical field $B_{cr,1}$ decreases with increasing Ga concentration because of the decrease of M_T. J_{RFe} was also calculated using the obtained values of n_{RT} and Eq. (1), and the values of J_{RT} are also shown in Fig. 4. They are in agreement with the results obtained by the mean field analysis of the Curie temperature.

IV. CONCLUSION

The substitution of Ga for Fe results in an increase in lattice constants and a transformation from the Th_2Ni_{17}-type structure to the Th_2Zn_{17} structure. A maximum of the Curie temperature with Ga concentration is due to the change of Fe–Fe and R–Fe exchange interaction and the decrease of average iron magnetic moment μ_{Fe}. The exchange interaction constants J_{TT} between Fe–Fe spins and J_{RT} between R–T spins have been derived, based on the mean field analysis of Curie temperature. It has been found that J_{TT} increases at first, going through a maximum at $x=3$, then decreases with increasing x, whereas J_{RT} is almost independent of the Ga content, which is consistent with the result obtained from a mean field analysis of the high field magnetization curves of the $Ho_2Fe_{17-x}Ga_x$. J_{FeFe} is about four times J_{RFe}. The critical field $B_{cr,1}$ decreases with increasing Ga concentration.

Magnetic properties of $Sm_2(Fe_{1-x}Ga_x)_{17}$ compounds and their nitrides have been studied. Substitution of Ga for Fe leads to an increase in lattice constants. Introduction of nitrogen results in a further increase in lattice constants. Substitution of Ga for Fe causes a dramatic change of the Curie temperature of the $Sm_2(Fe_{1-x}Ga_x)_{17}$ compounds. When $x=0.2$ the Curie temperature is enhanced by about 200 K. X-ray-diffraction patterns of aligned samples of $Sm_2(Fe_{1-x}Ga_x)_{17}$ compounds show that alloys with $x=0.15$, 0.20, and 0.25 exhibit uniaxial anisotropy at room temperature. The introduction of nitrogen made the samples with $x\leqslant 0.4$ exhibit uniaxial anisotropy at room temperature. The Curie temperature of the nitrides decreases with the Ga concentration. The anisotropy fields of the nitrides derived from the high-field magnetization. The changes of the magnetic anisotropy, saturation magnetization, and the moment of the Fe atoms in the nitrides and their parent compounds with Ga concentration are discussed.

I. INTRODUCTION

Recently many studies on improving the magnetic properties of R_2Fe_{17} compounds have been performed. The most striking improvements, the strong enhancements of the Curie temperature and uniaxial anisotropy, have been achieved by absorption of nitrogen.[1] The magnetic ordering temperature and other magnetic properties can also be improved by uptaking hydrogen or carbon as well as by substituting some elements such as Al, Si, and Co for Fe in R_2Fe_{17} compounds.[2–7]

In the present work we have focused our attention on the crystal structure and magnetic properties of $Sm_2(Fe_{1-x}Ga_x)_{17}$ ($x=0-0.5$) compounds and their nitrides, especially on magnetization and magnetocrystalline anisotropy. The effects of Ga substitution for Fe and of the introduction of interstitial nitrogen on the Curie temperature, the magnetic anisotropy, and the saturation magnetization have been determined.

II. EXPERIMENTAL METHODS

All $Sm_2(Fe_{1-x}Ga_x)_{17}$ host compounds with $x=0$, 0.01, 0.02, 0.04, 0.07, 0.1, 0.15, 0.2, 0.25, 0.3, 0.35, 0.4, and 0.5 were prepared by arc melting. The nitrides were formed by heating the powder samples of $Sm_2(Fe_{1-x}Ga_x)_{17}$ compounds in a mixture of NH_3 gas and H_2 gas under a pressure of 1 atm at 720 K for 20 min.

X-ray diffraction was employed to determine the structure, phase composition, the lattice parameters, and the anisotropy of aligned samples. The thermomagnetic σ-T curves were measured by means of a vibrating sample magnetometer in a field of 0.05 T. The Curie temperatures T_c were derived from σ^2-T plots.

The high-field magnetization curves were measured at 4.2 K in high fields up to 21 and 35 T for the host compounds and their nitrides, respectively, at the University of Amsterdam.[8] The anisotropy fields of the nitrides were derived from the intersection point of the high-field magnetization curves measured with the field applied parallel and perpendicular to the aligned direction. The saturation magnetization was deduced from σ_s-$1/B$ plots.

III. RESULTS AND DISCUSSION

Based on x-ray powder diffraction, all the investigated $Sm_2(Fe_{1-x}Ga_x)_{17}$ compounds and their nitrides crystallize in the Th_2Zn_{17}-type structure. A small amount of impurity was found in a few samples. Ga substitution for Fe does not change the structure of Sm_2Fe_{17}, but leads to an expansion of the unit cell (Fig. 1). This result may be ascribed to the larger atomic radius of Ga atom compared to Fe. After introduction of nitrogen, the volume of the unit cell further increases; but, the magnitude of increase is smaller than that resulting from the Ga substitution. The nitrogen content introduced into the compounds, determined by weighing, decreases linearly with Ga concentration from 2.6 for $x=0$ to 1 for $x=0.5$. One can conclude that the substitution of Ga for Fe prevents the introduction of nitrogen.

The Curie temperatures of $Sm_2(Fe_{1-x}Ga_x)_{17}$ compounds and their nitrides are shown in Fig. 2. This figure clearly displays that the Curie temperature of $Sm_2(Fe_{1-x}Ga_x)_{17}$ compounds first goes up, passes through a maximum at about $x=0.2$, then decreases with increasing Ga content. The initial increase of T_c is mainly due to the volume expansion. At higher Ga concentration, the average iron magnetic moment decreases dramatically and causes a decrease in T_c.[6] This variation of T_c may also be associated with preferential substitution of Ga atoms for Fe atoms.[9] Ga atoms preferentially substitute for Fe atoms at the sites responsible for negative exchange interaction. The Curie temperature of the nitrides decreases monotonically with Ga concentration.

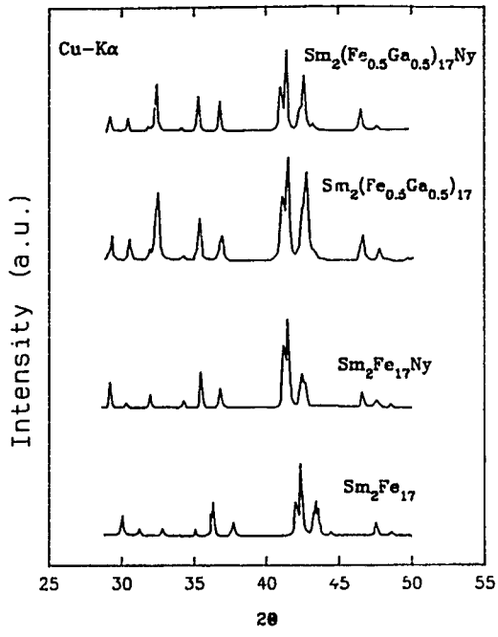

FIG 1. X-ray-diffraction patterns of $Sm_2(Fe_{1-x}Ga_x)_{17}$ compounds and their nitrides with $x=0.0$ and 0.5.

When $x \leqslant 0.2$, the Curie temperature of the nitrides is higher than that of their parent compounds, this indicates that the introduction of N atoms results in an enhancement of the exchange interaction.[10]

X-ray-diffraction patterns at room temperature with Co$K\alpha$ radiation for the aligned samples of $Sm_2(Fe_{1-x}Ga_x)_{17}$ show that the samples with $x=0.15$, 0.20, and 0.25 exhibit uniaxial anisotropy; the others are planar [Fig. 3(a)]. X-ray-diffraction patterns of $Sm_2(Fe_{1-x}Ga_x)_{17}N_y$ [Fig. 3(b)] show that the samples with $x \leqslant 0.3$ exhibit uniaxial anisotropy at room temperature. Ga substitution for Fe in $Sm_2(Fe_{1-x}Ga_x)_{17}$ compounds enhances the transition temperature of the anisotropy from easy plane to easy c axis.

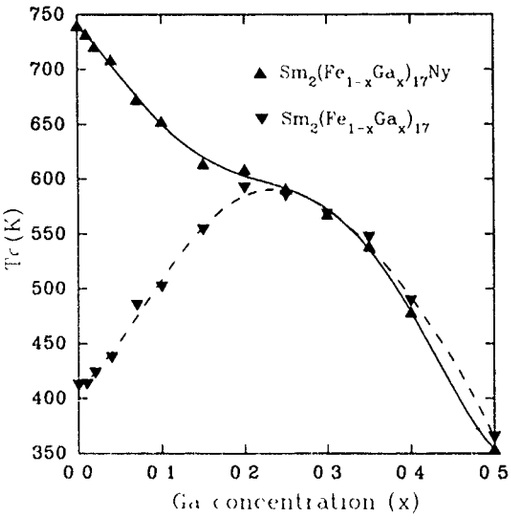

FIG. 2. Ga concentration dependence of the Curie temperature for $Sm_2(Fe_{1-x}Ga_x)_{17}$ compounds and their nitrides.

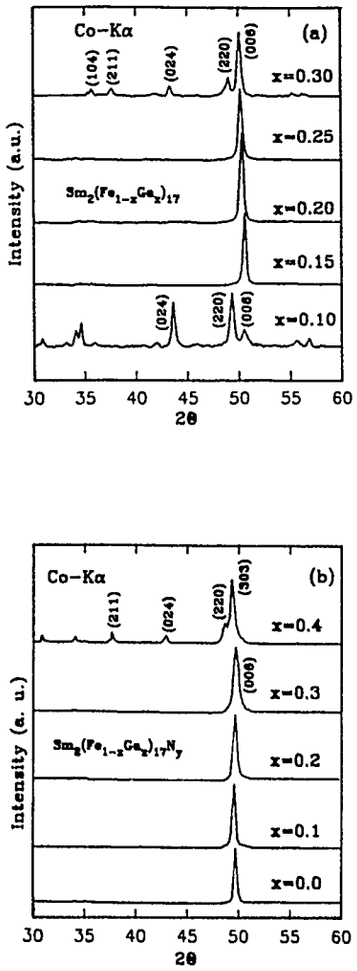

FIG. 3. (a) X-ray-diffraction patterns with Co$K\alpha$ radiation for aligned samples of $Sm_2(Fe_{1-x}Ga_x)_{17}$ compounds with $x=0.10$, 0.15, 0.20, 0.25, and 0.30, (b) x-ray-diffraction patterns with Co$K\alpha$ radiation for aligned samples of $Sm_2(Fe_{1-x}Ga_x)_{17}N_y$ compounds with $x=0$, 0.1, 0.2, 0 3, and 0.4.

This may be attributed to a change of the second crystal-field coefficients A_{20} at the rare-earth sites in $Sm_2(Fe_{1-x}Ga_x)_{17}$ compounds toward a more negative values. After the uptake of the N atoms, the A_{20} becomes more negative,[11,12] which makes the samples of $Sm_2(Fe_{1-x}Ga_x)_{17}N_y$ with $x \leqslant 0.3$ have uniaxial anisotropy at room temperature.

The saturation magnetization of $Sm_2(Fe_{1-x}Ga_x)_{17}$ and their nitrides decreases monotonically with Ga concentration. In order to get more information about the influence of Ga substitution on the magnetization, the average iron magnetic moment μ_{Fe} was calculated on the basis of the saturation magnetization measured at 4.2 K. In the process of evaluating μ_{Fe}, it was assumed that the magnetic moment of the Sm ion is independent of the Ga concentration, and that its magnetic moment was same as that of free Sm ion. Our results imply that both in the nitrides and in the parent compounds the iron moment μ_{Fe} decreases monotonically with Ga concentration. The average iron moment decreases with Ga concentration from $2.11\mu_B$ for $x=0$ to $1.51\mu_B$ for $x=0.5$ for the nitrides and from $1.96\mu_B$ for $x=0$ to $1.54\mu_B$ for $x=0.5$ for the parent compounds. This is a reduction of the Fe moment

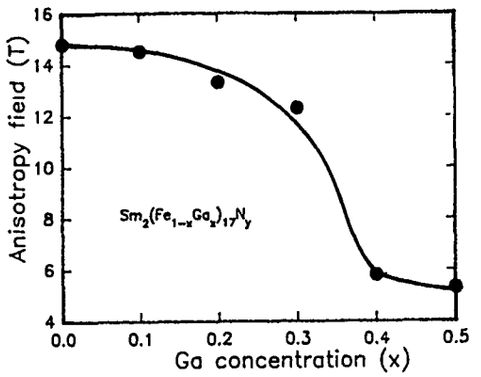

FIG. 4. Magnetic anisotropy field B_a for $Sm_2(Fe_{1-x}Ga_x)_{17}N_y$ compounds as a function of Ga concentration.

due to the substitution of Ga, which is very similar to the case of Al substitution for Fe in $Sm_2(Fe_{1-x}Al_x)_{17}$.[4]

Introduction of nitrogen leads to a change of the magnetic anisotropy of Sm_2Fe_{17} from planar to uniaxial in the whole temperature range up to T_c. Substitution of Ga for Fe also a significantly influences the anisotropy of the nitrides. Figure 4 shows the anisotropy field B_a as a function of Ga concentration for the $Sm_2(Fe_{1-x}Ga_x)_{17}N_y$ compounds. For $x \leq 0.3$, B_a decreases very slowly with Ga concentration. Obviously there is a contribution to the uniaxial anisotropy resulting from the substitution of Ga for Fe. for $x>0.3$, B_a decreases quickly. B_a becomes zero at $x=0.4$, which is in good agreement with the results of the x-ray diffraction mentioned above. It is well known[13] that in $Sm_2Fe_{17}N_y$ compounds the N atoms preferentially occupy $9e$ sites which are the nearest to the Sm atoms. The N atoms influence the crystal field at the Sm sites resulting in a significant increase of A_{20} of the Sm atoms,[11,12] so that the uniaxial anisotropy of the Sm sublattice increases. Ga substitution for Fe prevents the introduction of N atoms, so that the anisotropy field of $Sm_2(Fe_{1-x}Ga_x)_{17}N_y$ decreases with Ga concentration.

The effects of the substitution of Co for Fe on the formation, structure, and magnetic properties of $Sm_2Fe_{14}Ga_3C_2$ compounds were studied. Alloys with composition $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$ ($x=0$, 0.1, 0.2, 0.3, 0.4, and 0.5) were prepared by arc melting. X-ray diffraction shows that these alloys are single phase compounds of the rhombohedral Th_2Zn_{17}-type structure. The lattice constants a and c, and the unit cell volumes v of $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$ compounds decrease monotonically with increasing cobalt concentration. It is found that the Curie temperature increases from 615 K for $x=0$ to 666 K for $x=0.5$. Room-temperature saturation magnetization is 90.3 emu/g for $x=0$, and it decreases to 79.6 emu/g at $x=0.5$. All compounds of $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$ studied in this work exhibit an easy axis anisotropy at room temperature. The anisotropy field is higher than 90 kOe for $x\leq 0.2$, and it decreases slightly with $x\geq 0.3$.

I. INTRODUCTION

In our previous work,[1-3] it was found that the partial substitution of Ga, Al, or Si for Fe in $R_2Fe_{17}C_x$ helps the formation of high-carbon rare-earth iron compounds with a 2:17-type structure. It is found that the high-carbon $R_2Fe_{17}C_x$ compounds by the substitution of Ga, Al, or Si exhibit a high thermal stability, in contrast with the carbides or nitrides produced by the gas–solid reaction. We have prepared successfully single-phase compounds of $R_2(Fe,M)_{17}C_x$ (R=Y, Nd, Sm, Gd, Tb, Dy, Ho, Er, and Tm; M=Ga, Al, or Si; and $x\leq 3.0$), with the rhombohedral Th_2Zn_{17}-type or hexagonal Th_2Ni_{17}-type structures by arc melting, and studied their formation, structure, and magnetic properties.[1-4] It was found that the arc-melted $Sm_2(Fe,M)_{17}C_x$ compounds with $x\geq 1.5$ and relatively lower M concentration have a Curie temperature of higher than 600 K, and exhibit an easy c-axis anisotropy at room temperature and have an anisotropy field of higher than 90 kOe. The $Sm_2(Fe,M)_{17}C_x$ compounds are novel hard magnetic materials for sintering permanent magnets. A high-coercivity of 15 kOe at room temperature was obtained in the $Sm_2(Fe,Ga)_{17}C_x$ compounds by melt spinning.[1,5] In this paper, the structure and magnetic properties of $Sm_2(Fe_{1-x}Co_x)_{17}C_2$ ($0\leq x\leq 0.5$) compounds prepared by arc melting are reported.

II. EXPERIMENT

The $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$ alloys with $x=0$, 0.1, 0.2, 0.3, 0.4, and 0.5 were prepared by arc melting in an argon atmosphere of high purity. The raw materials of the Sm, Fe, Co, Ga, and Fe–C alloy were at least 99.9% pure. The ingots were melted at least four times to ensure homogeneity. An excess of 4.5% Sm was added to compensate for the evaporation of Sm during melting. X-ray diffraction measurements on powder samples were performed using Co K_α radiation to identify the single phase and determine the crystallographic structure. The room-temperature saturation magnetization was measured by an extracting sample magnetometer in a field of 65 kOe. The Curie temperatures were determined from the temperature dependence of magnetization measured by a vibrating sample magnetometer and a magnetic balance in a magnetic field of 1 kOe. The aligned samples for anisotropy field measurements were prepared by mixing the powder with epoxy resin and then aligning in a magnetic field of 10 kOe. The anisotropy field was determined from magnetization curves measured along and perpendicular to the orientation direction by using the extracting sample magnetometer with a magnetic field of up to 65 kOe at room temperature.

III. RESULTS AND DISCUSSION

X-ray diffraction measurements show that the $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$ alloys with $x\leq 0.2$ prepared by arc melting are single phase with the rhombohedral Th_2Zn_{17}-type structure. No significant diffraction from the impurity phase is observed. For $x>0.2$, the samples exhibit a predominant 2:17 phase and a few percent α-Fe as a second phase. However, the single-phase compounds with $x>0.2$ were obtained by melt spinning at a speed of 20 m/s. Both of the arc-melted and melt-spun $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$ carbides are found to be stable at high temperature. The stability of the samples results from the substitution of Ga, which helps the formation of the high-carbon rare-earth iron compounds with a 2:17-type structure.[1,2,4]

The lattice constants a and c, and the unit-cell volumes v obtained from the x-ray diffraction patterns of $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$ compounds with $0\leq x\leq 0.5$ are shown in Fig. 1 as a function of Co concentration. The substitution of Co for Fe in the $Sm_2Fe_{14}Ga_3C_2$ leads to a reduction of the unit-cell volume. An approximately linear decrease of the unit-cell volume with x is observed. For $x=0.5$, the unit-cell volume reduction is about 2.8%, compared with the cobalt-free compound. A similar result was also observed in other Fe–Co-based compounds.

The saturation magnetization M_s of $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$ compounds is shown in Fig. 2(a) as

 0021-8979/94/76(10)/6746/3/$6.00 © 1994 American Institute of Physics

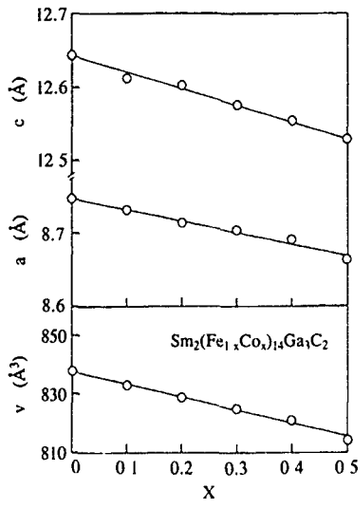

FIG. 1. The lattice constants a and c, and the unit cell volumes v of $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$ compounds as a function of Co concentration.

a function of Co concentration x. The room temperature saturation magnetization of these compounds is essentially constant at 90 emu/g for $x \leq 0.3$. However, higher Co concentration ($x > 0.3$) decreases M_s.

Figure 2(b) shows the Co-concentration dependence of the Curie temperature T_c of $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$ compounds. The T_c is found to increase monotonously from 615 K for $x=0$ to 666 K for $x=0.5$. In a previous study, it was shown that the introduction of interstitial carbon[6] or the substitution of Ga for Fe[7] in the Sm_2Fe_{17} compound results in the strong increase of Curie temperature. The enhancement of T_c can be suggested to be mainly due to the lattice expansion induced by the introduction of carbon atoms and the addition of Ga atoms. However, the increase of the Curie temperature with increasing x in $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$ is observed, although the substitution of Co results in a monotonic decrease of the unit cell. In general, the Fe–Fe interaction is dominant in the Fe-rich rare-earth iron compounds. In the Fe-based compounds by the substitution of cobalt, the Curie temperature is mainly determined by the Fe–Fe, Fe–Co, and Co–Co interactions. It has been shown previously that the exchange interaction between Fe–Co atoms is stronger than those between Fe–Fe or Co–Co atoms, resulting in the increase of T_c.[8]

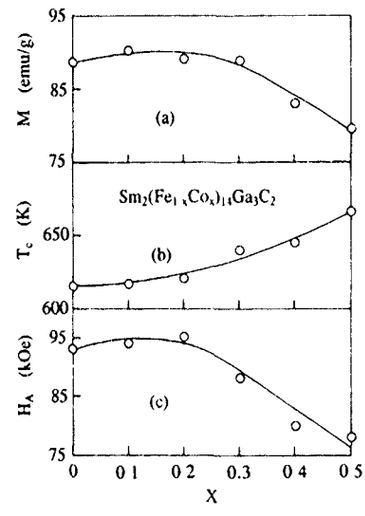

FIG. 2. The room-temperature saturation magnetization M_s (a), the Curie temperature T_c (b), and the room-temperature anisotropy field H_A (c) of $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$ compounds as a function of Co concentration.

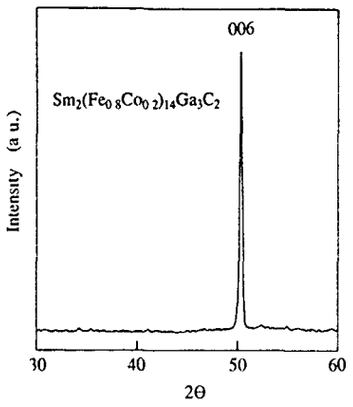

FIG. 3. X-ray diffractions pattern of magnetically aligned $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$ powder samples, with $x=0.2$

All compounds studied in this work exhibit an easy c-axis anisotropy at room temperature. Figure 3 shows the x-ray diffraction patterns of magnetically aligned powder samples of $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$, with $x=0.2$. A strong (0,0,6) reflection and the absence of $(h,k,0)$ indicates the characteristics of an uniaxial magnetocrystalline anisotropy. Figure 4 shows the magnetization curves of $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$ ($x=0.2$) compound measured along and perpendicular to the aligned directions at room temperature. The magnetocrystalline anisotropy field H_A estimated from magnetization curves is shown in Fig. 2(c) as a function of Co concentration x. The H_A is found to be greater than 90 kOe for $x \leq 0.2$, and it decreases slightly with increasing Co concentration. The anisotropy field of $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$ ($x \leq 0.5$) is comparable with that of $Nd_2Fe_{14}B$.

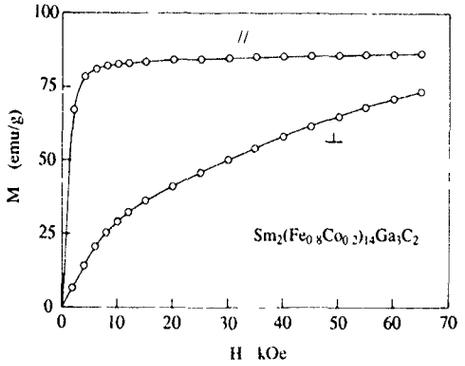

FIG. 4. The magnetization curves of the oriented $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$ ($x=0.2$) sample measured along and perpendicular to the aligned directic s

$DySi_xFe_{11-x}Co$ (x=0.5, 1.0, and 1.5) alloys and their nitrides are studied by x-ray diffraction, Mössbauer effect and neutron diffraction experiments. The results show that both Si and Co atoms can occupy the $8f$ and $8j$ sites, and more preferentially occupy the $8f$ sites. Nitrogen atoms as interstitial atoms enter into the $2b$ site. The nitrides have high Curie temperatures. The results of Mössbauer spectroscopy indicate that nitriding increases the hyperfine fields of all Fe sites.

I. INTRODUCTION

$ThMn_{12}$-type Fe-rich ternary compounds $R(Fe,T)_{12}$, in which R is a rare-earth element and T is a stabilizing element like Ti, V, Cr, Si, *et al.*,[1–4] have a high iron content and a large a/c ratio, and high values for saturation magnetization, Curie temperature, and magnetocrystalline anisotropy can be expected. The Sm-containing compounds especially show uniaxial anisotropy with an anisotropy field of up to 90 KOe, but the coercivity of samples prepared by standard powder metallurgy techniques does not exceed 1 KOe. The application of mechanical alloying or rapid quenching is more successful in achieving high coercivity, but the saturation magnetization of the samples is no higher than $1.35T$. Coey[5] and Yang *et al.*[6] discovered that the magnetic properties can be improved by introducing nitrogen atoms into the lattice interstitially. This work reports on such a study, by means of neutron diffraction and Mössbauer spectroscopy of the structure and magnetic properties of novel intermetallic compounds in which Fe is substituted by Co and Si atoms and nitrogen atoms are introduced interstitially.

II. EXPERIMENTAL DETAILS

Samples of $DySi_xFe_{11-x}Co$ (x=0.5, 1.0, and 1.5) were prepared by arc melting together with the raw elements with purities of Dy(99.9%), Fe(99.8%), Co(99.5%), and Si(99.999%). Melting was carried in a high purity argon atmosphere. The ingots were crushed into powder (<100 μm) in C_2H_5OH. Nitriding was carried out by heating powder samples at 500 °C for 1 h in nitrogen atmosphere. The phase detection was carried out by x-ray diffraction. Curie temperatures and saturation magnetizations were measured on a vibrating sample magnetometer (VSM). Neutron diffraction was used for analyzing the structure and the lattice occupation of N atoms. Mössbauer spectra were collected using a conventional constant acceleration spectrometer with a ^{57}Co (in Pd) source. The velocity scale was calibrated using an α-Fe absorber at room temperature.

III. RESULTS AND DISCUSSIONS

The x-ray diffraction patterns indicated that $DySi_xFe_{11-x}Co$ alloys were nearly single phase with the tetragonal $ThMn_{12}$-type structure. The nitrided alloy had high Curie temperature with T_c=450 °C and high saturation magnetization with δ=146 A M^2/kg.

The neutron diffraction experiment was carried out at room temperature and the neutron diffraction pattern is shown in Fig. 1. Table I shows the parameters for the crystal and magnetic structures of $DySiFe_{10}CoN_{0.42}$ alloys. Co atoms preferentially occupy the $8f$ and the $8j$ sites and N atoms enter into the $2b$ site. The Si atoms occupy the $8f$ and $8j$ sites as previously reported for $SmFe_{12-x}Si_x$ compounds in Refs. 2, 8, and 9.

Mössbauer spectra were obtained for $DySi_xFe_{11-x}Co$ (x =1.0 and 1.5) and their nitrides. The distribution of the Si atoms over the different lattice sites changes the near-neighbor environment of the Fe atoms and broadens the lines of the subspectra. Fitting of the Mössbauer spectra was done assuming that the Si atoms preferentially occupy $8j$ and $8f$ sites. For x=1.0 and 1.5, overall intensity ratios of 7.7:7.2:7.2 and 7.7:6.2:6.2 for $8i$:$8j$:$8f$ were imposed, respectively. The assignment takes into account the nearest-

neighbor environment of each respective site and the Fe-Fe distance. We considered that the largest H_{hf} corresponds to the site ($8i$), which had the largest TM coordination. The lowest H_{hf} was attributed to the $8f$ sites which had the same coordination number as the $8j$ site but the shortest mean Fe-Fe nearest-neighbor distance. The outer lines of the spectra in Si-containing compounds were much narrower than the inner ones, indicating the presence of a distribution of H_{hf}. The Mössbauer spectra showed that nitriding makes the hyperfine fields of all Fe sites increase.

IV. CONCLUSIONS

(1) The neutron diffraction study of $DySiFe_{10}CoN_{0.42}$ shows that the Si and Co atoms preferentially occupy the $8f$ site and N atoms enter into $2b$ site.

(2) Nitriding increases the hyperfine fields of all Fe sites.

A full electron LMTO-ASA study of electronic band structure and magnetic properties for $RFe_{11}TiN_x$ (R=Y, Nd, Sm; x=0,1)

W. Y. Hu, J. Z. Zhang, and Q. Q. Zheng

The band structure and magnetic properties are studied for $RFe_{11}TiN_x$ (R=Y, Nd, Sm; x=0,1) rare-earth iron intermetallic compounds using the linear muffin tin orbital with the atomic sphere approximation (LMTO-ASA) method. In order to elucidate the role played by the rare-earth atoms in these compounds, a full electron calculation is performed using a semirelativistic spin-polarized LMTO-ASA method in the local spin density approximation (LSDA) regime. The 4f electrons of the rare-earth atoms are considered to be valence electrons in the self-consistent calculations. For $NdFe_{11}TiN$, a calculation in which the 4f electrons are treated as core-frozen states is also performed, and is compared with the full electron calculation. The effects of N atoms in these compounds are also discussed.

I. INTRODUCTION

The rare-earth iron ternary intermetallic compounds have attracted great attention as promising new permanent magnetic materials. Theoretical first-principle calculations regarding these materials are few, because of the complexity of these systems and the presence of the rare-earth 4f electrons. In early works, band structure calculations of the electronic structure of these materials often focused on the Y compounds. For instance, Jaswal *et al.*[1] and Sakuma[2] have calculated the electronic structure of $Y_2Fe_{17}N_x$ (x=0,3) and $YFe_{11}TiN_x$ (x=0,1), respectively, using the LMTO-ASA band method. Choosing Y rather than the rare-earth atoms avoids the trouble of considering 4f electrons, but these systems differ from the realistic materials that have applied prospects. These results using Y may only provide some qualitative discussion about the rare-earth iron compounds. It is better to perform the electronic structure calculations for realistic systems. Jaswal[3] has used a simple method in which the 4f states were treated as frozen-core states for $Nd_2Fe_{14}B$. Hummler *et al.*[4] have studied $R_2Fe_{14}B$ (R=Gd, Tb, Dy, Ho, and Er) using a so-called "open core" approximation in which 4f electrons are not allowed to hybridize with other valence electrons. The latter approximate method can only consider the effects on the 4f energy level by the crystal field and the possible hybridization and charge transfer are neglected. Recently, Asano *et al.*[5] have studied the electronic structure of $RFe_{12}A$ (R=Y, Ce, Gd; A=N, C), and the 4f electrons were treated as valence electrons. Their results indicate that the calculation of the electronic structure can explain the experimental results in the frame of the Stoner–Wohlfarth theorem. In their work, the role of N or C atoms are not discussed sufficiently. Zeng *et al.*[6] have calculated the electronic structure of $R_2Fe_{17}N_{3-\delta}$ (R=Sm, Nd, and Gd; δ=0,3) using the cluster method. Their results imply that there are relatively strong hybridizations between 4f and other valence electrons. Many experiments also show that there exist differences in the properties of R–Fe–A compounds for different rare earths, especially for light rare earths. This difference cannot be attributed to the de Gennes factors completely. Hence, treatment of the 4f electrons as valence electrons in the band calculations is necessary.

In this work, the full-electron self-consistent spin-polarized band calculation for $RFe_{11}TiN_x$ (R=Y, Nd, and Sm; x=0,1) has been performed using the semirelativistic LMTO-ASA method. The frozen core approximation is used for the inner close shells for simplification. The maximum l is taken as l_{max}=3 for R, l_{max}=2 for Y, Fe, Ti, and l_{max}=1 for N. The crystal structure of $RFe_{11}TiN_x$ is as shown in Ref. 2 and the lattice parameters are from Refs. 2 and 8. The ratio of the atomic sphere radius is $r_R:r_{Fe}:r_{Ti}$=1.23:1.00:1.10 for $RFe_{11}Ti$ and $r_R:r_{Fe}:r_{Ti}:r_N$=1.40:1.15:1.25:1.00 for $RFe_{11}TiN_x$. As a comparison, a calculation of electronic structure for $NdFe_{11}TiN$ is also performed, with the 4f electrons of Nd in a frozen core approximation.

II. RESULTS AND DISCUSSION

A. Magnetic moments

The magnetic moments of R, Fe, and N (for x=1) atoms in $RFe_{11}TiN_x$ compounds are listed in Table I. In the case of x=0, the Fe(8i) atoms have the highest moments and the Fe(8f) atoms have the lowest ones. The average moment of Fe atoms is 2.14μ_b, 2.23μ_b, and 2.15μ_b for $YFe_{11}Ti$, $NdFe_{11}Ti$, and $SmFe_{11}Ti$, respectively. These results are similar to those of Asano *et al.* for $YFe_{11}Ti$[5] and those of Jaswal for $NdFe_{11}Ti$.[8] The calculated magnetic moments are slightly higher than the experimental values. This discrepancy seems to possess a systematic character and is insensitive to the radius of atomic sphere used in different works. It is interesting to note that the magnetic moments may slightly depend on the number of k points used in the band calculation. There are 126 k points in the irreducible Brillouin zone in our self-consistent calculation, which is smaller than the 215 k points used by Asano *et al.*[5] but larger than the six k points used by Jaswal.[8] The calculated total magnetic moments of transition metal atoms are 22.60μ_b, 23.57μ_b, and 22.76μ_b for $YFe_{11}Ti$, $NdFe_{11}Ti$, and $SmFe_{11}Ti$, respectively. In the LMTO calculation, the nonzero contribution of the orbital moment for rare-earth atoms was not evaluated. Due to the

magnetic anisotropy, the magnetic moments of the rare-earth and iron atoms may be not collinear. In Table I, only the spin moments are listed for the rare-earth atoms. The moment of each Y atom is $-0.42\mu_b$, which comes from the polarization of the 4d, 5s electr[illegible]. The spin moment of Nd and Sm in $RFe_{11}Ti$ is $2.73\mu_b$ [illegible] μ_b, respectively. Due to the neglecting of spin orbit coupling and the orbital moment in our semirelativistic LMTO-ASA calculations, one cannot compare the spin moments directly with experimental magnetic moments of rare-earth ions. However, our calculations will describe the coupling of moments between Fe and rare-earth atoms. The self-consistent calculations reveal a ferromagnetic coupling between the spin of Fe and Nd (or Sm) in Nd (or Sm) $Fe_{11}Ti$ compounds. The moment of each Ti atom is $-0.94\mu_b$, $-0.96\mu_b$, and $-0.89\mu_b$ for Y, Nd, and Sm compounds, respectively, which is antiferromagnetically coupled with the Fe moments. This antiferromagnetic coupling between Fe and Ti is similar to that of YFe_8T_4 discussed by Coehoorn.[9]

The magnetic moment of Fe atoms are increased by the uptake of nitrogen, which is in agreement with experiments. The largest Fe moments are still associated with the Fe(8i), but the largest increment of moments are associated with the Fe(8f) atoms, which is $0.55\mu_b$, $0.23\mu_b$, and $0.28\mu_b$ for $YFe_{11}TiN$, $NdFe_{11}TiN$, and $SmFe_{11}TiN$, respectively. The moments of Fe(8j) atoms, which are the nearest neighbors of N atoms, are not changed for $YFe_{11}TiN$, and even show a small reduction for $NdFe_{11}TiN$ and $SmFe_{11}TiN$. The moments of Ti are still antiferromagnetically coupled to the Fe sublattice, and have a $\sim 0.1\mu_b$ increment. There is a moment of $0.1\mu_b$ on N atoms due to the spin polarization of s,p electrons. The average moment of Fe atoms is $2.32\mu_b$, $2.30\mu_b$, and $2.25\mu_b$ for Y, Nd, and Sm compounds, respectively. It seems to be a general trend that the magnetic moment of Fe in iron nitride depends on the distance from neighboring N atoms. The results of Fe_4N, $Fe_{16}N_2$,[10] $R_2Fe_{17}N_3$,[6] and $RFe_{11}TiN$ show that the lowest magnetic moment of Fe always corresponds to the nearest neighbor of a N atom. The moments of Nd in Nd compounds and that of Sm in $SmFe_{11}Ti$ are ferromagnetically (FM) coupled to the moments of Fe. This coupling becomes antiferromagnetic (AFM) for the $SmFe_{11}TiN$ compound. This fact is qualitatively in agreement with the measurement results of Yang *et al.*[11]

B. Density of states

The calculated partial density of states (PDOS) of $YFe_{11}Ti$ and $YFe_{11}TiN$ are similar to that of Sakuma.[2] After uptaking N, the 3d band of Fe atoms become narrower, due to the increased distance between Fe atoms. The PDOS of majority moment of the 3d band is slightly low, which produces an enhancement of the moment of Fe and a reduction of the DOS at Fermi surface E_f. Then the reduction of $N(E_f)$ is responsible for the increase of Tc in these compounds. There is explicit hybridization between 3d of Fe(8j) and N 2p at an energy about 6 eV below E_f. The effect of the presence of N atoms is not only changing the crystalline field, but also producing a hybridization between electrons of N, Fe(8j), and Y.

The PDOS of $SmFe_{11}TiN_x$ (x=0,1) are shown in Fig. 1. The essential situation is similar to that of Y compounds, except for the PDOS of the rare-earth atoms. These facts confirm that the discussion based on the calculated results of Y compounds can give a qualitatively correct conclusion about magnetic moments. From these figures, the spin polarization of the N 2p band in these magnetic materials is small. The main contribution of the N 2p band is around the energy of −4.5−−8.0 eV. It is worthwhile to point out that the difference between the full electron and frozen 4f calculation reveals the effect of interaction among the 4f electrons of rare-earth atoms, 3d of Fe(8j), and 2p of N atoms. The hybridization is taking place among not only N 2p, Fe(8j) 3d and 4s, R(Nd, Sm) 5d and 6s, but also 4f of Nd or Sm. It is interesting to point out that, for the case of $SmFe_{11}TiN$, although we begin with a ferromagnetic coupling between moments of R and Fe, the self-consistent calculation gives an antiferromagnetic coupling between Fe sublattice moments and a Sm 4f moment, which is in agreement with the experiments of Yang *et al.*[11] It is well known that the spin–orbit

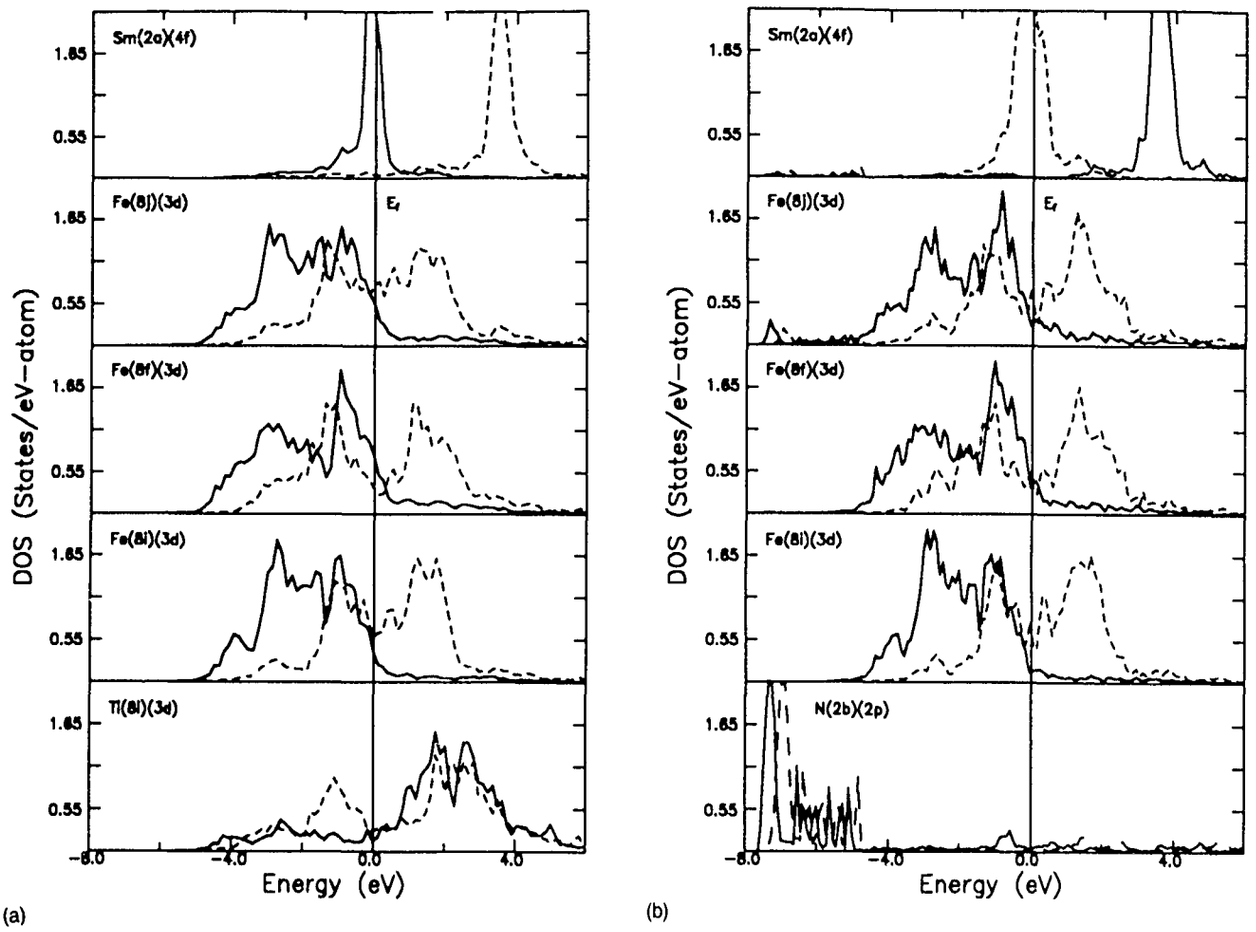

FIG. 1. The PDOS of (a) $SmFe_{11}Ti$, (b) $SmFe_{11}TiN$; the full and dotted curves show the up and down spin states, respectively

coupling is important for the rare-earth atoms. The spin–orbit interaction, together with the crystalline field, is the source of magnetic anisotropy of rare-earth atoms in these compounds. In this stage, the calculation including spin–orbit coupling may be important for a quantitative comparison.

In conclusion, we have studied the electronic structure of permanent magnetic materials $RFe_{11}TiN_x$ (R=Y, Nd, and Sm; $x=0,1$) using the LMTO-ASA band method. By comparing our full electron calculation with that for Y compounds, or using the frozen core approximation, the main conclusions can be summarized as (1) studies for Y compounds can give correct results of the magnetic moment of Fe atoms; (2) the $4f$ electrons of the rare-earth atoms do have hybridization with other valence electrons to some degree; and (3) a full electron calculation can give the correct relation of moments between rare-earth and iron atoms.

Magnetic properties and molecular field theory analysis of $RFe_{10}Mo_2$ alloys

Xie Xu and S. A. Shaheen
Department of Physics and Center for Materials Research and Technology (MARTECH), Florida State University, Tallahassee, Florida 32306

The $RFe_{10}Mo_2$ compounds (R=Y, Nd, Gd, Dy) with $ThMn_{12}$ type structure have been synthesized, and their magnetizations have been investigated in the temperature range from 2 to 800 K using a SQUID magnetometer. The Curie temperature, saturation moments, and measurements, as well as molecular field analysis of the temperature dependence of the magnetization are reported. Our work demonstrates that the molecular field analysis based on a two-sublattice model is capable of quite accurately describing the temperature dependence of the magnetization for the $RFe_{10}Mo_2$ compounds. The results also suggest that the moments of the R and Fe sublattices are nearly collinear in a large temperature range. According to the calculated molecular field coefficients, we find that the magnetic interactions are dominated by exchange between iron $3d$ electrons, and, on the other hand, the strength of the R–R interaction has even the same order as that of the R–Fe interaction.

I. INTRODUCTION

The Fe-rich ternary compounds $RFe_{1-x}TM_x$ (R=rare earth or yttrium, TM=Ti, V, Cr, Mo, Si, etc.; $x=1$ or 2)[1–5] have attracted much attention as possible candidates for permanent magnet applications. They crystallize in the tetragonal $ThMn_{12}$ type structure with space group I4/mm.[1] In this structure, the R atoms occupy the crystallographic $2a$ site and the $3d$ atoms occupy the $8i$, $8j$, $8f$ sites. The molecular field theory (MFT) is commonly used to describe the temperature dependence of magnetization in the R–T compounds, and it has been shown to be quite successful.[2–6] In this paper, we present studies of the $RFe_{10}Mo_2$ series with R=Y, Nd, Gd, and Dy. The molecular field theory based on a two sublattice model[2] was used to analyze the experimental data.

II. EXPERIMENT

Samples for this investigation were prepared by arc melting appropriate amounts of Fe, Mo, and rare earth elements (Y, Nd, Gd, and Dy) under a purified argon atmosphere. As cast samples were vacuum annealed at 1000 °C for a week. All samples are almost single phase, as determined by both x-ray powder diffraction and thermomagnetic analysis. A Quantum Design SQUID magnetometer with an external field up to 5.5 T was used to measure the magnetization of powdered samples in a temperature range from 2 K to their Curie temperatures. The experimental values of the Curie temperatures (T_C) were determined by means of the linear relationship $M^2(T)\propto(1-T/T_C)$ near the $T_C(T\leq T_C)$.

III. ANALYSIS AND RESULTS

According to the two sublattice MFT, the molecular field acting on the R sublattice and Fe sublattice is separated, and can be expressed, respectively, as follows:

$$H_R(T)=H+d[n_{RR}M_R(T)+10n_{RF}M_F(T)], \tag{1}$$

$$H_T(T)=H+d[10n_{FF}M_F(T)+n_{RF}M_R(T)], \tag{2}$$

where H is the applied field, $M_R(T)$ and $M_{Fe}(T)$ represent the magnetic moment per rare earth ion and per Fe ion, respectively, at temperature T. The factor d converts the moment per $RFe_{10}Mo_2$ in μ_B to Gauss: $d=N_A\mu_B\rho/A$, where N_A is Avogadro's number, ρ is the density of $RFe_{10}Mo_2$ in g/cm^3, and A is the formula weight of $RFe_{10}Mo_2$. n_{RR}, n_{RF}, and n_{FF} are the molecular field coefficients, which describe the R–R, R–Fe, and Fe–Fe magnetic interactions, respectively.

The temperature dependence of each sublattice magnetization is governed by a Brillouin function:

$$M_R(T)=M_R(0)B_{J_R}\left(\frac{M_R(0)H_R(T)}{k_BT}\right), \tag{3}$$

$$M_F(T)=M_F(0)B_{J_F}\left(\frac{M_F(0)H_F(T)}{k_BT}\right), \tag{4}$$

where $M_R(0)$ and $M_F(0)$ are the magnetic moments of R and Fe at zero temperature, respectively. J_R and J_F are the individual R and Fe angular moments.

In the calculations, the free ion moment is used for the rare earth ion, i.e., $M_R(0)=g_JJ_R$, and $M_F(0)$ can be deduced from the observed low temperature moment:

$$M_F(0)=[M_{exp}(0)\pm M_R(0)]/10, \tag{5}$$

where "$-$" applies for the light rare earths Nd and Y, and "$+$" applies for the heavy rare earths Gd and Dy.

The coefficients n_{ij} are determined by numerically solving Eqs. (1)–(4), under the condition that the calculated total moments,

$$M_{tot}(T)=M_R(T)\pm 10M_F(T), \tag{6}$$

correspond best with the experimental data. This is done by minimizing the percentage deviation,

$$R=100\,\frac{\Sigma|M_{exp}(T_i)-M_{tot}(T_i)|}{\Sigma M_{exp}(T_i)}, \tag{7}$$

where $M_{exp}(T_i)$ is the magnetization observed at temperature T_i. No other constraints are imposed. From Eqs. (3) and (4), the Curie temperature in the zero field is related to the n_{ij} by

TABLE I. Density ρ, rare earth gyromagnetic ratio g_J, and total angular momentum J_R used in MFT calculations. n_{FF}, n_{RF}, and n_{RR} are the computed molecular field coefficients The MFT calculated T_C and experimental T_C are listed. R% is the quality-of-fit index defined by Eq. (7).

R	ρ (g/cm^3)	g_J	J_R	$M_R(0)$ (μ_B)	$M_{Fe}(0)$ (μ_B)	n_{FF}	n_{RF}	n_{RR}	R% (%)	T_C (K) cal.	T_C (K) exp.
Y	8.03	...	...	...	1.73	4562	...	...	3.5	327	350
Nd	7 60	$\frac{8}{11}$	$\frac{9}{2}$	$\frac{36}{11}$	1.53	8780	2000	1900	4.0	445	420
Gd	8.0	2	$\frac{7}{2}$	7	1.65	6300	−2500	2300	4.0	465	480
Dy	7.83	$\frac{4}{3}$	$\frac{15}{2}$	10	1.61	6120	−1100	1000	3.0	383	390

$$T_C = \frac{(n_{FF}\alpha + n_{RR}\beta) + \sqrt{(n_{FF}\alpha + n_{RR}\beta)^2 - 4\alpha\beta(n_{FF}n_{RR} - n_{RF}^2)}}{2\alpha\beta}, \tag{8}$$

where

$$\alpha \equiv [3JR/(JR+1)][kB/\mu Bd]MR2(0);$$

$$\beta \equiv \frac{[3J_T/(J_T+1)][k_B/\mu_B d]}{10M_T^2(0)}. \tag{9}$$

For compounds with R=Y, we have

$$T_C = \frac{n_{FF}}{\beta} = 10 n_{FF} M_T^2(0)[(J_T+1)/3J_T][\mu_B d/k_B]. \tag{10}$$

Table I summarizes the experimental information, such as low temperature magnetization $M_s(0)$ and Curie temperature T_C of $RFe_{10}Mo_2$ intermetallics. The low temperature magnetization $M_s(0)$ was measured at 2 K in a field of 3 T by means of a SQUID magnetometer. The parameters used in the calculations and the MFT coefficients for each $RFe_{10}Mo_2$ compound by solving Eqs. (1)–(7) numerically are also summarized in Table I. The moment of an Fe atom at 0 K is about $1.7\mu_B$ in these compounds. We chose $J_F=1.0$ in the calculations.

In Figs. 1–4, the temperature dependence of the magnetization for four $RFe_{10}Mo_2$ compounds is plotted. The data are represented by circles, while the MFT calculation results for total moment $M_{tot}(T)$, rare earth sublattice moment $M_R(T)$, and Fe sublattice moment $M_{Fe}(T)$ are indicated by solid, dashed, and dot–dashed lines, respectively. MFT with a single coefficient (n_{FF}) provides a quite reasonable description of the temperature dependence of the magnetization for $YFe_{10}Mo_2$, as Fig. 1 shows. The percentage deviation between the measured and calculated values is $R=3.5\%$, and $T_C^{cal}=327$ K is about 6% lower than the observed Curie temperature of 350 K.

Figures 3 and 4 show that the two-sublattice model with the assumption of ferrimagnetically coupled R and Fe moments yields results in excellent correspondence with the data for $GdFe_{10}Mo_2$ and $DyFe_{10}Mo_2$. The Curie temperatures calculated are consistent with the experimental values.

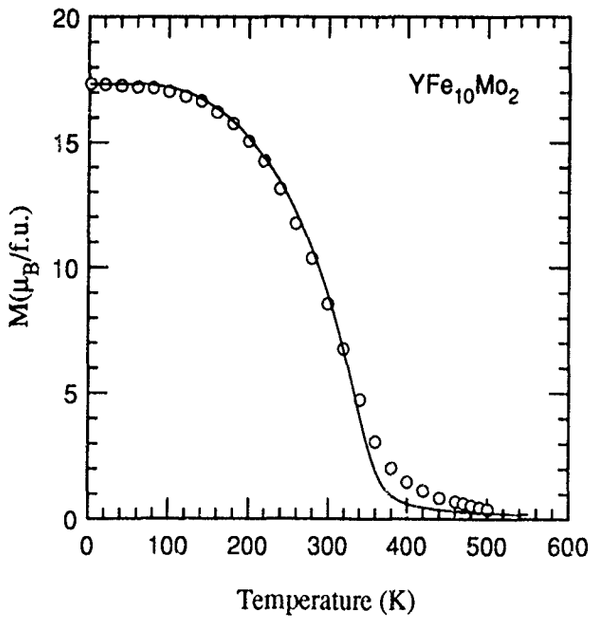

FIG. 1 The temperature dependence of the magnetization of $YFe_{10}Mo_2$ Circles represent the experimental data and the solid line represents the MFT results

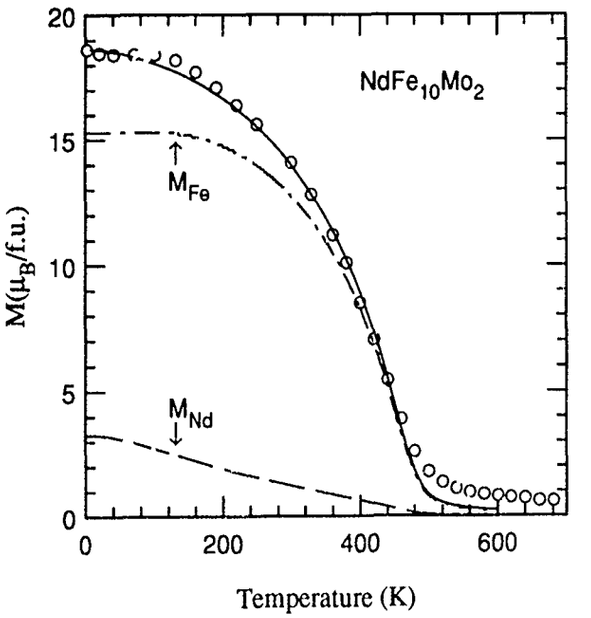

FIG 2 The temperature dependence of the magnetization of $NdFe_{10}Mo_2$ Circles represent the experimental data. Lines represent the MFT results

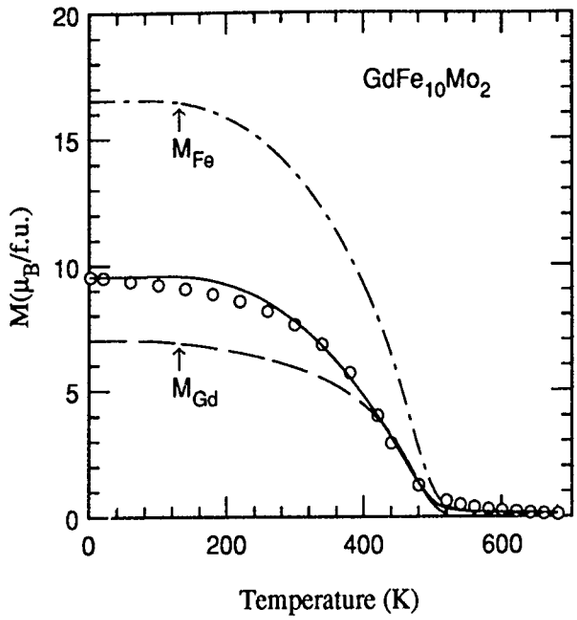

FIG 3 The temperature dependence of the magnetization of $GdFe_{10}Mo_2$. Circles represent experimental data. Lines represent MFT results.

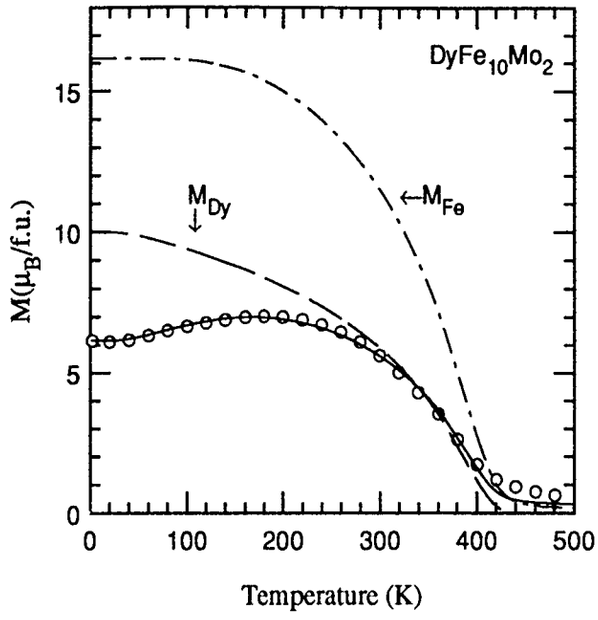

FIG 4. The temperature dependence of the magnetization of $DyFe_{10}Mo_2$ Circles represent experimental data. Lines represent MFT results.

Our calculations demonstrate that the two-sublattice MFT is quite successful in describing the temperature dependence of magnetization in the $RFe_{10}Mo_2$ series. The results also suggest that the moments of R and Fe sublattices are nearly collinear. In all instances, we found that n_{FF} is the largest of the computed molecular field coefficients (cf. Table I). This implies that the magnetic interactions are dominated by the exchange between $3d$ electrons. On the other hand, the strength of the R–R interaction cannot be neglected, as it has nearly the same magnitude as that of the R–Fe interaction. Such behavior seems to a common feature in a number of R–T compounds, for example, RFe_3,[2] R_2Co_{17},[5] $RFe_{10}V_2$,[7] and $R_2Fe_{14}B$.[8] These observations suggest that, in order to obtain a more realistic account of magnetic behavior in R–T intermetallic compounds, one may have to consider the effect of crystal field interactions on the R sites.

Magnetic alignment in powder magnet processing

S. Liu
University of Dayton Research Institute, Dayton, Ohio 45469-0170

A strong magnetic field is used to align single-crystal powder particles in the process of producing sintered powder permanent magnets, including hard ferrites and rare-earth permanent magnets. The applied magnetic field aligns the easy direction of magnetization of each particle, owing to strong crystalline anisotropy. Shape anisotropy, existence of particles containing multigrains, and physical interlock between particles reduce the degree of alignment. This study provides a quantitative analysis of magnetic alignment in powder magnet processing. We assume (1) the powder particle is a single crystal; (2) it has the shape of an oblate spheroid and its short axis is the easy direction of magnetization; and (3) the applied magnetic field is strong enough to overcome the resistance of alignment. By applying the minimum-energy principle, it was concluded that the necessary and sufficient condition for a complete magnetic alignment is that the magnetocrystalline anisotropy constant K_1 of the particles is greater than its shape anisotropy constant K_s, provided the applied magnetic field is strong enough. When $K_s > K_1 + 2K_2$, the angle between the short axis of the oblate particle and the direction of applied magnetic field is 90°, and when $K_1 \leq K_s \leq K_1 + 2K_2$, the angle is $\arcsin\sqrt{(K_s - K_1)/2K_2}$.

The fabrication of powder magnet materials involves a complicated multistep process. For example, the production of high performance sintered $Sm_2(Co,Fe,Cu,Zr)_{17}$ permanent magnets involves seven major steps: melting and casting, homogenization, crushing and milling, magnetic alignment and compacting, sintering, solid solution treatment, and aging. Each step includes three or more process variables. A quantitative analysis of each step in powder magnet processing would lead to an insight into the physical and/or chemical processes involved in each step. This is not yet possible for all steps in the processes due to the complexity of the problem. Magnetic alignment is perhaps the simplest step in the whole processing procedure for producing powder magnets; therefore, it is possible to explore this step in some detail.

The most useful magnets are anisotropic with a single preferred axis of magnetization, requiring that the c axes of all grains in the sintered magnet are aligned parallel. This is achieved by applying a magnetic field strong enough to align the particles against the frictional force, and then compacting to immobilize them in this state. The crystal texture is maintained through the subsequent sintering and homogenizing if properly conducted.[1] Magnetic alignment is used to produce all types of anisotropic powder permanent magnets, including hard ferrites, $SmCo_5$, Sm_2TM_{17}, and Nd–Fe–B magnets.

If all particles are perfect single-crystal spheres, or if the long axes of all particles happen to be the easy direction of magnetization, then perfect alignment can be obtained, provided the applied magnetic field is strong enough. Obviously, the real case is more complicated. Shape anisotropy (if the long axis of a particle does not happen to be the easy direction of magnetization), the existence of particles containing multigrains, and the physical interlock between particles reduce the degree of alignment.

Assume (1) the powder particle is a single crystal; (2) it has the shape of an oblate spheroid and its short axis is the easy direction of magnetization; and (3) the applied magnetic field is strong enough to overcome the resistance of alignment. These assumptions are appropriate for several reasons. First, the size of the powder particle used for powder magnet production is usually in the range of 1–5 μm, far smaller than the grain size of the starting materials. Therefore, most powder particles can be considered single-crystal particles. Second, all powder magnet materials are of uniaxial crystal structure (hexagonal, rhombohedral, or tetragonal), and the basal plane is the most densely packed crystal plane. Breaking into particles having a shape similar to an oblate spheroid with its c axis to be the short axis rather than a prolate spheroid with its c axis to be the long axis during crushing and milling is an energetically favorable process. Actually, needle-like particles (prolate spheroid) are seldom observed for either hard ferrites or rare earth-transition metal alloys. Third, in practice, the applied magnetic field for powder alignment is either a dc magnetic field of 20–30 kOe or a pulse field of 70–100 kOe. These fields are proved strong enough to overcome any resistance of alignment.

When a magnetic field is applied, the shape anisotropy tends to align the long axis (a axis) parallel with the direction of the applied field. On the other hand, the crystalline anisotropy tends to align the short axis (c axis) parallel with the applied field. Obviously, the orientation of the particle in a given applied field is determined by the balance between the shape anisotropy energy and the crystalline anisotropy energy, rather than simply by the strength of the field. Suppose the angle between the c axis of the oblate particle and the direction of applied field H is ϕ, as shown in Fig. 1, the shape anisotropy energy, E_s, and the crystalline anisotropy energy, E_c, of the particle are

$$E_s = K_s \sin^2(90 - \phi) = K_s \cos^2 \phi, \tag{1}$$

$$E_c = K_1 \sin^2 \phi + K_2 \sin^4 \phi, \tag{2}$$

respectively, where K_s is the shape anisotropy constant and K_1 and K_2 are the crystalline anisotropy constants of a uniaxial crystal, which all powder magnets, including hard ferrites and rare earth magnets, belong to. The total energy of the system is

 0021-8979/94/76(10)/6757/3/$6 00 © 1994 American Institute of Physics

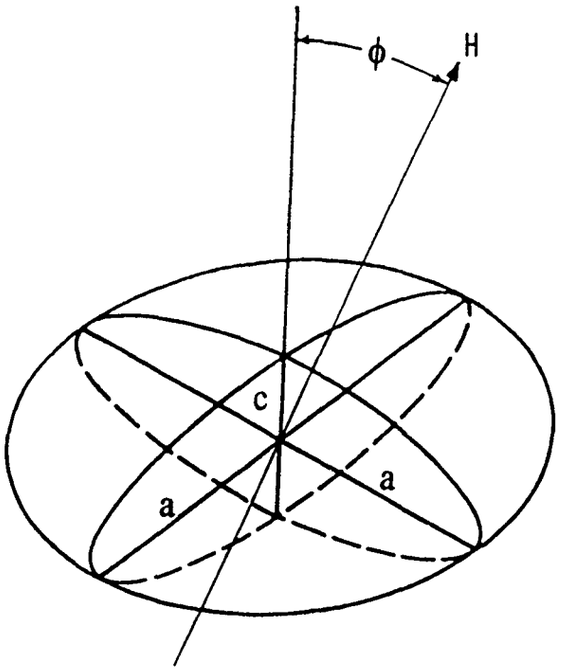

FIG. 1. Orientation of an oblate spheroid in a magnetic field.

$$E=E_c+E_s, \tag{3}$$

and the minimum energy condition requires

$$\frac{dE}{d\phi}=0. \tag{4}$$

Let us determine the angle ϕ corresponding to the minimum energy condition by the following two steps.

Step I. Considering only a single anisotropy constant, K_1.

In this case, Eq. (3) becomes

$$E=K_1 \sin^2 \phi+K_s \cos^2 \phi. \tag{5}$$

For the minimum energy condition, we have

$$\frac{dE}{d\phi}==K_1 \sin 2\phi-K_s \sin 2\phi=(K_1-K_s)\sin 2\phi=0. \tag{6}$$

If $K_1=K_s$, ϕ can have any value (but not only 45°, as common sense may lead to). If $K_1\neq K_s$, then $dE/d\phi=0$ when $\sin 2\phi=0$ or $\phi=0$ or 90°. In order to determine ϕ, corresponding to the minimum energy condition, the second derivative,

$$\frac{d^2E}{d\phi^2}=2(K_1-K_s)\cos 2\phi, \tag{7}$$

should be positive. If $K_1>K_s$, when $\phi=0°$, $\cos 2\phi=1$, and thus $d^2E/d\phi^2>0$. Therefore, E has the minimum value. If $K_1<K_s$, when $\phi=90°$, $\cos 2\phi=-1$, $d^2E/d\phi^2>0$, E also has the minimum value, as shown in Table I.

Step II. Taking into consideration both K_1 and K_2.

In this case, Eq. (3) becomes

$$E=(K_1-K_s)\sin^2 \phi+K_2 \sin^4 \phi+K_s. \tag{8}$$

TABLE I. Angle ϕ corresponding to the minimum energy condition.

K_2	Relation among K_s, K_1, and K_2	ϕ For minimum energy
$K_2=0$	$K_s=K_1$	any ϕ
	$K_s>K_1$	90°
	$K_s<K_1$	0°
$K_2>0$	$K_s>K_1+2K_2$	90°
	$K_s<K_1$	0°
	$K_1\leq K_s\leq K_1+2K_2$	$\arcsin\sqrt{(K_s-K_1)/2K_2}$

For a minimum energy condition, we have

$$\frac{dE}{d\phi}=(K_1-K_s)\sin 2\phi+2K_2 \sin^2 \phi \sin 2\phi=0. \tag{9}$$

It is obvious that the first two solutions of Eq. (9) are $\phi_1=0°$ and $\phi_2=90°$. In order to determine ϕ corresponding to the minimum energy, we calculate the secondary derivative,

$$\frac{d^2E}{d\phi^2}=2(K_1-K_s)\cos 2\phi+2K_2(\sin^2 2\phi +2 \sin^2 \phi \cos 2\phi). \tag{10}$$

If $K_1>K_s$, when $\phi=0°$, we have $\cos 2\phi=1$, $\sin 2\phi=0$, and $\sin^2 \phi=0$. So, $d^2E/d\phi^2>0$. Therefore, E has a minimum value. Substituting $\phi=90°$ into Eq. (10) yields

$$\frac{d^2E}{d\phi^2}=2[K_s-(K_1+2K_2)], \tag{11}$$

when $K_s>K_1+2K_2$, $d^2E/d\phi^2>0$. Thus, E has a minimum value.

If $\phi\neq0°$, $\phi\neq90°$, and $0°<\phi<90°$, then $\sin 2\phi\neq0°$, and Eq. (9) becomes

$$\frac{dE}{d\phi}=(K_1-K_s)+2K_2 \sin^2 \phi=0 \tag{12}$$

or

$$\sin^2 \phi=(K_s-K_1)/2K_2, \quad \phi=\arcsin\sqrt{(K_s-K_1)/2K_2}, \tag{13}$$

and obviously K_s must not be smaller than K_1, and K_s-K_1 must not be greater than $2K_2$. The secondary derivative of E, with respect to ϕ, should be evaluated at the angle ϕ for which $dE/d\phi=0$. It is obvious from Eq. (12) that

$$\frac{d^2E}{d\phi^2}=2K_2 \sin 2\phi. \tag{14}$$

When $0°<\phi<90°$ and $K_2>0$, $d^2E/d\phi^2>0$; thus E has a minimum value. The above results are summarized in Table I.

It is obvious that increasing the strength of the applied magnetic field only helps to overcome the resistance of alignment caused by the physical interlock between particles, but cannot align the powders unless $K_s<K_1$. In other words, the necessary and sufficient condition for a complete magnetic alignment is $K_s<K_1$, provided the applied magnetic field is strong enough. This conclusion was supported by our

TABLE II. Data summary for crystalline anisotropy constants of $(Sm_{1-x-y}Pr_xNd_y)_2(Co_{1-v}Fe_v)_{17}$ (10^6 erg/cm^3).

x	y	v	K_1	K_2	Reference
0	0	0	32		3
0	0	0.2	43		3
0	0	0.3	35	1.4	4
0	0	0.4	14		3
0	0.1	0.2	29		5
0	0.3	0.2	16		5
0	0.5	0.2	15		5
0	0.5	0.3	11		5
0.3	0	0.3	17		5

experiments of Nd, Pr substituted Sm_2TM_{17} permanent magnets. Table II summarizes crystalline anisotropy constant values for $(Sm_{1-x-y}Pr_xNd_y)_2(Co_{1-v}Fe_v)_{17}$. Table III lists the calculated demagnetizing factors and shape anisotropy constants for a oblate spheroid with various a/c ratios, r. Equations used for these calculation are as follows:[2]

$$N_c = 4\pi r^2/(r^2-1)[1-\sqrt{1/(r^2-1)}\,\sin^{-1}\sqrt{r^2-1}/r, \tag{15}$$

$$N_a = 0.5(4\pi - N_c), \tag{16}$$

$$K_s = 0.5(N_c - N_a)M^2. \tag{17}$$

It can be seen from comparing Tables II and III that for magnet alloys of $(Sm_{1-x-y}Pr_xNd_y)_2(Co_{1-v}Fe_v)_{17}$ in most cases, $K_1 \gg K_s$. This means that crystalline anisotropy dominates. However, with further extensive increasing Fe substitution for Co, or with further extensive increasing Pr and/or Nd substitution for Sm, it is possible for K_1 to drop to a level lower than K_s. This would decrease the degree of alignment and reduce values of remanence, B_r, and the maximum energy product, $(BH)_{max}$, of the magnets. For powder permanent magnet materials with uniaxial crystal structure, the demagnetizing curves in the first quadrant are more or less like a straight line, and the slope of this line reflects the degree of powder alignment. What happens in the first quadrant demagnetizing process is that the magnetization vector in every grain (each individual grain was developed from one or more

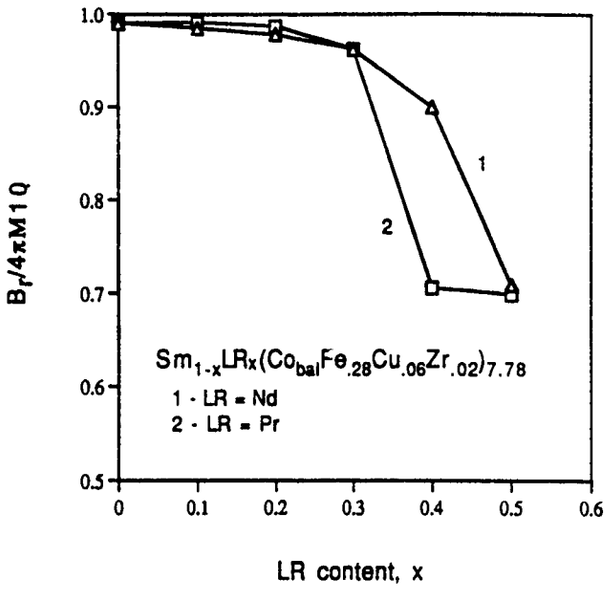

FIG. 2. Dependence of $B_r/4\pi M_{10}$ on LR content, x.

powder particles during the sintering process) turns back to the nearest easy magnetization direction. If the powder particles are perfectly aligned and this crystal texture is maintained during the sintering process, then the demagnetization curve in the first quadrant would be a straight line parallel to the horizontal axis, and the ratio of $B_r/4\pi M_s$ would be equal to 1. In another extreme, if the powder particles are of a completely random distribution, then, according to Chikazumi's calculation,[6] $B_r/4\pi M_s$ would be equal to 0.5. Therefore, for a material with uniaxial crystal structure, the ratio of $B_r/4\pi M_s$ should have a value ranging from 0.5 (corresponding to a completely random distribution) to 1.0 (corresponding to a perfect alignment). So, $B_r/4\pi M_s$ can serve as a good measure for the degree of particle alignment.

In practice, $4\pi M_{10}$, the magnetization value in a 10 kOe applied magnetic field, is a good approximation to $4\pi M_s$. Figure 2 shows the dependence of $B_r/4\pi M_{10}$ upon the light rare earth (LR) content, x, for $Sm_{1-x}LR_x(Co_{bal}Fe_{0.28}Cu_{0.06}Zr_{0.02})_{7.78}$ with LR=Nd or Pr. It can be seen from Fig. 2 that $B_r/4\pi M_{10}$ drops sharply when x exceeds 0.3. The author believes this indicates that the crystalline anisotropy constant K_1 is no longer greater than its shape anisotropy K_s when $x > 0.3$ for this particular magnet composition.

Sputter synthesis of $TbCu_7$ type Sm(CoFeCuZr) films with controlled easy axis orientation

H. Hegde, P. Samarasekara, R. Rani, A. Navarathna, K. Tracy, and F. J. Cadieu
Department of Physics, Queens College of CUNY, Flushing, New York 11367

Single phase $TbCu_7$ type films of Sm(CoFeCuZr) have been sputter synthesized for a range of sputter gas pressure, deposition temperature, and two different gas species: Ar and Ar50%Xe. The magnetic and crystallographic properties of these films as a function of sputter deposition parameters have been studied. Films synthesized at temperatures near their crystallization temperatures at sputter gas pressures exceeding 60 mTorr of Ar50%Xe, had a strong c-axis in-plane texture. The remanent magnetization ratio for measurement perpendicular to the film plane versus in plane was close to zero for such films. X-ray diffraction patterns of these films showed only (hk0) type reflections. At gas pressures around 30 mTorr predominant reflection was (111) type. The perpendicular to the in-plane B_R ratio for such films was around 0.55. For films with in-plane c-axis texture, in-plane B_r of 9.0 kGauss and coercivities in the range 3–10 kOe were possible. Pressures of Ar and Ar50%Xe correlated roughly in the ratio 1:2 for the synthesis of films, with comparable crystallographic and magnetic properties.

I. INTRODUCTION

Permanent magnets based on the $Sm_2(CoFeCuZr)_{17}$ rhombohedral 2-17 type structure are extremely attractive because of their high temperature stability, fairly high saturation moment, and energy product.[1,2] Such magnets consist of a cellular structure of 2-17 regions with $SmCo_5$ based grain boundaries to enhance the coercivity.[3] The magnetic properties of such two phase cellular structures are very sensitive to thermal treatments. In contrast to this, $TbCu_7$ type single phase film magnets that exhibit a high degree of in-plane c-axis texture and energy product have been sputter synthesized in recent years.[4] The $TbCu_7$ type films are single phase, whereas bulk samples of similar composition exhibit the cellular structure. The magnetic properties of the single phase sputtered film samples exhibit optimal magnetic properties as deposited and are very insensitive to subsequent thermal treatments. Such films are extremely important in applications involving magnetic biasing of magnetoresistive, magneto-optic, microwave devices, etc.[5–7] We have now studied the texture change and resultant change in magnetic properties of these permanent magnet $TbCu_7$ type films, as a function of their sputter deposition parameters.

II. EXPERIMENT

The films in the study were sputter synthesized from commercially available 2-17 bulk magnets of the type $Sm_2(CoFeCuZr)_{17}$. The films were deposited on polycrystalline Al_2O_3 substrates. The film thickness were generally in the 2 μ range. The deposition temperatures for all films in this study exceeded the minimum temperature required for their crystallization, so that they were directly crystallized as deposited, with no post deposition heat treatments required. Two varieties of sputter gases were used, 100% Ar, and equal mixtures of Ar and Xe referred to henceforth as Ar50%Xe. For all films in this study, the target to substrate distance was held constant at 5 cm. The crystal phase and film texture were determined with Cu K_α radiation by x-ray diffractometer measurements using a Si(Li) solid state detector to allow fluorescence discrimination. Magnetic measurements were performed using a VSM for fields up to 18 kOe. Film compositions were determined by electron excited x-ray fluorescence using a PGT System 4 Plus unit coupled to a scanning electron microscope.

III. RESULTS AND DISCUSSION

The Sm concentrations in the films were dependent on sputter gas species, pressure, and deposition temperature due to the high volatility of Sm and the preferential scattering of the low mass TM atoms out of the sputtered atom beam.[7] However, the relative concentrations of the TM atoms in the films were fairly constant, at 24, 9, 3, and 1 for Co, Fe, Cu, and Zr, respectively. These TM relative concentrations were about the same as in the target.

All films in this study exhibited the $TbCu_7$ type disordered crystalline phase, even though the target magnets were a 2-17 cellular based structure. For the deposition temperature range, 300 °C–475 °C, and Fe concentration used, the ordered 2-17 phase was not formed.[8] The crystallite c-axis orientation was found to depend on the deposition temperature, as shown in Fig. 1. At lower temperatures, the films were strongly c-axis in-plane textured. As the temperature was raised, the degree of in-plane texturing was reduced. Even with a modest increase in temperature of 55 °C, from the initial temperature of 345 °C, crystallites with the c axis oriented away from the film plane were observed, as indicated by (hkl) reflections, $l \neq 0$, in Fig. 1. As the net easy axis direction deviates from the film plane, the ratio of the remanent magnetic moments, in directions perpendicular to the film plane versus in-plane increases.[9] This is clearly seen from Fig. 3(a). For Ar50%Xe, at 60 mTorr pressure, this ratio is only 0.07 for a deposition temperature of 345 °C, increasing to 0.40 at 450 °C. However, for 100%Ar, at 60 mTorr pressure, the degree of the c-axis in-plane texturing was rather poor for all deposition temperatures tried. The texture change with pressure is shown in Fig. 2. At deposition temperature of 345 °C for sputter gas Ar50%Xe, the films could be formed with the c-axis in-plane texture at pressures of 60

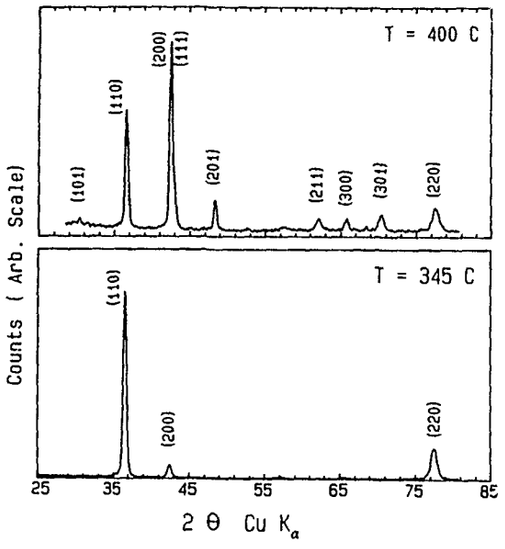

FIG. 1. The texture change with deposition temperature, for films synthesized in Ar50%Xe at 60 mTorr pressure. X-ray diffraction is using CuK_α radiation.

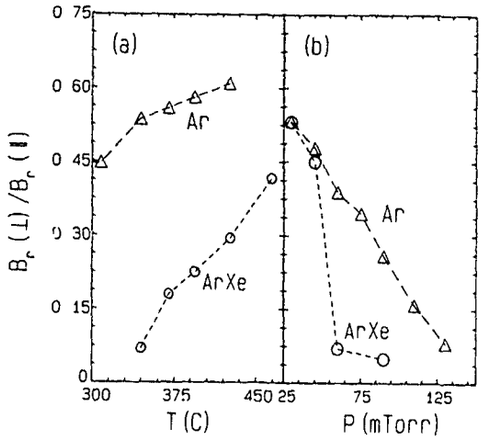

FIG. 3. Variations of ratios of remanent magnetizations perpendicular to the film plane to that in plane for films synthesized in 100%Ar and Ar50%Xe. (a) Variation with temperature at 60 mTorr pressure. (b) Variation with pressure at temperature 345 °C.

mTorr and above. For sputter gas 100%Ar, a similar pure in-plane texture could only be obtained at pressures exceeding 120 mTorr. In terms of texture control, this suggests that 60 mTorr of Ar50%Xe is equivalent to about 120 mTorr of Ar.

The film magnetic properties and their Sm at. % are shown in Fig. 4 and Fig. 5. The coercivities of the films are found to be strongly correlated to the film Sm concentration. This is attributable to the increase in the magnetocrystalline anisotropy of the 1-7 phase with Sm concentration. However, a fairly significant departure in the correlated behavior of Sm at. % and coercivity is observable for films formed at pressures below 45 mTorr, Fig. 5. This is due to defects caused by increased energy bombardment of the growing film at lower pressures. Previous calculations have shown that to completely thermalize the sputtered atoms, the pressures required are around 60 mTorr of Ar50%Xe.[10] The rather sharp deviation of coercivity from its correlated behavior with Sm at. %, in Fig. 4, below 345 °C, is attributable to incomplete crystallization of the film. High resolution SEM studies of the films have not revealed any type of cellular structure, as observed in bulk 2-17 type magnets.

No attempt to saturate the film magnetization was made, due to the large fields required. However, the $4\pi M_s$ values of the films are expected to decrease with increased Sm concentration. For films sputtered in Ar50%Xe, the film Sm at. % is given in Fig. 4, and Fig. 5, as a function of deposition temperature at 60 mTorr pressure and as a function of gas pressure at a deposition temperature of 345 °C. Figure 4 and Fig. 5 also show the remanance B_r, energy product

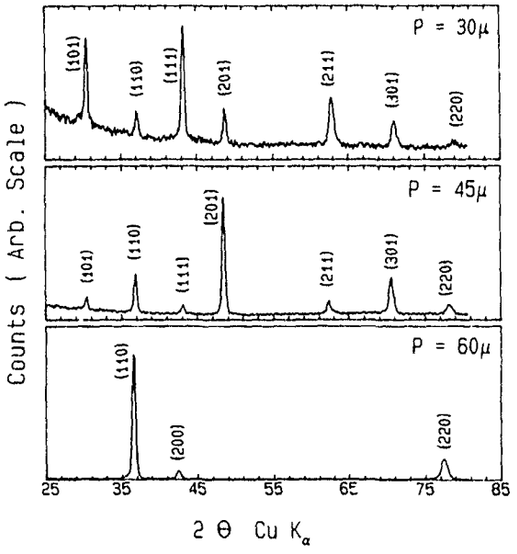

FIG. 2. The texture change with pressure, for films synthesized in Ar50%Xe at 345 °C. X-ray diffraction is using Cu K_α radiation.

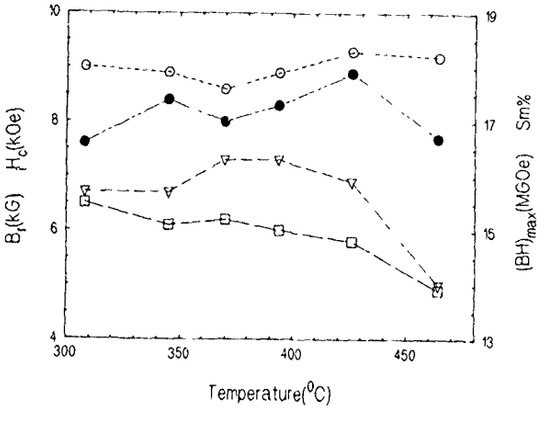

FIG. 4. Variation with deposition temperature, of remanent magnetization B_R (open circle), coercivity H_c (triangle), energy product BH_{max} (shaded circle), and Sm at. % (square) Magnetic measurements are in the film plane Films synthesized in Ar50%Xe, at 60 mTorr.

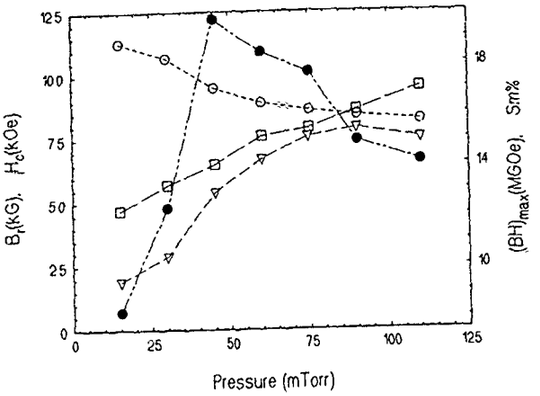

FIG. 5. Variation with pressure, of remanent magnetization B_R (open circle), coercivity $_iH_c$ (triangle), energy product BH_{max} (shaded circle), and Sm at. % (square). Magnetic measurements are in the film plane. Films synthesized in Ar50%Xe, at 345 °C.

BH_{max}, and coercivity $_iH_c$, for magnetic measurements made in the film plane. From Fig. 4, the remanance is seen to be fairly constant, with respect to deposition temperature. It appears that at higher deposition temperatures, the increase in the saturation moment is offset by the lower degree of in-plane c-axis texturing. The energy product BH_{max} is seen to be fairly constant at a reasonably large value around 18 MGOe, for the entire temperature range at this pressure. The energy product, BH_{max}, of the films is sharply dependent on the gas pressure, Fig. 5. In fact, the best energy products, in excess of 18 MGOe, are obtainable in only a narrow pressure range from 45 to 75 mTorr.

For films sputtered in Ar at pressures around 120 mTorr, the general variation of texturing with temperature was similar to that of films sputtered at 60 mTorr of Ar50%Xe, showing the pressure equivalence of these different gas species, in terms of their thermalization efficiency.

In conclusion, the magnetic properties and texture control of sputter synthesized $TbCu_7$ type permanent magnet films have been studied in terms of their sputter deposition parameters. The sputtering parameters for the best in-plane c-axis texture, the optimum energy products, and coercivity have been identified. The pressure equivalence of two types of gas species in terms of their thermalization efficacy has been established

Metastable $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ ($0 \leq x \leq 1.0$) compounds with the 2:23:3-type structure

Bao-gen Shen, Bo Zhang, Fang-wei Wang, Jun-xian Zhang, Bing Liang, Wen-shan Zhan, Hui-qun Guo, and Jian-gao Zhao
State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, P.O. Box 603, Beijing 100080, People's Republic of China

Amorphous $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ ($0 \leq x \leq 1.0$) alloys were prepared by melt spinning at a speed of 47 m/s. When the amorphous samples were annealed at 900 K for 20 min, they crystallized to the metastable 2:23:3 single phase for all x. A detailed study of structure and magnetic properties of metastable $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ compounds has been made by x-ray diffraction and magnetization measurements. They are body-centered cubic, and the lattice constant decreases linearly from $a=14.16$ Å for $x=0$ to 13.86 Å for $x=1.0$. The Fe atom moment $\bar{\mu}_{Fe}$ for $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ was found to increase with x from $2.02\mu_B$ for $x=0$ to $2.17\mu_B$ for $x=0.8$, when the Co atom moment $\bar{\mu}_{Co}$ is assumed to be constant, as made in previous papers for crystalline Fe–Co alloys. The Curie temperature T_c is found to increase monotonically with increasing x from 659 K for $x=0$ to about 1218 K for $x=1.0$. The thermomagnetic measurements showed that when the $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ compounds were heated to certain temperatures, they decomposed to $Nd_2(Fe,Co)_{14}B$ and α-(Fe,Co) phases. The decomposition temperature of metastable compounds was about 990 ± 15 K, and was almost independent of the Co concentration x.

I. INTRODUCTION

Since the discovery of the Nd–Fe–B permanent magnet materials, a number of investigations on rapidly quenched Nd–Fe–B ternary alloys systems have been reported. Most of these studies focus on their hard magnetic properties, while the investigations on crystallization behaviors and magnetic properties of amorphous Nd–Fe–B alloys are relatively fewer. Buschow *et al.*[1] studied the crystallization of amorphous alloys of Fe-rich composition in the Nd–Fe–B system, and found a novel ternary compound $Nd_2Fe_{23}B_3$. The compound is metastable magnetic. Its crystal structure is body-centered cubic, space group $I\bar{4}3d$, the lattice constant $a=14.19$ Å.[2] Shen *et al.*[3] have prepared amorphous alloys in a wide composition range of the Nd–Fe–B system, and studied the phase diagram of crystallization and magnetic properties of the metastable phase. A study of crystalline phases of amorphous $Nd_2Fe_{23}B_3$ and the formation and magnetic properties of metastable $Nd_2Fe_{23}B_3$ compound has been made using x-ray diffraction and magnetization measurements.[4] Gou *et al.*[5] have reported the powder neutron diffraction study of magnetic structure of metastable $Nd_2Fe_{23}B_3$ compound. In order to obtain more information about the structure and magnetic properties of metastable compound, we have studied the effect of the substitution of Co for Fe on the crystal structure and magnetic properties of $Nd_2Fe_{23}B_3$ compound. In this paper, some results of the investigation are reported.

II. EXPERIMENTAL

Iron (purity, 99.9%), cobalt (purity, 99.9%), neodymium (purity, 99.9%) and Fe–B alloy (purity, 98.6%) were melted by arc melting in an argon atmosphere of high purity into homogeneous buttons with the compositions $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ ($x=0$, 0.2, 0.4, 0.6, 0.8, and 1.0). Amorphous ribbons about 1 mm wide and 20 μm thick were prepared by melt spinning in an argon atmosphere in a polished Cu drum of 20 cm diam with a speed of about 47 m/s and were then annealed in a steel tube in a vacuum of 10^{-5} Torr at different temperatures and times.

X-ray diffraction measurements were performed on the annealed ribbons using Co K_α radiation to identify the phase components and determine the crystallographic structure. The Curie temperature T_c of the compounds were determined from the temperature dependence of magnetization. High-field magnetization measurements at 1.5 K were made on these samples using an extracting sample magnetometer in fields ranging from 0 to 65 kOe.

III. RESULTS AND DISCUSSION

The $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ alloys prepared at a speed of 47 m/s were amorphous, and its x-ray diffraction pattern exhibited a diffuse broad maximum. The amorphous ribbons annealed at different temperatures of higher than their crystallization temperature produced different crystalline phases. For the annealing temperature of about 900 K, the amorphous samples crystallized to the metastable $Nd_2(Fe,Co)_{23}B_3$ phase. When the annealing temperature was higher than 925 K, the α-(Fe,Co) phase appeared, coexisting with the $Nd_2(Fe,Co)_{23}B_3$ phase.

Figure 1 shows an example of the x-ray diffraction patterns of $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ ($x=0.2$ and 1.0) after annealing at 900 K for 20 min. It is found that with increasing Co concentration, the diffraction line was shifted to higher angles, indicating that the lattice constants decrease with x. The present study shows that the substitution of Co for Fe in the $Nd_2Fe_{23}B_3$ compound does not change its crystal structure. The complete substitution obtains a new single-phase compound of $Nd_2Co_{23}B_3$. The crystal structure of the $Nd_2(Fe,Co)_{23}B_3$ compound is body-centered cubic, space group $I\bar{4}3d$. The lattice constant calculated from the x-ray

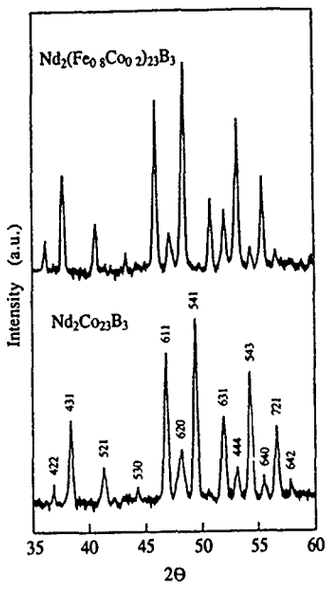

FIG. 1. X-ray diffraction patterns of metastable $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ compounds with $x=0.2$ and 1.0.

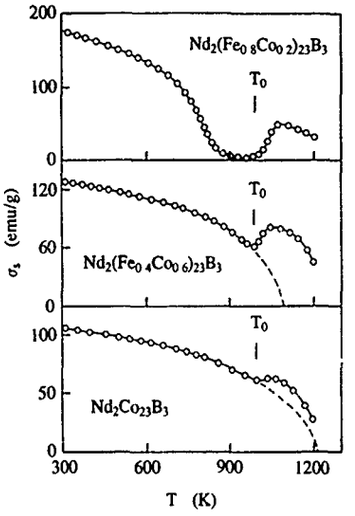

FIG. 2. Temperature dependence of the saturation magnetization σ_s of $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ compounds with $x=0.2$, 0.6, and 1.0.

diffraction patterns are found to decrease linearly from $a=14.16$ Å for $x=0$ to 13.86 Å for $x=1.0$, as shown in Table I.

X-ray diffraction and thermomagnetic measurements showed that the $Nd_2(Fe,Co)_{23}B_3$ compounds obtained by the crystallization from corresponding amorphous alloys were metastable. When the compounds were heated to certain temperature T_0, as shown in Fig. 2, they decomposed to $Nd_2(Fe,Co)_{14}B$ and α-(Fe,Co) phases. The decomposition temperature of the metastable compounds was about 990 ± 15 K, and was almost independent of the Co concentration x.

Figure 3 shows the magnetization σ of metastable $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ compounds at 1.5 K as a function of the external field H. The spontaneous magnetization $\sigma_s(1.5)$ at 1.5 K were obtained by a liner extrapolation of magnetization curves to $H=0$. The $\sigma_s(1.5)$ shows a monotonic decrease with increasing Co concentration from 184 emu/g to 113 emu/g as x increases from 0 to 1.0, as shown in Table I. A similar result was observed in other Fe–Co-based alloys.[6]

The magnetic moment per unit formula μ_s of $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ compounds is shown in Fig. 4(a) as a function of Co concentration x. The μ_s is found to decrease from $52.9\mu_B$ for $x=0$ to $33.9\mu_B$ for $x=1.0$. If the magnetic moment of the Nd atom $\bar{\mu}_{Nd}$ is suggested to be $3.27\mu_B$, which is the moment of a free Nd^{3+} ion, the average magnetic moment $\bar{\mu}_{Fe+Co}$ per Fe+Co atom can be obtained, according to $\mu_s=23\bar{\mu}_{Fe+Co}+2\bar{\mu}_{Nd}$. The composition dependence of the average moment $\bar{\mu}_{Fe+Co}$ may be written as $\bar{\mu}_{Fe+Co}=\bar{\mu}_{Fe}(1-x)+\bar{\mu}_{Co}x$, where $\bar{\mu}_{Fe}$ and $\bar{\mu}_{Co}$ are the effective magnetic moments per the Fe atom and the Co atom, respectively. A study of Collins *et al.*[7] on the crystalline Fe–Co alloys using polarized neutron diffraction demonstrated that the average moment $\bar{\mu}_{Fe}$ per Fe atom increases with increasing Co concentration, and the average moment $\bar{\mu}_{Co}$ per Co atom remains an essential value. Similar results were found in other Fe–Co-based alloys.[8] If $\bar{\mu}_{Co}$ of $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ is assumed to keep the constant value of $1.20\mu_B$ (the value of $\bar{\mu}_{Co}$ in $Nd_2Co_{23}B_3$ compound), the $\bar{\mu}_{Fe}$ is found to rise with increasing Co concentration from $2.02\mu_B$ for $x=0$ to $2.17\mu_B$ for $x=0.8$.

TABLE I. The lattice constant a, saturation magnetization σ_s at 1.5 K and the Curie temperature T_c of $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ compounds.

x	a (Å)	σ_s (emu/g)	T_c (K)
0.0	14.16	184	659
0.2	14.11	177	831
0.4	14.06	162	~978
0.6	13.99	146	~1097
0.8	13.90	129	~1156
1.0	13.86	113	~1218

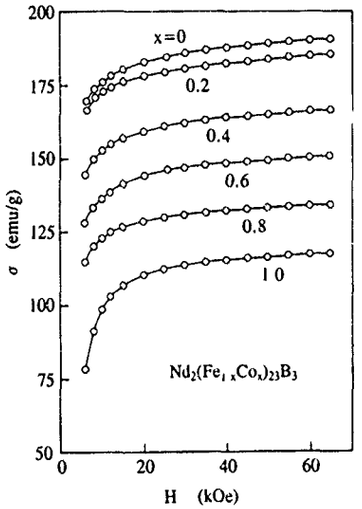

FIG. 3. Magnetization curves of $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ compounds.

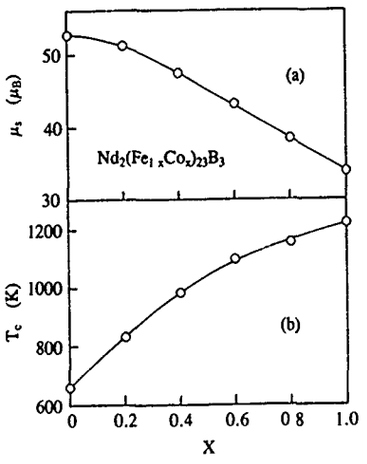

FIG. 4. The magnetic moment per unit formula μ_s at 1.5 K (a) and the Curie temperature T_c (b) of $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ compounds as a function of Co concentration x.

The temperature dependence of the saturation magnetization σ_s of $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ compounds with $x=0.2$, 0.6, and 1.0 is shown in Fig. 2. For $x \geq 4$, the Curie temperature T_c of the metastable compounds was higher than the decomposition temperature. The T_c of the samples was obtained by linear extrapolation of the squared magnetization σ_s^2 versus temperature curves to $\sigma_s^2=0$. Figure 4(b) and Table I show the Curie temperature of $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ compounds as a function of Co concentration. The T_c was found to increase monotonically from 659 K for $x=0$ to about 1218 K for $x=1.0$. The variation of T_c with x was different from that of the crystalline Fe–Co alloys and some amorphous Fe–Co-based alloys,[6,8] in which T_c showed a maximum value. According to the average molecular-field model, the Curie temperature is directly proportional to the exchange interactions between magnetic atoms and the number of nearest-neighbor magnetic atoms. For $Nd_2(Fe_{1-x}Co_x)_{23}B_3$, the T_c depends mainly on Fe–Fe exchange interactions for the Fe-rich region or Co–Co exchange interactions for the Co-rich region. The strong increase of T_c with x for $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ compounds indicated that the contribution of the exchange interactions between the Co–Co atom on T_c was much larger than that between Fe–Fe atoms.

Magnetic properties of $(Nd_{0.9}R_{0.1})_5Fe_{17}$ with R=Sm, Gd, and Y

Cong-Xiao Liu, Yun-Xi Sun, Zun-Xiao Liu, and Chin Lin
Department of Physics, Peking University, Beijing, People's Republic of China

Magnetic properties of $(Nd_{0.9}R_{0.1})_5Fe_{17}$ have been investigated. Samples were prepared by arc melting and annealed at 600 °C for 48 days. X-ray diffraction and thermomagnetic analyses showed that the samples are almost single phase with the Nd_5Fe_{17} structure when R=Sm, Gd, and Y, but this structure cannot be formed when R=Pr. The effects of R substitution on saturation magnetization, Curie temperature, and lattice parameters are reported. X-ray diffraction analyses of aligned powders suggests that these samples have basal plane anisotropy. The magnetization does not fully saturate along the field in a field up to 70 kOe although the magnetization curves show the characteristic behavior of a soft ferromagnetic material.

I. INTRODUCTION

Recently, a revised Nd–Fe phase diagram, including the new stable phase Nd_5Fe_{17}, was reported.[1] The crystal structure of Nd_5Fe_{17} belongs to the hexagonal space group $P6_3/mcm$, with 12 formula units per cell.[2–4] Magnetic measurements[5,6] showed that Nd_5Fe_{17} is a ferromagnet with T_c=503 K and saturation magnetization 162 emu/g at 4.2 K. Mossbauer spectra[5] were fitted with five Fe sites, yielding an average B_{eff}=30.7 T at 10 K, from which an average Fe moment of 2.12 μ_B is deduced. X-ray diffraction analyses of magnetically aligned powders suggest basal plane anisotropy. This compound is not considered to be a promising permanent magnetic material.[6] On the other hand, a high coercivity Sm–Fe–Ti phase was produced by sputtering,[7,8] mechanical alloying,[9] and melt spinning.[10] This Sm–Fe–Ti phase was identified as having the Nd_5Fe_{17} structure by x-ray indexing.[4] The substitution of V and Ti for approximately 10% of Fe yields a systematic expansion of the unit-cell volume.[11] Binary Sm_5Fe_{17} was also synthesized.[11] Because the Stevens factor α_J is of a different sign for Sm and for Nd, Sm_5Fe_{17} has uniaxial anisotropy. Magnetically hard $Sm_5(Fe, Co, Ti)_{17}$ phases have been synthesized by a conventional powder metallurgical method.[12] $Sm_5(Fe_{0.94}Ti_{0.06})_{17}$ showed a room-temperature coercivity $_jH_c$=21.5 kOe. In this work, we substitute 10% of Nd in Nd_5Fe_{17} by other rare earth elements and investigate their structural and magnetic properties.

II. EXPERIMENT

Samples were prepared by arc melting $(Nd_{0.9}R_{0.1})$ and Fe in the proportion of 1 to 3 under a purified argon atmosphere, with R=Nd, Pr, Sm, Gd, and Y. The samples were annealed in vacuum at 600 °C for 48 days. Structural analyses were carried out on powdered samples with a Rigaku D/MAX-RB diffractometer using Cu K_α radiation. X-ray diffraction and thermomagnetic analyses showed that the samples are almost single phase with the Nd_5Fe_{17} structure when R=Nd, Sm, Gd, and Y. Small amounts of metallic rare earth elements and R_2Fe_{17} were found in some samples. The Nd_5Fe_{17} structure could not formed when 10% of the Nd was substituted by Pr.

Magnetic measurements were performed with an extraction magnetometer, in a field up to 70 kOe on bulk polycrystalline samples. Powdered samples were aligned in a field of 10 kOe at room temperature and fixed in epoxy resin. The easy magnetization direction was determined by x-ray diffraction analyses of aligned powders. Thermomagnetic

TABLE I. Lattice parameters, Curie temperature and saturation magnetization at 1.5 K.

	a(Å)	c(Å)	T_c(K)	$M_s(\mu_B/fu)$
Nd_5Fe_{17}	20.207	12.341	507	48.2
$(Nd_{0.9}Sm_{0.1})_5Fe_{17}$	20.204	12.354	508	48.9
$(Nd_{0.9}Gd_{0.1})_5Fe_{17}$	20.226	12 348	526	43.7
$(Nd_{0.9}Y_{0.1})_5Fe_{17}$	20.207	12 354	499	47.5

curves at temperatures higher than room temperature were measured by a vibrating sample magnetometer operating at a low field. The Curie temperature was determined by plotting M^2 vs T near T_c and extrapolating the linear part to $M=0$. It may be slightly higher than that determined by the "kink-point" method.[2]

III. RESULTS AND DISCUSSION

Thermomagnetic curves of $(Nd_{0.9}R_{0.1})_5Fe_{17}$ with R=Nd, Sm, Gd, and Y are shown in Fig. 1. Gd substitution increases T_c slightly and Y substitution decreases T_c. A small amount of R_2Fe_{17} is observed in the Y-substituted sample. X-ray diffraction patterns of magnetically aligned and random powder $(Nd_{0.9}Sm_{0.1})_5Fe_{17}$ are shown in Figs. 2(a) and 2(b), respectively. The intensity of the (314) reflection, which is the strongest in random powders, is reduced in aligned powders. The intensities of (hkl) with $l=0$ are enhanced. The (004) and (006) reflections are still weak. This suggests that the sample has basal plane anisotropy. Similar results were obtained for Gd and Y substituted samples. Lattice parameters and Curie temperatures of these samples are listed in Table I.

The initial composition of these samples is off-stoichiometric. However, considering that there is negligible loss in weight in the arc melting, the materials should have rare earth metals, as in the starting composition. Nd, Sm, and Gd are antiferromagnetic ordering at 1.5 K. Their contributions to magnetization are negligible in our experiments, so that the magnetizations of $(Nd_{0.9}R_{0.1})_5Fe_{17}$ are deduced from the measured values. The magnetization curve and the magnetic hysteresis loop in the second quadrant for Nd_5Fe_{17} at

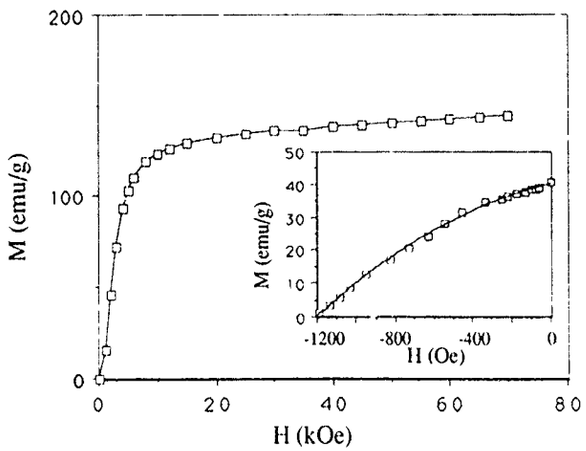

FIG. 3. Magnetization curve at 1.5 K for Nd_5Fe_{17}. The inset is the magnetic hysteresis loop in the second quadrant.

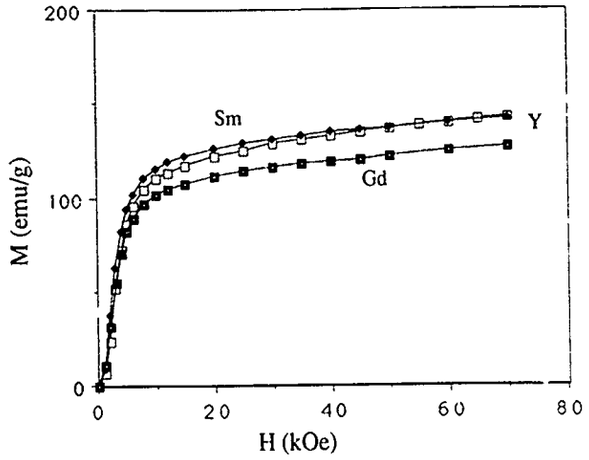

FIG. 4. Magnetization curves at 1.5 K for $(Nd_{0.9}R_{0.1})_5Fe_{17}$, with R=Sm, Y, and Gd.

1.5 K are shown in Fig. 3. Magnetization curves at 1.5 K for $(Nd_{0.9}R_{0.1})_5Fe_{17}$ with R=Sm, Y, and Gd are shown in Fig. 4. The samples do not fully saturate along the field in a field up to 70 kOe, due to the large in-plane magnetocrystalline anisotropy. The saturation magnetization M_s was deduced by fitting the data to a law of the type

$$M=M_s(1-a/H-b/H^2).$$

The results are also listed in Table I. Y has no magnetic moment. The magnetic moment of Gd is $7\mu_B$. If we take the average Fe moment to be $2.17\mu_B$,[5] and Nd moment $2.44\mu_B$, the effects of Y and Gd substitution are in agreement with the calculated values of M_s.

Our results show that although only 10% of the Nd is substituted, the effects are evident. The substitution of Pr destroys the Nd_5Fe_{17} structure. Y lowers the stability of the structure, the R_2Fe_{17} phase appears. Gd has the largest de Gennes factor. It enhances T_c but decreases magnetization, due to the antiferromagnetic coupling between Gd and Fe. The formation of quasibinary $(Nd,Sm)_5Fe_{17}$ reveals a possibility that a uniaxial anisotropy could be obtained by increasing the substitution of Sm for Nd. Further investigations are in progress.

New permanent magnetic MnBiDy alloy films

Fang Ruiyi, Fang Qingqing, Zhang Sheng, Peng Chubing, and Dai Daosheng
Department of Physics, Peking University, Beijing 100871, China

We have studied the magnetic properties of MnBiDy films fabricated by the thermal coevaporation method and annealed subsequently in a vacuum oven at temperatures of 350 °C–425 °C. The thicknesses of these films are in the range from 60 to 1200 nm. X-ray diffraction analyses have confirmed that those samples have an hcp structure. Magnetic measurements revealed that the saturation magnetization σ_s=46–78 emu/g, remanence ratio R=0.67–0.98, coercive force μHc=2.2–7.3 kOe, and magnetic energy product $(BH)m$=3.3–14.3 MGOe. These values are sensitive to the film thicknesses. It was found that μHc reaches a maximum at $d\approx$400 nm.

I. INTRODUCTION

Recently, studies on the permanent magnet films are concentrated on rare earth-transition metal compounds and alloys. The films of $SmCo_5$ and SmCo-based systems exhibit very high in-plane anisotropy, and high magnetic energy products about 21 MGOe.[11] In Sm–Co 2:17-type films, the energy product can reach 20 MGOe.[2] NdFeB films have a high intrinsic coercive force with an energy product about 12 MGOe,[3] but with a relatively low Curie temperature. The Sm_1Fe_{12}-type allow films exhibit a perpendicular anisotropy with energy product 20.7 MGOe.[4] Generally, these films are deposited at very high substrate temperatures of 500 °C–700 °C and are necessary to apply an external magnetic field (~2 kOe) during the process of deposition for controlling the growth of out-plane texture.

We have prepared new permanent magnet films of MnBi doped with rare earth elements Dy and Sm by using the vacuum deposition method. In this paper the magnetic properties are reported.

II. SAMPLE PREPARATION AND MEASUREMENT

MnBi films doped with Dy or Sm were fabricated by using thermal evaporation at a vacuum of 1×10^{-6} Torr. First a Bi buffer layer of suitable thickness was deposited onto a glass substrate cooled by liquid nitrogen; then Mn, Bi, and Dy (or Sm), with an atomic ratio of 2:1:0.10 were simultaneously deposited onto the buffer layer with a different thickness, ranging from 60 to 1200 nm. Finally, a SiO_2 overlayer of about 300 nm was deposited to prevent samples from oxidation. The as-deposited samples were annealed in a vacuum oven (2×10^{-6} Torr) at different of temperatures 350 °C, 375 °C, 400 °C, and 425 °C for 4 h. The composition of all samples were analyzed by electron probe and an Auger profile. These results show that the samples exhibit the component ratio of Mn:Bi:Dy of about 1:1:0.10.[5] So we refer to these samples as MnBiDy. The crystal structure of the prepared films was analyzed by x-ray diffraction. It shows that the films have the NiAs structure with their c axes perpendicular to the film plane. The magnetic hysteresis loops at room temperature were measured with a VSM (LDJ 9500).

III. RESULTS AND DISCUSSIONS

Figure 1 shows the hysteresis loops of MnBiDy films for several film thickness (d=60, 257, 377, 622, 913, and 1200 nm) at the external magnetic field He=0–2.0 T. The saturation magnetizations of the MnBiDy films for all annealing temperatures decreases as d increases for d<300 nm. This can be explained by the increase in the amount of free Bi and Bi_3Mn_2 phases as the film thickness increases. This is confirmed by the x-ray diffraction analysis. The intrinsic coercive force μHc as a function of d is shown in Fig. 3. μHc increases with d for d<400 nm. This may be caused by the nucleation. Then μHc decreases as d increases for d>400 nm; this is due to the domain rotation during the demagnetizing process. The reasons are given as follows.

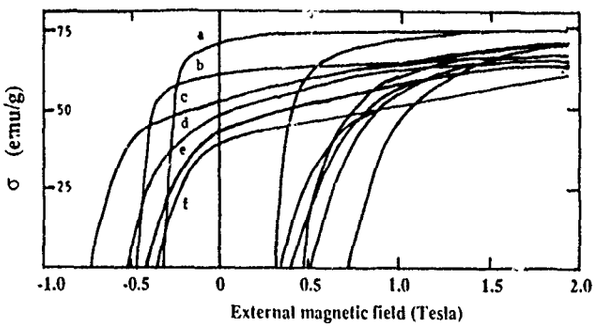

FIG 1. Hysteresis loops as a function of film thicknesses d=60 nm (a), d=257 nm (b), d=377 nm (c), d=622 nm (d), d=913 nm (e), and d=1200 nm (f) for MnBiDy films.

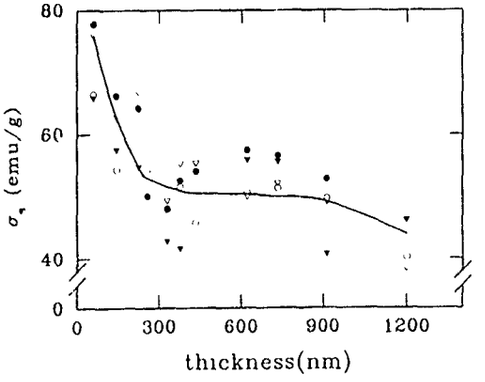

FIG. 2. Thickness dependence of the saturation magnetization of MnBiDy films annealed at 350 °C (○), 375 °C (●), 400 °C (▼), and 425 °C (▽) for 4 h.

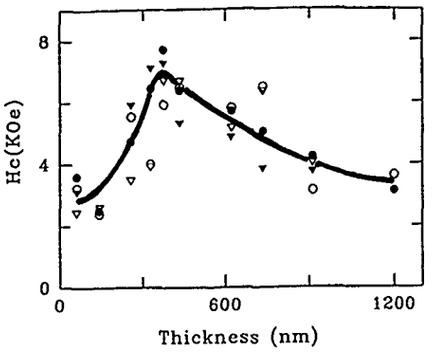

FIG. 3. Thickness dependence of the intrinsic coercive force of MnBiDy films annealed at 350 °C (○), 375 °C (●), 400 °C (▼), and 425 °C (▽) for 4 h.

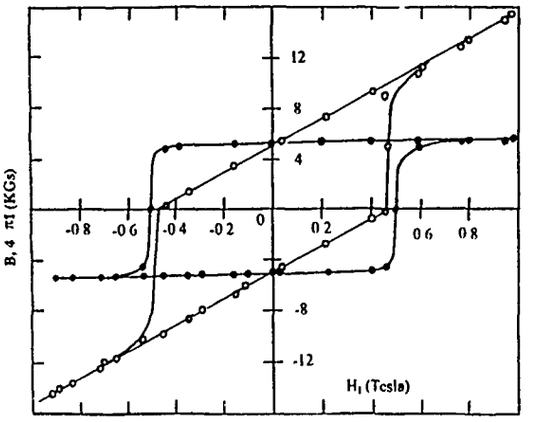

FIG. 5. The $4\pi M$-Hi and B-Hi hysteresis loops of the MnBiDy film annealed at 375 °C for 4 h. d=230 nm, μHc=5 kOe, $_{13}Hc$=4.7 kOe, and $(BH)m$ 8.3 MGOe.

The intrinsic coercive force may result from three irreversible magnetization processes: (a) nucleation and growth of the reverse domain; (b) domain wall pinning; and (c) irreversible domain rotation. In order to identify which process the Hc comes from for MnBiDy films, we also measured the magnetic hysteresis loops for those films under various magnetic fields, as shown in Fig. 4. Evidently, as $d=60$ and 143 nm, the Hc value increases with the applied field, but the magnetization does not vary with the field when the field is high. This feature reveals that Hc results from the nucleation and growth. This is also confirmed by the observation of nucleation processes using polarized light microscopy patterns. As $d=622$ and 913 nm, the shape of hysteresis loops is completely different from those for $d=60$ nm, indicating that the coercivity does not result from the nucleation and growth. Hence, we suggest that it results from the domain rotation. According to the domain rotation model for films with uniaxial anisotropy, the value of Hc is estimated to be about 3.7 kOe for the $d=913$ nm sample, which is nearly equal to the experimental data (about 4.0 kOe at the magnetic field of 2 T).

According to the measured data of the hysteresis loops, we can obtain the magnetization $4\pi M$ and magnetic induction B as a function of the intrinsic magnetic field Hi (see Fig. 5) by using the relations Hi=He-NM and B=Hi+$4\pi M$, when N is the demagnetizing factor ($N=4\pi$ for films when He is perpendicular to the plane, and the effective anisotropy field is neglected). Then, the maximum magnetic energy product $(BH)m$ as a function of film thickness d, which is shown in Fig. 6, can be obtained. It decreases quickly as d increases for $d\leqslant 350$ nm, and then remains as a constant for $d>350$ nm. This can be understood due to the behaviors related to thickness dependence of the μHc and magnetization of these films.

In conclusion, we have prepared MnBiDy permanent magnet films with a large magnetic energy product and also studied the saturation magnetization, coercive force and $(BH)m$ as a function of film thicknesses for these films.

Neutron scattering studies of the vortex lattice in niobium and ℜ123 superconductors (invited)

N. Rosov, J. W Lynn,[a] and T. E. Grigereit[a]
Reactor Radiation Division, National Institute of Standards and Technology, Gaithersburg, Maryland 20899

The magnetic flux lattice undergoes a melting transition not only in high-T_c oxide superconductors, but also in conventional superconductors, as recently observed in superconducting niobium films. Small-angle neutron scattering was used to investigate the properties of the magnetic flux lattice in a large, high-quality single crystal of niobium. The small London penetration depth of niobium gives a large magnetic scattering signal, and the use of a high-quality single crystal eliminates other unwanted scattering (from twin boundaries, voids, etc.). The signal-to-noise ratio is therefore improved by several orders of magnitude over the best available measurements of high-T_c oxide superconductors. A sixfold hexagonal pattern of peaks is observed in the mixed state ($H_{c1}<H<H_{c2}$) at all temperatures. These peaks are resolution limited below the irreversibility line; above it, the width in the transverse direction increases with temperature due to the vortex dynamics. Close to H_{c2}, the radial widths of the peaks also broaden. The increase in broadening is a direct observation of a transition to a disordered phase. Nevertheless, the basic hexagonal pattern of peaks is maintained throughout the mixed state, indicating that a correlated flux fluid exists in the reversible regime. Some results on the vortex lattice in superconducting $DyBa_2Cu_3O_7$ are presented and some of the possible exotic states resulting from the coexistence of antiferromagnetic order and superconductivity are described.

I. INTRODUCTION

The melting of the flux lattice in high-temperature oxide superconductors is currently a subject of great fundamental and practical interest. The early discovery of an irreversibility line[1] in the cuprate superconductors suggested that the basic vortex behavior was quite different from previously known superconductors, perhaps due to the much higher critical temperature T_c. Neutron scattering studies of the melting process to probe the exact nature of the melting transition would be most interesting, especially since techniques such as Bitter decoration are restricted to low fields. Unfortunately, the very nature of the high-T_c superconductors makes observing such a melting transition via neutrons extremely difficult. The London penetration depth λ_L in the oxide superconductors is a factor of 4 or 5 larger than for niobium (for which $\lambda_L \approx 350$ Å). As a result, the neutron scattering intensity from the flux lattice, which goes as λ_L^{-4}, is much smaller for the high-T_c materials. An additional technical difficulty is that presently available large single crystals of 123 superconductors have grain boundaries, twin boundaries, and various other defects that give rise to scattering in the same small-angle region as the vortex scattering. This dramatically reduces the signal-to-noise ratio for the vortex scattering, and makes the vortex scattering pattern much more difficult to study.

Irreversibility lines have also been recently observed in niobium, which is an ideal candidate for neutron studies of the vortex lattice, with the combined benefits of large signal and low background due to the availability of large, high-quality single crystals. Pure, defect-free niobium has a Ginzburg–Landau parameter κ of 0.77, just slightly greater than the minimum value ($1/\sqrt{2}$) for type II behavior. In addition, niobium is a material for which κ can be dramatically increased by the influence of defects such as grain boundaries or by the introduction of impurities. Neutron diffraction experiments on the flux line lattice in niobium have been performed over the last thirty years, beginning with a study by Cribier *et al.*[2] that explicitly demonstrated the existence of a triangular vortex lattice, and continuing with much more detailed work by groups at Jülich[3] and Oak Ridge.[4] The subsequent work focused on the interaction of the flux lattice with the crystalline lattice, concentrated mainly on the region of the phase diagram well below the upper critical field $H_{c2}(T)$. The work[5] that we review here extends the measurements to the $H_{c2}(T)$ line.

In the first part of this article we describe the basics of the neutron scattering experiments and the features of the vortex lattice over the (H,T) plane in niobium. We continue with a description of our detailed measurements of the melting of the vortex lattice in niobium and conclude with a description of some recent work on rare-earth 123 superconductors.

II. EXPERIMENT

A. Neutron scattering

The bulk of the experimental results described here were obtained on the 30 m small-angle neutron scattering (SANS) spectrometers of the Cold Neutron Research Facility at the National Institute of Standards and Technology. Both spectrometers operate in the same way: A beam of neutrons moderated by a cold source is incident on a neutron velocity selector, which produces a triangular wavelength distribution of neutrons with $\Delta\lambda/\lambda \approx 15\%$. The neutrons pass down a long ($\lesssim$15 m) variable-length flight path with a pinhole collimator at each end, which fixes the incident neutron momentum $\mathbf{k}_i$. After the sample there is another variable-length flight path to a multidetector, which allows the simultaneous collection of data over some range of momentum transfer $\mathbf{Q}=\mathbf{k}_i-\mathbf{k}_f$.

Our sample is a 95 g single crystal of niobium, 9 cm in length, with a diameter of 1.25 cm. The cylinder axis is the [110] crystallographic axis, which was oriented perpendicular to the applied field. The neutron beam illuminated a section of approximately 1 cm diameter near the midpoint of the cylinder. Initial measurements were performed in a flow cryostat with an Al vacuum shroud and 77 K heat shield that was mounted in an electromagnet with holes for the neutron beam drilled through the pole pieces. Later measurements were performed in a horizontal superconducting magnet cryostat specially designed for SANS measurements, with single-crystal sapphire windows along the beam path to reduce unwanted cryostat scattering.

At low temperatures a crystalline vortex lattice is formed, and the scattering pattern of neutrons from the flux lattice directly reveals the reciprocal lattice. Our experimental configuration involved applying the magnetic field nearly along the incoming neutron direction $\mathbf{k}_i$. In this case, the possible momentum transfers for all six 10 reflections are approximately parallel to the plane of the detector, so a pattern such as Fig. 1 will appear on the detector. The simultaneous appearance of all six spots in this case results from some domain structure in the formation of the lattice. If the lattice is formed carefully, it is possible to observe a single diffraction spot as in Fig. 1(bottom).

This pattern [Fig. 1(top)] was collected in two minutes. In comparison, a similarly sized single crystal of $YBa_2Cu_3O_7$ (Ref. 6) requires the subtraction of a zero-field cooled background scan from the applied field scan, each of which takes several hours counting time. The excellent quality of the Nb single crystal—with an almost complete lack of sample-dependent small-angle scattering, incoherent scattering, and absorption—not only allowed the rapid collection of data in the low-temperature regime, but in fact permitted the analysis of the behavior near the H_{c2} phase boundary, where the signal is drastically reduced.

The reciprocal lattice of a triangular lattice with lattice constant a is a self-similar triangular lattice with lattice constant $a^*=4\pi/\sqrt{3}a$. Since the flux quantum $\phi_0=2.068\times10^{-15}$ T m^2 and the area per flux quantum is $\sqrt{3}a^2/2$, we can relate the internal magnetic field B to the lattice parameter by $\phi_0=\sqrt{3}Ba^2/2$. The position in reciprocal

space of the 10 reflection, which occurs at a momentum transfer $Q_{10}=a^*$, is

$$Q_{10}=2\pi\sqrt{2B/\sqrt{3}\phi_0}. \tag{1}$$

In the $\mathbf{H}\|\mathbf{k}_i$ configuration, there are a number of ways to view the data. One way is a "radial scan," which is performed by summing the scattering at a particular Q around a portion, or all, of the detector [see Fig. 2(a)]. These scans (or sums, in this case) determine the translational correlations between the flux lines in the lattice. Another possibility is a "transverse scan," a sum of the scattering over a small range of Q as a function of angle ϕ around the detector [see Fig. 2(b)], which gives the angular correlations between the flux lines. Finally, we can perform rocking scans [see Fig. 2(c)], where the intensity in a particular region of the detector is

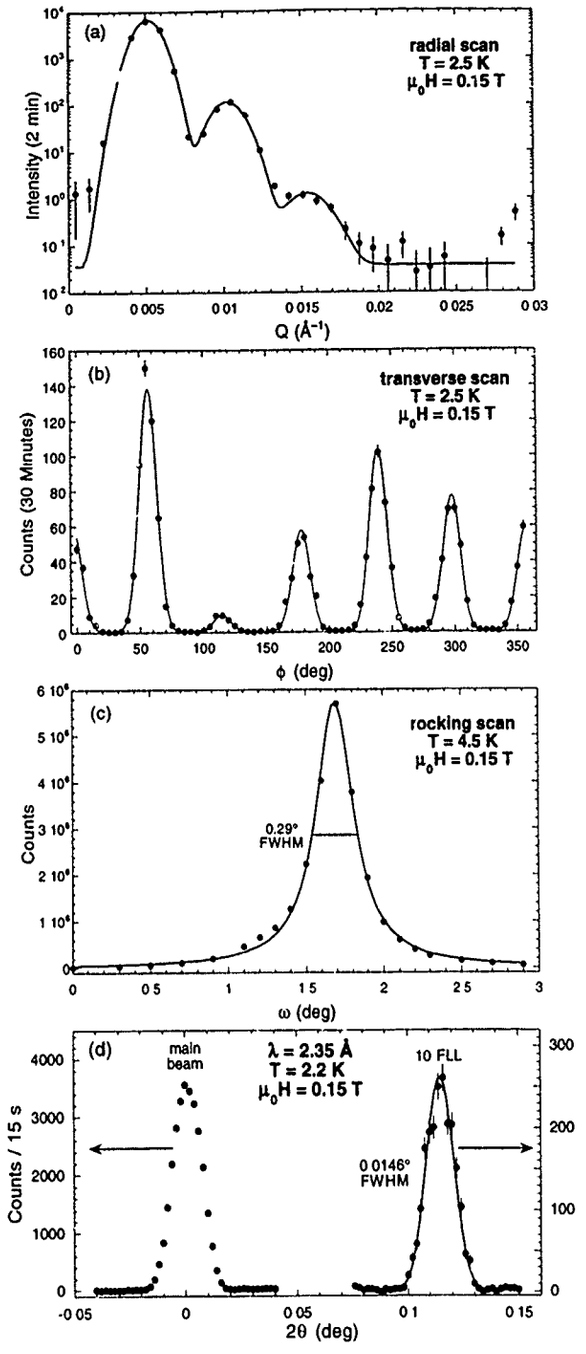

FIG. 2. Various summations of the Fig. 1(top) pattern: (a) Radial and (b) transverse scans at $T=2.5$ K and $\mu_0 H=0.15$ T. (d) Radial scan of 10 peak with improved resolution performed on the BT-7 reflectometer.

recorded as a function of magnet rotation angle ω. In this configuration, the rocking scans primarily determine the straightness of the flux lines.

B. The flux line lattice in Nb

In the Meissner state, the magnetic field in the sample must vanish, i.e., $\mathbf{B}=0$. The magnetization $\mathbf{M}$ of the sample then depends directly on the applied magnetic field $\mathbf{H}_{app}$ to produce the required cancellation. The boundary conditions on the field imply a demagnetizing field, due to the sample magnetization, that opposes the applied field, and so

$$\mathbf{H}=\mathbf{H}_{app}-\eta\mathbf{M}, \tag{2}$$

where η is the demagnetization factor. In the case of an infinite right cylinder with a field applied perpendicularly to the cylinder axis $\eta=1/2$, the H inside the sample is actually $2H_{app}$ in the Meissner state. For the internal field to reach the lower critical field H_{c1}, a field $H_{app}=\frac{1}{2}H_{c1}$ needs to be applied.

For $H_{app}\geq\frac{1}{2}H_{c1}$, flux will penetrate the sample. The competition between the short-range repulsion and long-range attraction of the fluxoids initially causes the formation of domains of flux lines with a density B_0 determined by the strength of the long-range attraction. In this intermediate mixed state (IMS), the sample magnetization is $\mathbf{M}=f\mathbf{B}_0/\mu_0-\mathbf{H}$, where f is the fraction of the sample in the vortex state. As the applied field is $\mathbf{H}_{app}=\mathbf{H}+\eta\mathbf{M}$, in the IMS the relation between the applied field and the internal fields is

$$\mathbf{H}_{app}=(1-\eta)\mathbf{H}+f\eta(\mathbf{B}_0/\mu_0). \tag{3}$$

In our experimental configuration, f increases linearly from 0 at $H_{app}=\frac{1}{2}H_{c1}$ to 1 at $H_{app}=\frac{1}{2}H_{c1}+\frac{1}{2}B_0/\mu_0\equiv H_2$. With further increase of H_{app} above H_2, the flux lattice density increases throughout the sample. Just below H_{c2} the flux lattice achieves its highest density, and ultimately, at $H_{app}=H_{c2}$, the sample magnetization goes to zero and the sample is no longer superconducting.

We thus expect to observe the following behavior as a function of field in a SANS measurement: For $H_{app}<\frac{1}{2}H_{c1}$ the sample is in the Meissner state and there is no scattering. Just above $\frac{1}{2}H_{c1}$ flux penetrates the sample and is confined to regions with constant flux density B_0; elsewhere in the sample, the flux density is zero. At this point, a scattering pattern can be observed, with a lattice spacing corresponding to the flux density B_0,

$$a_0=\sqrt{\frac{2}{\sqrt{3}}\frac{\Phi_0}{B_0}}. \tag{4}$$

This lattice spacing remains constant while the scattering intensity increases linearly with field, until $H_{app}=H_2$, where the flux lattice fills the entire sample. Above H_2, the flux density increases, but the scattering intensity decreases as the fluxoids overlap each other and the contrast is consequently reduced. The sample magnetization is $\mathbf{M}=\mathbf{B}/\mu_0-\mathbf{H}$, so the flux density is then $B=\mu_0[H_{app}-(1-\eta)H]/\eta$. Exactly this behavior has been observed for niobium by Christen *et al.*[4]

We can also make the SANS measurements as a function of temperature in a constant applied field. Since $H=-M+B/\mu_0$, then

$$B=\mu_0(H_{app}+\tfrac{1}{2}M) \tag{5}$$

for our experimental configuration. As the magnetization is negative and approaches zero near the superconducting phase boundary, the flux density increases as the phase boundary is approached, and so the diffraction peaks move out from their low-temperature position. Since the magneti-

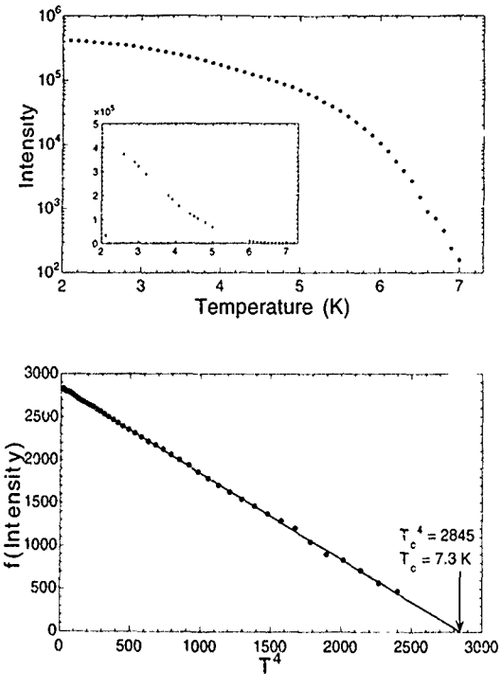

FIG. 3. (a) Intensity of the 10 peak as a function of temperature and (b) linearized plot of $f(I)$ vs T^4, showing the extrapolation to obtain $T_c(H)$.

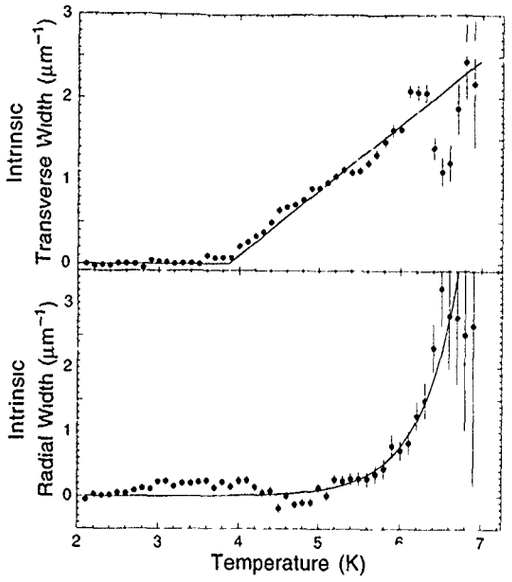

FIG. 4. Intrinsic transverse (top) and radial (bottom) widths as a function of T.

zation goes to zero at H_{c2}, the demagnetization factor does not affect the determination of the upper critical field, and the magnetic scattering will disappear at $H_{app}=H_{c2}$.

III. MELTING OF THE FLUX LATTICE IN NIOBIUM

The observation of irreversibility lines and the implication of melting phenomena occurring in the flux lattice of the high-T_c superconductors prompted a reexamination of "conventional" superconductors to see if similar phenomena were possible in these systems. Drulis *et al.*[7] observed irreversibility effects from flux depinning in vibrating reed measurements on cold-rolled niobium foils. Later work by Schmidt *et al.*[8] demonstrated the existence of a magnetic irreversibility line in sputtered Nb films that followed the expectations for a melting line.

One would naively expect that the melting of the flux line lattice might be manifested by a sudden transition from the low-temperature hexagonal pattern of Fig. 1 to an isotropic ring of scattering on the detector, indicative of an isotropic liquid state. We therefore performed field cooling measurements, starting well above the superconducting transition at constant H_{app}, and then slowly (<0.1 K/5 min and even slower near the H_{c2} line) lowered the temperature, collecting scattering patterns at various temperatures. Care was taken to avoid overshooting the new temperature set point on changing the temperature. From our discussion above, we expect the intensity to appear just below $T_c(H)$, as the magnetic contrast appears, and this is in fact what happens [see Fig. 3(a)]. We note that since κ is small for our niobium sample, the two-fluid model does not exactly apply; however, we have used the T^4 behavior of the London model to guide us in linearizing the temperature dependence of the scattering intensity, and so allow the extrapolation of the intensity to zero and the determination of $T_c(H)$ [Fig. 3(b)]. From our temperature scans we were able to determine the H_{c2} phase boundary. In addition, we immediately noticed that (i) the temperature dependence of the scattering was smooth, with no discontinuities; (ii) the scattering intensity was not lost until just below the extrapolated H_{c2} line; and (iii) we always had a sixfold pattern—no ring of scattering ever appeared. Not only did the scattering from the vortices maintain its hexagonal symmetry at all fields and temperatures in the mixed state, but it was locked by the crystalline anisotropy, since we consistently observed the same orientation for the sixfold diffraction pattern over many different experimental configurations.

If, however, we examined the widths of the peaks in the radial and transverse directions as a function of temperature, we found (see Fig. 4) that at some temperature $T_t(H)$ well below $T_c(H)$, an intrinsic width developed in the transverse direction. This width determines the degree of orientational correlations. The radial width remained resolution limited until some higher temperature $T_r(H)$, whereupon it also developed an intrinsic width. We also measured the scattering pattern from the vortex lattice on the NIST BT-7 reflectometer. The spectrometer resolution here is a factor of 3 better for radial scans than the corresponding SANS resolution [see Fig. 2(d)]. We observed the radial width increase above the resolution limit with the reflectometer at the same temperature as we had observed on the SANS, and this therefore lends confidence the intrinsic radial widths develop at higher temperatures than the intrinsic transverse widths.

To further clarify the nature of these two transitions, we performed isothermal field sweeps and found that the peak intensities and widths were reversible above the T_t line and hysteretic below. The restoration of the reversible behavior above T_t leads us to believe that we have observed the onset of a correlated flux fluid state above T_t. This state may not

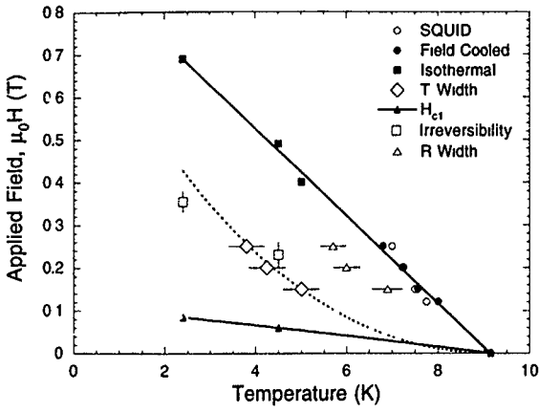

FIG. 5. Phase diagram H vs T for Nb as determined by neutron scattering. The H_{c1} and H_{c2} boundaries are indicated, as are the points where the radial and transverse widths broaden.

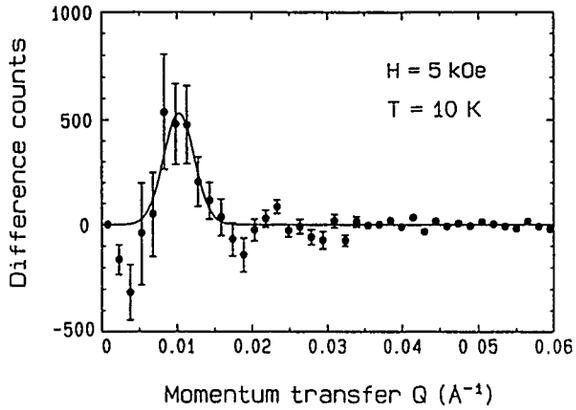

FIG. 6. Radial sum of the difference pattern between field-cooled and zero-field cooled Dy123 at $T=10$ K and $\mu_0 H=0.5$ T. The peak position indicates that the lattice is close to triangular.

be a hexatic phase, since in hexatic systems both the transverse and radial widths appear to be coupled and therefore the intrinsic widths would be expected to develop together.[9]

Figure 5 displays the experimentally determined phase diagram for our niobium crystal. The lower and upper critical fields have been determined via neutrons by the respective onset and loss of scattering from the flux lattice. We can estimate from the two-fluid model that $\kappa \approx \sqrt{H_{c2}/H_{c1}} \approx 2$. This is larger than the value of $\kappa \approx 0.8$ obtained for high purity and defect-free niobium.[4,10] Our sample and those of Drulis *et al.*[7] and Schmidt *et al.*[8] are high purity niobium; however, the various preparation methods created samples with varying defect and grain boundary concentrations, as reflected by the value of κ. Those samples with larger κ have a larger $H_{c2}(T)$: the $\kappa \approx 7$ cold-rolled foil[7] higher than our sample and the $\kappa \approx 10$ sputtered film[8] still larger. The phase diagram also shows $T_r(H)$, $T_t(H)$, and the irreversibility line $T_{irr}(H)$. The irreversibility line and $T_t(H)$, which we identify with a melting curve, are well below that reported for the cold-rolled foils,[7] which is lower again than the melting curve for the sputtered niobium films.[8] This supports the reasonable expectation that T_{irr} depends on the pinning strength and defect density.

The broadening is definitely dynamic in origin, and there are two possibilities for the behavior which we observe. The first possibility is that the onset of broadening in the transverse width indicates a transition to an orientationally disordered phase and that the broadening of the radial width at a higher temperature is associated with the loss of translational order. In this case, the low-temperature phase is crystalline, the transition to an orientationally disordered phase occurs at $T_t(H)$, and a correlated flux fluid exists above $T_r(H)$.

The second possibility is that the transverse broadening is "lattice dynamical" in origin, associated with the same soft shear mode of the vortex lattice that would be involved in melting. This would imply that if much higher instrumental resolution were available, we would see wings of inelastic scattering on the sides of an elastic Bragg peak. The present (best available) resolution would convolve the elastic and inelastic scattering into a single broadened peak. In this case, we would be observing the effect of the inelastic scattering on the linewidth at T_t, and the lattice would not melt until the intrinsic radial width begins to develop.

Given the correlation between the onset of irreversibility in the isothermal scans and the abrupt onset of an intrinsic transverse width in the constant field scans, we believe that the first explanation is the correct one. We cannot entirely rule out the second; however, in either case we observe a correlated flux fluid, due to the non-negligible interactions of the crystal with the vortices. It is interesting to note that broadening in the radial and transverse widths, similar to what we have observed for this two-dimensional system, has also been observed in melting transitions in two-dimensional colloidal suspensions.[11]

IV. THE FLUX LINE LATTICE IN MAGNETIC ℜ123 SUPERCONDUCTORS

The coexistence of antiferromagnetism and superconductivity poses the question: What is the effect of an underlying magnetic order on the vortex lattice? The high-T_c compounds $DyBa_2Cu_3O_7$ and $ErBa_2Cu_3O_7$ are already known to have a very well-defined zero-field ordering of the rare-earth moments at low temperatures ($T_N \approx 1$ K) (Ref. 12) without significant detriment to the superconductivity. We have observed the flux line lattice in a 250 mg single crystal of $DyBa_2Cu_3O_7$, at 10 K in a 5 T applied field (see Fig. 6), well above any temperature where one would expect any effects from the ordering of the rare-earth sublattice. The 10 peak appears at $Q_{10}=0.0105$ Å^{-1}, which is expected for a vortex lattice that is close to triangular, as has been observed by Keimer *et al.*[13] in $YBa_2Cu_3O_7$.

At lower temperatures there are several possible interesting behaviors. Above the onset of long-range order, the enhanced susceptibility of the rare-earth moments would allow a variation of the rare-earth moment alignment that would decorate the vortices. Since the total magnetic flux must be quantized, the addition of the Dy magnetization M_{Dy} will then give a new momentum transfer for scattering from the vortex lattice

$$Q_{M10}=2\pi\sqrt{2\mu_0(H+M_{Dy})/\sqrt{3}\phi_0}. \quad (6)$$

The measured saturated Dy moment is approximately 7 μ_B, which implies that $\mu_0 M_{Dy} \approx 1$ T. In a 0.1 T applied field, we would then expect that the vortex density would increase by roughly a factor of 3 due to the saturated alignment of the Dy moments.

Below T_N, the Dy magnetization will be close to zero at modest applied fields, and so we would return to the original behavior for the flux lattice. However, another possible behavior below T_N could be observed by applying a field strong enough to put the Dy moments through a metamagnetic or spin-flop transition. If the sample has a nonzero demagnetization factor, there would then be coexistence of "paramagnetic" domains that have a net magnetization, with reflections as described by Eq. (6), and "antiferromagnetic" domains where there is no net magnetization, as described by Eq. (1).[14] Another possibility proposed by Buzdin *et al.* is the existence of two-quanta vortices in metamagnetic superconductors, which could occur if the applied field for the metamagnetic or spin-flop transition is near H_{c1}. In this regime, because of the spatial variation of the vortex field, the metamagnetic transition could be localized to a region near the vortex core and substantially affect the structure of the vortex. Work is in progress to experimentally explore these possibilities.

Extensive small angle neutron scattering experiments have been conducted on the vortex system in $YBa_2Cu_3O_7$ in a magnetic field range of $0.5\ T \leq H \leq 5\ T$, and with various orientations of the magnetic field with respect to the crystallographic axes. For H parallel to the c axis, the vortex lattice is oblique with two nearly equal lattice constants and an angle of 73° between primitive vectors. One principal axis of the vortex lattice coincides with the (110) direction of the crystal lattice. It is shown that this structure cannot be explained in the framework of a purely electrodynamic (London) model, and that it is intimately related to the in-plane anisotropy of the superconducting coherence length. When the field is inclined with respect to the c axis, the uniaxial anisotropy due to the layered crystal structure of $YBa_2Cu_3O_7$ becomes relevant. The interplay between the square in-plane anisotropy and the uniaxial anisotropy leads to both a continous structural transition and a reorientation of the vortex lattice as a function of inclination angle. For the largest inclination angles, the vortex lattice decomposes into independent chains.

I. INTRODUCTION

The vortex system in the cuprate superconductors has received a high level of attention mostly because of its novel phase behavior inferred from transport experiments at high temperatures and high magnetic fields. Small angle neutron scattering (SANS) is applicable in high magnetic fields and capable of measuring the relevant correlation lenghts of the vortex lattice. SANS is therefore very promising as a tool to further elucidate this behavior. However, since the signal intensity at high temperatures is very small, these experiments are difficult. Our approach has therefore been to first develop a thorough experimental description of the vortex system at low temperatures as a function of field strength and field orientation with respect to the crystallographic axes, before studying thermal effects in detail. We have found that the behavior of the vortex lattice is very rich even at low temperatures. In particular, our experiments indicate a close relation between the structure of the vortex lattice and the microscopic electronic structure of $YBa_2Cu_3O_7$. The following is a preliminary summary of these studies.

II. EXPERIMENTAL DETAILS

Our sample is a disk-shaped single crystal of $YBa_2Cu_3O_7$ of volume $\sim 2.5\ cm^3$ and mosaicity $\sim 1.5°$. The sample is too large to fit into a superconducting quantum interference device (SQUID) magnetometer, but small pieces cut off from samples prepared under identical conditions showed sharp superconducting transitions at ~93 K. The microstructure of these samples has been extensively characterized by transmission electron microscopy. Prominent microstructural features are μm sized Y_2BaCuO_5 inclusions with a total volume fraction ~10%, twin boundaries of average separation ~900 Å extending in the (110) or $(1\bar{1}0)$ crystallographic directions, and stacking faults perpendicular to the (001) direction. The latter two features occur on length scales comparable to intervortex distances and therefore give rise to background small angle scattering in the experimentally relevant range of scattering angles. This (temperature independent) background is comparable to or larger than the magnetic scattering from the vortex lattice and must be subtracted from the raw data.

All experiments were performed on the NG-3 and NG-7 SANS spectrometers at the Cold Neutron Research Facility of the National Institute of Standards and Technology. We mostly used the standard horizontal-field scattering geometry[1] with the neutron beam almost parallel to the magnetic field. Horizontal magnetic fields of 0.5 T or less were generated by an electromagnet, larger fields were achieved in a horizontal-field superconducting magnet. For some experiments we also used a vertical-field electromagnet.

The experimental geometry is illustrated in Fig. 1. The x (horizontal) axis in this figure is the magnetic field direction. The scattered neutrons are collected as a function of the coordinates y and z perpendicular to the field by an area detector behind the sample. During the experiment the angle be-

 0021-8979/94/76(10)/6778/6/$6.00 © 1994 American Institute of Physics

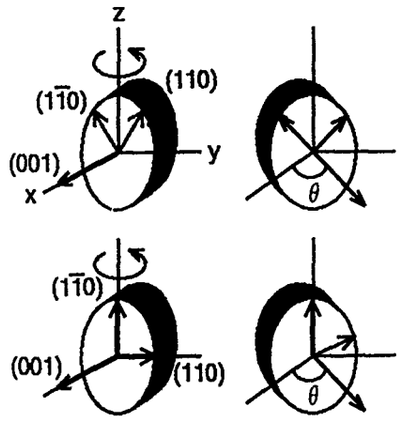

FIG. 1. Coordinate system illustrating the experimental geometry of our experiments. The x axis is the magnetic field direction. The neutron beam is almost parallel to the magnetic field (i.e., the scattering angle is small). The angle θ (rotation angle around $\hat{z}$ relative to the x axis) can be changed during the experiment. The orientation of the crystalline axes with respect to x,y,z is chosen by orienting the crystal outside the cryostat. Two different crystal orientations are shown: (top) (100) parallel to $\hat{z}$ and (bottom) (110) parallel to $\hat{z}$. The axes $\hat{y}$ and $\hat{z}$ perpendicular to the magnetic field are the horizontal and vertical axes in the diffraction patterns below.

tween the neutron beam and the magnetic field (i.e., the scattering angle ϑ) can be varied, and the sample can be turned around the vertical $\hat{z}$ axis without remounting the sample. We denote the angle between the crystalline (001) direction and the magnetic field by θ. The crystallographic direction coinciding with the $\hat{z}$ axis is selected by orienting the sample by x-ray and thermal neutron scattering outside the cryostat. We chose three different sample orientations: (i) (100) parallel to $\hat{z}$ (Fig. 1, top); (ii) (110) parallel to $\hat{z}$ (Fig. 1, bottom); and (iii) a low-symmetry crystallographic direction parallel to $\hat{z}$ (not shown). A uniform flux profile within the sample is achieved by field cooling the crystal for each crystal orientation. Typical counting times for high quality diffraction patterns are several hours.

In order to optimize both resolution and signal intensity, different spectrometer settings were chosen at each magnetic field. We mostly used neutrons of wavelengths 5 or 6 Å and wavelength spread $\Delta\lambda/\lambda=0.31$, source and sample apertures of 5 and 1.27 cm diameter, respectively, and source-to-sample distances between 11 and 13 m. A parameter of particular importance is the angular resolution in the plane of the area detector (yz plane in Fig. 1). At a given wavelength and source aperture (chosen to optimize the neutron flux on the sample), this quantity is primarily controlled by the distance between the sample and the detector.[2] For larger magnetic fields (corresponding to larger scattering angles), smaller sample-to-detector distances can be chosen, and the angular resolution is improved. On the other hand, because of the decreasing form factor the signal-to-background ratio becomes worse for larger fields. We found that data of optimal overall quality could be taken for $H=2$ T.

III. VORTEX LATTICE SYMMETRY AND ELECTRONIC STRUCTURE

Early SANS experiments on $YBa_2Cu_3O_7$ for $H=0.8$ T revealed a diffraction pattern with fourfold symmetry when

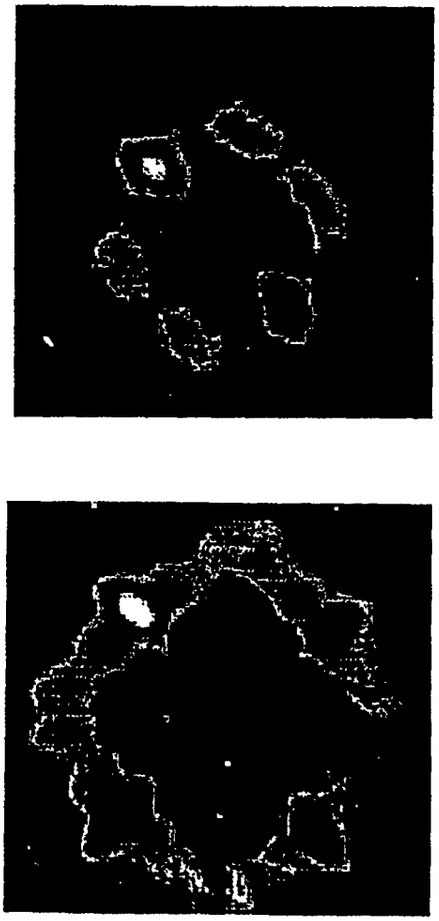

FIG. 2. Grey scale images of SANS diffraction patterns taken for (top) $H=0.5$ T, $\theta\sim10°$, obtained by rotating around a low-symmetry crystallographic direction and (bottom) $H=2$ T, $\theta=0$.

the magnetic field is aligned with the (001) crystalline direction.[3] This pattern was subsequently shown to consist of two sixfold symmetric patterns with 90° relative orientation.[4] However, the angular resolution of these patterns was not sufficient to determine the structure of the vortex lattice for this field orientation in detail. We have now used the improved angular resolution achievable in higher magnetic fields to resolve this issue definitively. The bottom panel of Fig. 2 shows that a total of 16 weak and 4 strong Bragg reflections can be resolved for fields of 2 T and above. (Note that all patterns shown here are for ϑ fixed. Since by Bragg's law each reflection corresponds to a different ϑ, not all of the 20 spots appear in a single pattern. The remaining spots can be moved into the resolution volume by adjusting ϑ appropriately.)

The real-space lattice corresponding to this diffraction pattern, shown in Fig. 3, can be regarded as intermediate between triangular (with an angle of $\beta=60°$ between primitive vectors) and square (corresponding to $\beta=90°$). In a high resolution measurement at $H=2$ T we obtained $\beta=(73\pm1)°$. We also found that the lattice constants differ by $(5\pm5)\%$; the unit cell area satisfies the flux quantization rule within the experimental accuracy. We can therefore not distinguish

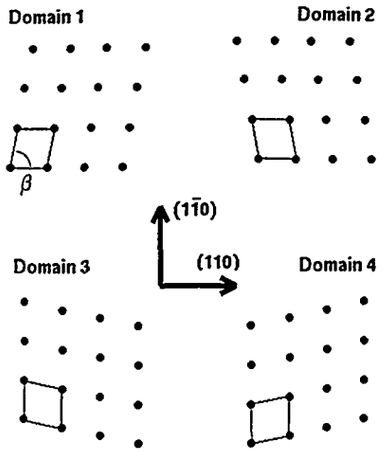

FIG. 3. Real-space structures corresponding to the diffraction patterns of Fig. 2. The top pattern of that figure is taken under conditions in which only two of the domains are populated (1 and 2, or 3 and 4). In the bottom pattern all four domains are populated.

experimentally between oblique (unequal lattice constants, space group $p2$) or rectangular (equal lattice constants, space group $c2mm$) vortex lattice symmetry. As the figure indicates, four domains with different orientations of the unit cell are observed. One of the nearest-neighbor directions of the vortex lattice coincides with either the (110) or the (1$\bar{1}$0) direction of the crystal lattice. Superposition of the diffraction patterns of these four domains results in the experimentally observed pattern of Fig. 2; the four strong reflections originate from two domains, the 16 weak reflections from one domain. A deconvolution of the patterns for $H=0.5$ T and $H=5$ T which takes the appropriate spectrometer resolution into account yields the same value for β. Note that with the spectrometer settings that had to be chosen for $H=0.5$ T two of the weak spots could not be resolved completely (Fig. 2, top).

When H is precisely aligned with the c axis, these four domains are degenerate and occupy equal fractions of the sample volume. However, the degeneracy between the domains is lifted even by a subtle inclination of the field with respect to the c axis. Tilting often favors two of the domains over the remaining two, as shown in Fig. 2. The mechanism for creation of this domain imbalance will be discussed in the next section.

The oblique structure we observe is manifestly different from the triangular lattice expected when the vortices interact purely electrodynamically. We have therefore evaluated the Gibbs free energies of vortex lattices with different β, taking the nonzero extent of the vortex core into account. In the London approximation, the Gibbs free energy density can be written as[5]

$$G=\frac{B^2}{8\pi}\left(\sum_Q \frac{1}{1+\lambda^2 Q^2}\right)-\frac{HB}{4\pi}, \tag{1}$$

where $\lambda\sim1500$ Å is the penetration depth, B is the magnetic induction, and the sum runs over all reciprocal lattice vectors Q. The finite extent of the vortex core is approximated by a circular "hard core" cutoff $Q_{max}=2\pi/\xi$, where $\xi\sim15$ Å is the in-plane coherence length. At each applied field H and for each β the magnetic induction, B, is computed by numerically evaluating $\partial G/\partial B=0$. While at low magnetic fields our calculation is insensitive to the size of the vortex core and reproduces the well-known free energy minimum at $\beta=60°$, $G(\beta)$ becomes extremely sensitive to the core cutoff in fields of several tesla. Typical numerical data are shown in Fig. 4. This means that the structure of the vortex core begins to have a significant influence on the structure of the vortex lattice in the field regime investigated in our experiments. The shape of the vortex core and the behavior of the superconducting order parameter near the core reflect the underly-

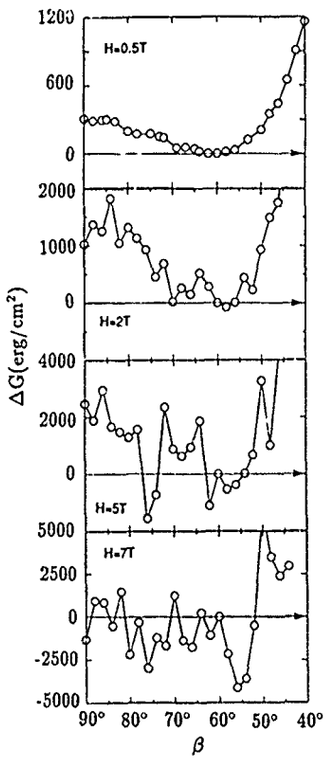

FIG. 4. Numerically computed Gibbs free energy density of a vortex lattice with space group $c2mm$ and angle β between primitive vectors (Fig. 3), relative to the triangular lattice ($\beta=60°$). The calculations are based on Eq. (1) with $\lambda=1500$ Å and $\xi=16$ Å. The numerical errors are much smaller than the symbol size.

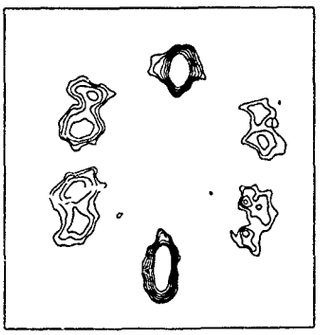

FIG. 5 Contour plot of SANS pattern for $H=2$ T, $\theta=20°$, obtained by rotating around (110).

ing microscopic electronic structure of the superconductor, in particular the spatial variation of the energy gap.

The link between the microscopic electronic structure and the mesoscopic structure of the vortex lattice is provided by the gap equation in a magnetic field. Even for an isotropic Bardeen–Cooper–Schrieffer (BCS) superconductor this equation is difficult to solve at a general magnetic field. Additional difficulties arise in the cuprates because the functional form of the gap equation is still under debate. However, as first shown by Abrikosov,[6] the equations simplify significantly near the upper critical field, where the magnetic induction is almost uniform. While for isotropic superconductors the equilibrium vortex lattice structure is the triangular lattice near H_{c2},[7] a $c2mm$ structure of the type we observe here has been observed before in the cubic superconductor Nb,[8] when the field is oriented in a fourfold crystallographic direction. This observation was explained theoretically by Takanaka,[9] who solved the gap equation of a superconductor with a cubic Fermi surface and found that in general structures of $c2mm$ symmetry have lower free energies than the triangular lattice. The angle β between primitive vectors depends on the degree of Fermi surface anisotropy through the parameter $\langle e^{i4\varphi}\rangle$, where φ is the azimuthal angle in the yz plane perpendicular to the magnetic field, and the brackets denote an average on the Fermi surface. We have parametrized the Fermi surface extracted from photoemission experiments[10] by two harmonics invariant under the point symmetry of the lattice

$$E_F(\varphi)=E_{F0}+E_{F1}\sin^2\varphi\cos^2\varphi, \tag{2}$$

with $E_{F1}\approx E_{F2}$, and obtain $\langle e^{i4\varphi}\rangle\approx E_{F1}/16E_{F0}$. According to the numerical calculations of Ref. 9, this value of $\langle e^{i4\varphi}\rangle$ corresponds to $\beta=63°$, much closer to 60° than the angle we observe. The origin of this discrepancy is likely to be an energy gap anisotropy contributed by the pairing interaction in the cuprates. It is already known that significant modifications to the standard gap equation are needed to account for the large directional variation of the energy gap observed in photoemission experiments on $Bi_2Sr_2CaCu_2O_{8+\delta}$.[11] Another possible origin of the quantitative discrepancy between theory and our observations is an in-plane penetration depth anisotropy, which various authors have determined to be between ~1.1 (Ref. 12) and ~1.5.[13] While a quantitative explanation of our data thus has to await more elaborate calculations based on realistic gap equations, it is remarkable that the symmetry of the vortex lattice is correctly predicted by an analysis whose only ingredient is the fourfold symmetry of the vortex core.

A more extensive treatment of anisotropic vortex lattices in type-II superconductors with a small ratio of penetration depth to coherence length has been given by Teichler,[14] who considered a cubic superconductor with an anisotropic pairing interaction. The resulting gap anisotropy leads to an attractive interaction between the vortices, in addition to the electrodynamic repulsion. The magnitude of the attractive interaction is largest in the direction of minimum energy gap, which is the (110) direction in $Bi_2Sr_2CaCu_2O_{8+\delta}$(Ref. 11) and presumably also in $YBa_2Cu_3O_7$. Teichler's analysis will likely need substantial modifications in the case of $YBa_2Cu_3O_7$. In particular, the energy gap in the (110) direction is extremely small and possibly zero, which may lead to a long range interaction between vortices. Nevertheless, the directional variation of the energy gap in the CuO_2 planes is a plausible explanation for the observed coupling between vortex lattice and crystal lattice orientations.

We[4] and others[3] had previously attributed this unique orientation of the vortex lattice to pinning by twin boundaries. However, the persistence of this orientation even as the field is inclined by up to 40° with respect to the twin boundaries is difficult to reconcile with this model. Moreover, the persistence of the same structure over an order of magnitude in magnetic field which we have now observed argues against a significant influence of twin boundaries on the vortex lattice structure and orientation. (Whereas at $H=0.5$ T the intervortex distance is comparable to the average twin boundary spacing, at $H=5$ T it is almost five times smaller.)

Since near H_{c1} the size of the vortex core is negligible compared to the intervortex distance, vortex core effects cannot play a role in determining the vortex lattice structure and orientation in very low magnetic fields. Indeed, Bitter decoration experiments near H_{c1} have revealed the expected triangular lattice with an orientation unrelated to any crystalline high-symmetry direction.[12,15] We thus expect a crossover between an orientationally degenerate triangular lattice and the oblique structure with unique orientation in an intermediate field range. There are some indications that this crossover actually occurs at a very low field, as expected for a large gap anisotropy: For $B\sim0.0065$ T, close to the largest field for which the Bitter decoration technique is applicable, Dolan *et al.*[13] observed a structure that is completely consistent with the one we observed (Fig. 3), except that $\beta=(65°\pm5°)$. Note that these measurements were taken in untwinned sections of $YBa_2Cu_3O_7$ crystals, further supporting our argument for an intrinsic origin of the coupling between the crystal lattice and vortex lattice. The field independence of β in the field range we have investigated suggests that β has already saturated at its H_{c2} value.

IV. TILT-INDUCED STRUCTURAL TRANSITION

We observe a potentially related structural transition as the magnetic field is inclined by an angle θ with respect to the c axis. This transition is superposed by an overall distortion of the vortex lattice due to the quasi two dimensionality of the electronic structure.[4,16] For inclination angles up to $\theta\sim60°$, the structure of the vortex lattice remains dominated by interactions within the CuO_2 sheets. The vortex lattice for small θ can thus be thought of as the projection of an isotropic two-dimensional lattice onto the field direction. This effect gives rise to an elliptical distortion of the vortex lattice; the semimajor axis of the ellipse coincides with $\hat{H}\times\hat{c}$, and the aspect ratio is $\cos\theta$ for small θ. (As three-dimensional interactions become relevant for larger θ, the aspect ratio becomes $\sqrt{\epsilon^2\sin^2\theta+\cos^2\theta}$, where $\epsilon\sim0.2$ is the penetration depth anisotropy.)

In addition to this overall anisotropy, we observe a continuous structural transition of the in-plane isotropic lattice as a function of θ: The angle $\beta=73°$ observed for $\theta\sim0$ de-

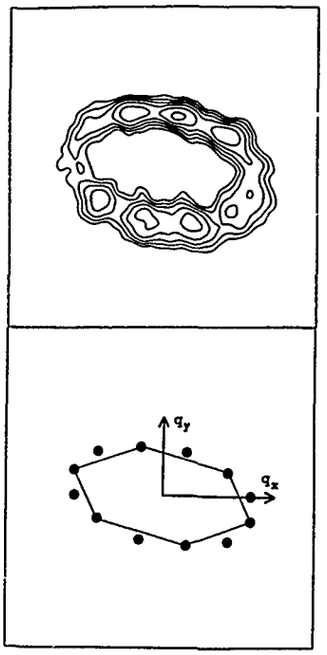

FIG. 6. (Top) contour plot of SANS pattern for $H=0.5$ T, $\theta=60°$, obtained by rotating around a low-symmetry crystallographic direction. (Bottom) projection of two isotropic triangular lattices in the CuO_2 layers onto the field direction for the same geometry. The lattices are oriented such that nearest-neighbor pairs point in either the (110) or the $(1\bar{1}0)$ direction. One of these domains is highlighted.

creases continuously and reaches $\beta=60°$, corresponding to the triangular lattice, for $\theta\sim50°$ (Fig. 6). The nearest-neighbor direction remains the in-plane (110) direction.

While the structural transition occurs for all three experimental geometries discussed in Sec. I, the domain structure of the observed lattice depends on the crystallographic direction chosen as the axis of rotation. If the field inclination is achieved by rotating around (100), all four domains of Fig. 3 continue to be populated. However, once β has reached 60°, domains 1 and 2, as well as domains 3 and 4, become identical. If the rotation axis is (110), a two-domain lattice is observed (Fig. 5). For the two observed domains, the projection of $(1\bar{1}0)$ is parallel to the direction $\hat{H}\times(\hat{H}\times\hat{c})$, i.e., the y axis in Fig. 1. [Note that the diffraction pattern can be obtained from the real lattice by a 90° rotation and rescaling, and that because of twinning (110) and $(1\bar{1}0)$ are superposed in our crystal.] This is the nearest-neighbor direction favored by the uniaxial anisotropy reflecting the quasi two-dimensional electronic structure.[17] The uniaxial anisotropy can thus lift the degeneracy between the domains.

We have also chosen an experimental geometry in which the inclination is achieved by rotating around a low-symmetry crystallographic direction such that (110) and $(1\bar{1}0)$ subtend identical angles with the rotation axis.[4] In this case we also observe a two-domain lattice for small θ, although the uniaxial anisotropy does not distinguish between the two domain pairs. However, the vortices in the two domain pairs subtend different angles with respect to both sets of twin boundaries.[4] Pinning interactions between vortices and twin boundaries favor the pair of domains subtending the smaller angle with respect to the twin boundaries, because the vortices have to bend less in order to gain advantage of the pinning energy. Although, as discussed above, the structure and orientation of the vortex lattice are determined by electronic energies that are presumably much larger than pinning energies, pinning effects appear to provide enough energy to select between otherwise degenerate domains.

It may not be coincidental that the triangular structure observed in inclined fields is just the structure expected in the London limit, since the in-plane vortex lattice is only sensitive to a reduced field component $H\cos\theta$ perpendicular to the CuO_2 sheets. Moreover, for large θ the effective core size shrinks because of the reduced coherence length in the c-axis direction. Electrodynamic effects should thus become more relevant for larger inclinations. Detailed numerical calculations to test these ideas are currently underway.

V. TILT-INDUCED REORIENTATION AND VORTEX CHAIN STATE

In agreement with this general scenario, we observe a reorientation of the vortex lattice into the unique orientation predicted by the anisotropic London model when the inclination is achieved by rotating around (100). In this case the orientation favored by the in-plane energy gap anisotropy is different from the orientation favored by the anisotropic electrodynamic interactions between the vortices. For small θ the electrodynamic energies favoring the $\hat{H}\times(\hat{H}\times\hat{c})$ direction as the nearest-neighbor direction are small,[17] and the in-plane anisotropy determines the vortex lattice orientation. As the shielding currents around the vortices begin to flow in the c-axis direction for large θ, in-plane anisotropy effects diminish and the electrodynamic effects associated with the uniaxial penetration depth anisotropy begin to dominate. The crossover between these two orientations is gradual and begins at $\theta\sim70°$ in this geometry, coming to completion for $\theta\sim80°$.

In the large-θ orientation, the vortex lattice can be considered as a collection of chains with locked periodicity extending in the $\hat{H}\times(\hat{H}\times\hat{c})$ direction. Because of the penetration depth anisotropy, the distance between the chains is much larger than the nearest-neighbor distance within the chains. Based on calculations in the London limit, an extremely small modulus for shear in the chain direction has been predicted,[18] thus causing a decoupling of the chains even for very weak pinning disorder or thermal fluctuations. This vortex chain state has indeed been observed in Bitter decoration experiments in very low magnetic fields.[19] We have observed the same instability in fields of 0.5 and 2 T. Its experimental signature is a continuous broadening of all Bragg reflections not exclusively associated with the distance between the chains. For $\theta=80°$ only the two reflections with Bragg planes parallel to the chain direction remain sharp and observable. Note that all of our diffraction patterns were taken after field cooling the sample to low temperatures. The disordered vortex chain state is thus presumably frozen in at high temperatures.

We have carefully measured the width of the "rocking curves" of the vortex chain state reflections at $H=0.3$ T, using a vertical-field electromagnet. This measurement pro-

vides direct information about the "straightness" of the vortices in the bulk of the sample. A temperature dependence of the rocking curve could thus herald dimensional crossover effects or thermal wandering of three-dimensional vortices. We find that the rocking curves, as well as the width of the reflections perpendicular to the field direction, remain resolution limited up to at least $T=80$ K. The signal-to-background ratio became too low to extract reliable information from measurements taken at higher temperatures. We plan to repeat these measurements in higher magnetic fields, where we expect the conditions to be more favorable

VI. CONCLUSIONS

In conclusion, we have demonstrated an unanticipated connection between the vortex lattice structure in magnetic fields of order 1 T and the microscopic electronic structure of $YBa_2Cu_3O_7$. As a result of the directional variation of the energy gap in the CuO_2 plane, the symmetry and orientation of the vortex lattice is coupled to the underlying crystal lattice when the field is applied in the c-axis direction. This coupling diminishes gradually as the field is inclined with respect to the c axis. As a function of increasing inclination angle we observe a two-step transition of the vortex lattice into the symmetry and orientation predicted by the London model with uniaxial anisotropy.

A flux-line lattice (FLL) was observed in a single crystal of $Bi_{2.15}Sr_{1.95}CaCu_2O_{8+x}$ (BSCCO) using small-angle neutron scattering methods. The sample has a superconducting transition at 85 K. The flux-line lattice is observed to melt. evidenced by the rapid disappearance of diffracted intensity as the temperature is increased above a field-dependent melting temperature. Diffracted intensity due to the vortex lattice also falls off as the applied field is increased. It is believed that this is a manifestation of the transition of the three-dimensional flux lines into two-dimensional pancake vortices. The Bragg intensity of the FLL peak is inversely proportional to the fourth power of the London penetration depth (λ_L). Hence, the temperature (T) dependence of the order parameter can be measured quite accurately from the intensity of the Bragg spots at different temperatures. In BSCCO with an applied field of 50 mT, the measured T dependence appears linear. The low-T behavior is of great interest for an understanding of the underlying mechanism for superconductivity in these materials.

INTRODUCTION

In type-*I* superconductors, an applied field is completely screened till the field strength exceeds the critical field. A higher field causes the superconductor to become normal, that is, nonsuperconducting. In 1957, Abrikosov[1] in his theory of type-*II* superconductors predicted the existence of the "mixed" state, where flux carried by quantized flux lines or vortices penetrate the bulk material, causing parts of the superconducting material to become normal. This occurs for applied fields (B) such that $H_{c1}<B<H_{c2}$, where H_{c1} and H_{c2} are the lower and upper critical fields, respectively.

The interaction between vortices is repulsive, hence vortices form a lattice which maintains the maximum distance between them. Each vortex line contains a total flux equal to the flux quantum $\Phi_0=hc/2e$, where h is Planck's constant, c is the speed of light, and e the charge of an electron. Hence the total number of flux lines in the sample is determined by the external applied field.

The arrangement of flux lines was first observed in Bitter patterns or decoration experiments. When a thin layer of finely ground ferromagnetic particles are deposited on the surface of a superconductor which is then cooled in a field, the magnetic dust settles at the normal cores of the vortex. The resulting decoration reflects the underlying field distribution. Extremely clear decorations have been seen by a number of groups, both in the conventional as well as in the high-T_c materials. It is also the method by which defects in vortex lattices were first observed. More recently, scanning tunneling microscopes equipped with a magnetic tip have been used to look at the field distribution in conventional superconductors. The most serious limitation of both these techniques is that they probe only the surface. Also, the fields used to get a good decoration must be quite low to distinguish between the cores. To their advantage, samples can be quite small. Invariably, more perfect samples can be obtained when large size is not required.

The properties of the flux lattice as a function of field and temperature are important both for a better understanding of the nature of the interaction causing pair formation in high-T_c superconductors and also for applications of the material in devices. Using small-angle neutron scattering (SANS), the temperature (T) dependence of the London depth is vital information that can be measured. In the London model, the intensity of the Bragg peaks is proportional to the inverse fourth power of the London penetration depth; because of this strong dependence, this length can be accurately determined. Of all the high-T_c superconductors, $YBa_2Cu_3O_7$ (YBCO) is of particular interest in applications since the large pinning, due to twin plane defects, leads to

 0021-8979/94/76(10)/6784/4/$6.00 © 1994 American Institute of Physics

high critical currents. However, the transition mechanism in high-T_c superconductors is a topic of ongoing debate and the high density of the twin plane defects in the samples of YBCO that have been studied cast some doubt on whether or not the observed temperature dependence is intrinsic or due to the defects combined with the fact that the temperatures involved are quite high and thermal effects can be substantial. Hence, measuring the temperature dependence of the order parameter in a material with relatively few defects, such as our sample of $Bi_{2.15}Sr_{1.95}CaCu_2O_{8+x}$ (BSCCO), is quite important.

In addition, it has been clear for some time that YBCO and BSCCO behave quite differently. BSCCO is much more anisotropic than YBCO. A variety of vortex structures that have been suggested for high-T_c superconductors in general vortex lattice melting with increase in temperature and $3d$-$2d$ dissociation have been invoked to explain experimental data. Although this is expected in YBCO as well, the effects in BSCCO were larger and occurred at lower fields and temperatures because of its larger anisotropy. It was apparent that the B-T phase diagram for BSCCO was not dull.

The anisotropy of the high-T_c superconductors is, in general, nominally uniaxial since the a-b (basal plane) anisotropy is fairly small and the c axis is considerably larger. In BSCCO, the crystal structure is nearly tetragonal with the a/b ratio close to unity and $c \approx 5.5a$. Consequently, the high symmetry configuration for the observation of the vortex lattice is with the applied field parallel to the crystallographic c axis of the crystal. The information about the ratio of the in-plane effective mass to that out of plane is obtained from FLL's in the geometry where the applied field is at a large angle to the c axis of the crystal.

In the last few years, we have carried out SANS experiments in the high-T_c superconductors YBCO and BSCCO. In this article we discuss the measurements that we have made of the flux lattice in single-crystal samples of BSCCO both with the field parallel to the c axis and with the field at an angle of up to 15° from the c axis. We also discuss the experimental technique and the information that it gives in some detail.

EXPERIMENT

Small-angle neutron scattering experiments were first suggested by deGennes and Matricon.[2] (Since neutrons have a magnetic moment, they interact with the field modulation caused by an array of flux lines.) Shortly thereafter, a Bragg diffraction peak from a flux-line lattice corresponding to the predicted triangular arrangement was observed by Cribier and co-workers[3] in a single-crystal sample of niobium on which a magnetic field was applied. Since then, extensive measurements have been made in Jülich[4] and Oak Ridge,[5] on niobium as well as other conventional superconductors, probing the details of the lattice structure, the effect of defects, the exact nature of the form factor and of the temperature-dependent order parameter.

The d spacing, d, of the first-order reflection of a triangular isotropic lattice, determined solely by the applied field and the flux quantum, is given by

$$d = \left(\sqrt{\frac{2}{3}} \frac{\Phi_0}{B} \right)^{1/2}, \tag{1}$$

where B is the applied field and Φ_0 is the flux quantum. (The intervortex spacing, $a, = d/\cos 30.$) For an applied field of 100 mT, this distance is approximately 1350 Å, corresponding to a q value of 0.0047 $Å^{-1}$. Hence, the angles at which this scattering can be observed are small. The vortex is a line of magnetic flux; the lateral extent of the field distribution is determined by the London penetration depth, λ_L. The intensity of a diffraction peak, I_{hk}, is given by

$$\frac{I_{hk}}{I_0} = 2\pi \left(\frac{\mu}{4} \right)^2 \frac{1}{q_{hk}} \left(\frac{V\lambda_n^2}{\phi_0^2} \right)^2 \left(\frac{B}{1+q_{hk}^2\lambda_L^2} \right)^2, \tag{2}$$

where I_0 is the incident neutron flux, μ the neutron magnetic moment in Bohr magnetons ($\mu = 1.91$), V the sample volume, λ_n the neutron wavelength, λ_L the London penetration depth, B is the applied magnetic field, and Φ_0 is the flux quantum.

The London depth is approximately the half-width at half maximum of the field distribution of a single flux line, hence there is less contrast for larger λ_L. For niobium, $\lambda_L \approx 400$ Å, whereas for the high T_c materials, it is at least three times larger. The signal to be measured is therefore lower by approximately two orders of magnitude. Also, the signal for the first-order reflections, barring other complications, is relatively independent of the applied field except for a geometrical $1/q$ factor. On the one hand, there is less contrast between the peak and valley at a higher field due to larger number of flux lines; on the other, the number of scatterers is higher which balances the equation. However, there is considerable gain in utilizing a larger field in order to get away from the incident beam and the metallurgical scattering as much as possible in order to increase the signal to noise ratio.

In order to obtain the integrated intensity, the rocking curve (or mosaic width), $\Delta\theta$, of the Bragg scattering must be measured. This mosaic is a measure of the straightness of the flux lines along the applied field direction or a measure of the length over which they remain straight. If it is assumed that the mosaic is entirely due to finite sample size (i.e., flux-line length), the lower limit on this length is determined. A scattering object of finite size leads to an extended object in reciprocal space. If it is assumed that the flux lines are straight over length l, the Fourier width on reciprocal space is given by

$$\left(\frac{2\pi}{l} \right) \Big/ q = \Delta\theta, \quad \text{hence} \quad l = \frac{d}{\Delta\theta}. \tag{3}$$

Because the measured rocking width convolutes this length effect with any meandering of the flux lines away from the field direction, l is a lower limit on the length of the lines.

Data were taken on the small-angle spectrometer at Risø National Laboratory using an incident neutron wavelength of nearly 20 Å and a $\delta\lambda/\lambda$ of 18%. The lowest applied field was 200 mT.

The sample used for most of these measurements was a platelike single crystal weighing 180 mg. This sample had a (crystal) mosaic width of approximately 0.5°. Other samples were also studied briefly thus far; all had a nominal compo-

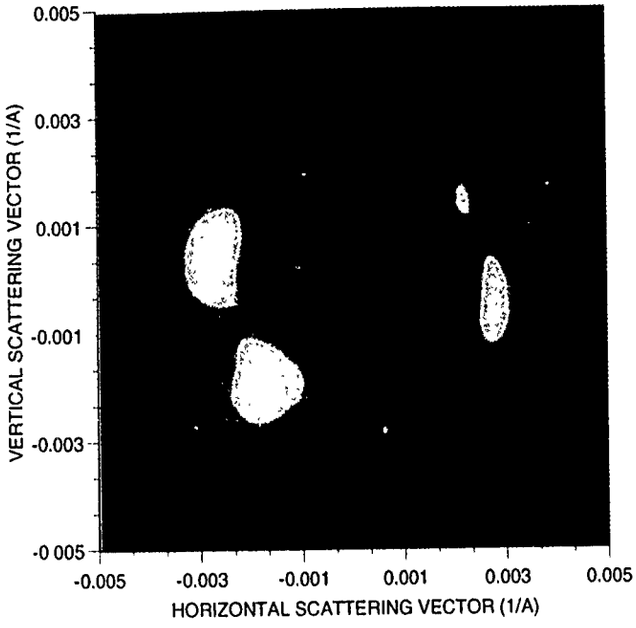

FIG. 1. The flux-lattice signal seen in a difference measurement between field-cooled (40 mT) and zero-field-cooled data.

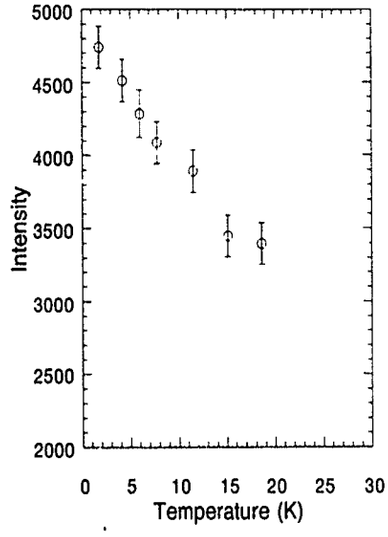

FIG. 2. The temperature dependence of the order parameter at low temperature.

sition given by $Bi_{2.15}Sr_{1.95}CaCu_2O_{8+x}$. The samples appear to be untwinned; front and back faces had the same relative orientation of the a axis in x-ray characterizations.

RESULTS AND DISCUSSION

At the lowest temperatures, with the applied field (50 mT) parallel to the c axis of the sample, the flux-line lattice was seen[6] in the difference signal between field-cooled and zero-field-cooled runs, shown in Fig. 1. The lattice has six-fold symmetry and is aligned with the crystalline b axis in all the samples measured. It is likely that the samples are untwinned since the flux lattice consists of only one domain. (A twinned crystal would give rise to a second domain rotated by 90°.) The mosaic width of this lattice was approximately 1.2(2)°, giving a minimum flux-line length of approximately 10 μm. From the integrated intensity, the London penetration depth obtained for BSCCO at the lowest temperatures is approximately 1800 Å, not significantly different from YBCO.

As the applied field was increased, the signal intensity decreased faster than expected from the $(1/q)$ factor. The signal intensity began to decrease as the field was raised above 50 mT and for fields above 100 mT, no flux lattice was observed at all. We believe this to be a manifestation of the dissociation of three-dimensional flux lines into $2d$ pancakes. This was also observed in μSR measurements[7] on samples prepared by the same method. The $3d$-$2d$ transition occurs at the same field that appears to be independent of temperature.

The intensity, which is inversely proportional to the fourth power of the London penetration depth, decreases linearly at low temperatures in BSCCO, as shown in Fig. 2. This is unlike conventional s-wave superconductors where intensity changes very little for T less than about $T_c/3$. Also, there appears to be no anisotropy within the measured errors in the plane. That is, the T dependence of the Bragg peaks aligned along b compared to the peaks 60° from b show no significant difference. However, it must be emphasized that the linear slope at low temperatures does not imply d-wave superconductivity, the interpretation of the T dependence is still an open question.

At a temperature that is dependent on the applied magnetic field, we observe the rapid decrease of the intensity associated with melting of the flux lattice. The melting occurs at the same temperature at which finite resistance appears within the the superconducting state. The melting line in the B-T phase diagram appears to coincide with measurements of the irreversibility line. The schematic B-T phase diagram from neutron scattering and magnetic measurements is shown in Fig. 3. The solid line in the figure is found by using the relation[8]

$$B_{3D}(T_m) \approx \frac{1}{\{[4\sqrt{2}-1)+1]^2 \pi \mu_0^2\}} \left[\frac{\phi_0 c_L^4}{[\gamma k_B T_c \lambda_{ab}^2(0)]^2}\right] \times \left[\frac{1-(T_m/T_c)^n}{T_m/T_c}\right]^2, \quad (4)$$

with the Lindemann melting parameter, $c_L=0.2$, the mass ratio, $\gamma^2=140^2$, the in-plane London penetration depth at zero temperature, $\lambda_{ab}(0)=1800$ Å, and $n=3.3$. This line is in good agreement with the observation of flux-lattice melting observed here as well as by the muon spin rotation measurements. It is reasonable to assume that this decrease in intensity represents the melting of the 3-d lattice. Careful analyses show no broadening or any other indication that the flux line is approaching the melting temperature. We do not see any signal at all above T_m even though a ring of scattering is expected, presumably because the disordered flux liquid is not a strong enough scatterer to give a measurable count. The coherent Bragg signal could not be seen in the raw data but only in a difference as stated earlier. Hence it is not unex-

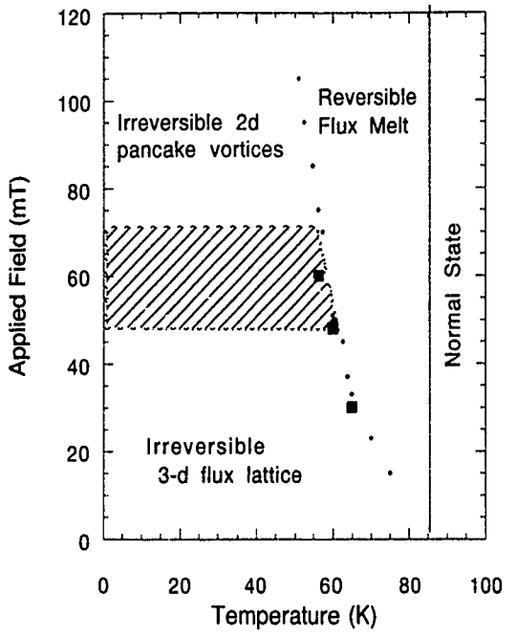

FIG. 3. The B-T phase diagram for BSCCO.

pected that a signal from a disordered liquid having the same total scattering contrast would be beyond what can be measured here in a reasonable time. Since the melting is associated with finite resistance, applications may not have advantages in using BSCCO. Materials with lower anisotropies and stronger pinning will probably make better candidates for devices.

In our earlier work[9] on YBCO, the effects of anisotropy were clearly seen as the angle between the applied field and c axis of the crystal, Θ, was increased and the effective mass ratio was determined. In BSCCO, an effort to measure this ratio resulted in very odd behavior. In this system, when the angle Θ was increased, the signal from the vortex lattice dropped sharply at a moderate applied field of 30 mT. In fact, by the time Θ was increased to 15°, no measurable scattering was observed. The loss of intensity could arise due to melting at a lower temperature when Θ is increased, but this is inconsistent with the μSR data[7] in which a three-dimensional lattice is clearly seen for larger angles at the same field. It is possible that the c axis is a preferred direction for the flux line (in a manner similar to YBCO, although twin plane defects are thought to cause the effect in that compound), perhaps because the currents prefer to flow in the a-b plane. To test this hypothesis, we searched for the scattering signal with the q vector perpendicular to the c axis but did not observe any. (NOTE: In the latter configuration, the field direction was Θ from the incident neutron direction and the c axis was now parallel to the incident neutrons.) More experiments are planned in order to elucidate this matter. Clearly, much more remains to be learned about these superconducting systems.

Neutron diffraction from the vortex lattice in the heavy fermion superconductor UPt_3 (invited) (abstract)

The heavy fermion superconductor UPt_3 is thought to have a d-wave pairing ground state. The principal experimental evidence for this consists of the anisotropy of the power-law behavior observed in transverse ultrasound and μ^+ SR measurements. The observation of a complex phase diagram in the superconducting state in ultrasound, torsional oscillator, and specific heat measurements may be a further indication of an unconventional pairing state. Theoretical investigations suggest the possibility of vortex lattices that are unconventional in their symmetry, their quantization, or the structure of their composite vortex cores. Transitions between such exotic vortex lattices are in principle allowed and could explain the observed features at $\mathbf{H}\approx 0.6\, H_{c2}$ (for $H\|\hat{c}$) and $H\approx 0.3 H_{c2}$ (for $\mathbf{H}\perp\hat{c}$). Neutron diffraction is an ideal bulk probe of the microscopic properties of the vortex lattice. We have studied the vortex lattice with $\mathbf{H}\perp\hat{c}$ and $T\approx 50$ mK in the field range $0.75<H<10$ kG. The structure of the vortex lattice and the quantization of the vortices, in addition to the London penetration depth, λ_L, the coherence length, ξ, and the effective mass anisotropy are all well determined by our measurements.[1] The lattice is oblique hexagonal with conventional quantization. Its anisotropy can be explained by considering a combination of Fermi surface and gap anisotropy. However, the lattice does not appear to change near the transition between superconducting phases identified by other techniques.

Small angle neutron scattering from the vortex lattice in $2H$-$NbSe_2$ (invited) (abstract)

We report on small angle neutron scattering studies of the flux-line lattice in single crystal 2H-$NbSe_2$. For fields inclined with respect to the c axis, we find distortions and form factors consistent with Ginzburg–Landau corrections to the London equations with a mass anisotropy $\Gamma=10.1\pm0.9$. The flux lattice orientation, however, remains pinned to the crystal lattice for all tilts studied, in disagreement with the orientation defined by anisotropic London theory.[1] For fields below 2 kG parallel to the c axis, the peaks are no longer resolution limited. The correlation lengths extracted are history dependent, and show that the lattice is annealed when a current greater than the critical current is applied. This occurs both when a direct transport current is used, or an induced current in a zero field cooled experiment. The annealing is seen in both the transverse and longitudinal correlation lengths, and calls into question the relationship between the Larkin–Ovchinnikov correlation length and the measured critical currents in this system.

Giant magnetoresistance in sputtered Cr-Fe heterogeneous alloy films

K. Takanashi, T. Sugawara, K. Hono, and H. Fujimori
Institute for Materials Research, Tohoku University Sendai 980-77, Japan

We have observed large negative magnetoresistance (MR) in Cr-Fe heterogeneous alloy films sputter deposited on heated substrates. The largest MR, 37.3% at 4.2 K and 14 T, appears around the Fe concentration of 20 at. %. While a large substrate temperature dependence of MR is observed when the Fe concentration is lower than 20 at. %, MR does not vary noticeably with changes in the substrate temperature when Fe concentration exceeds 20 at. %.

I. INTRODUCTION

Recently, giant magnetoresistance (GMR) in heterogeneous alloy films such as Cu-Co,[1,2] Ag-Co,[3,4] and Ag-Fe,[4-6] in which ferromagnetic particles of nanometer size are homogeneously distributed in the nonmagnetic matrix, has been attracting much interest. GMR was found in multilayered Cr/Fe for the first time;[7,8] however it has never been reported in Cr-Fe heterogeneous alloys. This is the first report on GMR behavior in sputtered Cr-Fe heterogeneous alloy films.

Cr-Fe has an isostructure two phase region below 475 °C but the solubility limit of Fe in Cr is considerable. The σ phase is present in the temperature range from 475 to 821 °C, which makes high temperature annealing for inducing phase separation without an appearance of σ phase difficult. Above 821 °C, Cr and Fe are entirely miscible.[9] These features are in contrast to the Cu-Co, Ag-Co, and Ag-Fe systems, in which GMR has been reported in the heterogeneous structure. In such alloy systems, the heterogeneous structure can been obtained upon annealing nonequilibrium solid solutions prepared by sputtering or rapid quenching. In the case of Cr-Fe, however, post-deposition annealing is not appropriate for phase separation because of the slow kinetics. Hence, in the present study, we have deposited Cr-Fe alloy films at elevated temperatures. Sputter deposition on heated substrates is expected to promote phase separation due to surface diffusion which is many orders of magnitude faster than the volume diffusion that would otherwise control the kinetics of the post-deposition annealing.[10]

II. EXPERIMENT

Cr-Fe heterogeneous alloy films were prepared by the rf sputtering method on Si substrates heated up to 200 °C. For comparison, Cr-Fe homogeneous alloy films were also prepared by rf sputtering on Si substrates cooled by liquid nitrogen. The composition of the alloy films was varied from 0 to 40 at. % Fe by the number of Fe sheets (10×10 mm^2) on a Cr target (ϕ100 mm). The composition of the films was determined by inductively coupled plasma (ICP) emission spectroscopy analysis. In this article, the sample with the Fe concentration of x at. % deposited at the heated/cooled substrate is denoted as h/c-$Cr_{1-x}Fe_x$. The background pressure of the sputtering chamber was approximately 1×10^{-6} Torr. Sputtering was carried out in an atmosphere of Ar gas at 5×10^{-3} Torr by applying a power of 500 W. The distance between the target and the substrate was 100 mm. The deposition rate was typically 1.5 Å/s, and the films were 1–2 μm thick. The microstructure of the samples was observed by a 120 kV transmission electron microscope (TEM), Philips CM12. TEM specimens were prepared by ion milling after mechanically grinding the substrate. The Ar ion current for ion milling was set to be 0.5 mA at 4 kV. Magnetoresistance (MR) was measured at 4.2 K by the conventional four-probe method. An electromagnet was used in a low field range of $\pm$0.6 T, and a superconducting magnet was used in high fields up to 14 T. Magnetization versus applied magnetic field (M-H) curves were measured at 4.5 K in the range of $\pm$5.5 T, using a SQUID magnetometer (Quantum Design, MPMS).

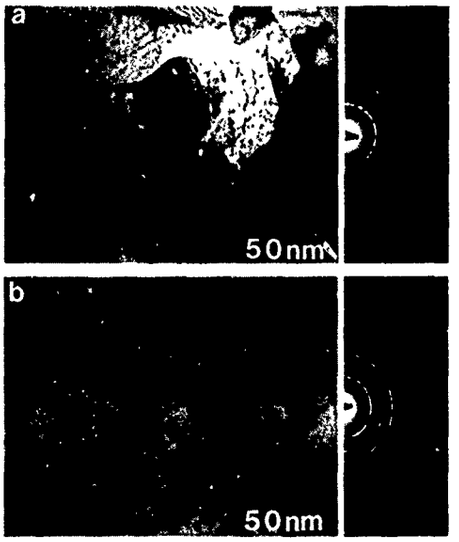

FIG. 1. Bright field TEM images and selected area diffraction patterns of (a) a $Cr_{83.9}Fe_{16.1}$ film sputtered on the heated substrate (h-$Cr_{83.9}Fe_{16.1}$) and (b) a $Cr_{83.1}Fe_{16.9}$ film sputtered on the cooled substrate (c-$Cr_{83.1}Fe_{16.9}$).

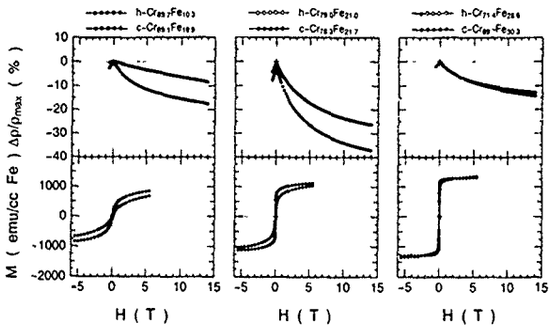

FIG. 2. MR (upper) and M-H (lower) curves of (a) a $Cr_{89.7}Fe_{10.3}$ film sputtered on the heated substrate (h-$Cr_{89.7}Fe_{10.3}$) and a $Cr_{89.1}Fe_{10.9}$ film sputtered on the cooled substrate (c-$Cr_{89.1}Fe_{10.9}$), (b) h-$Cr_{79.0}Fe_{21.0}$ and c-$Cr_{78.3}Fe_{21.7}$, and (c) h-$Cr_{71.4}Fe_{28.6}$ and c-$Cr_{69.7}Fe_{30.3}$. The MR curve is represented as the resistivity normalized by the maximum around zero field, $\Delta\rho/\rho_{max}$, as a function of applied field, H. In the M-H curves, the values per Fe volume are shown.

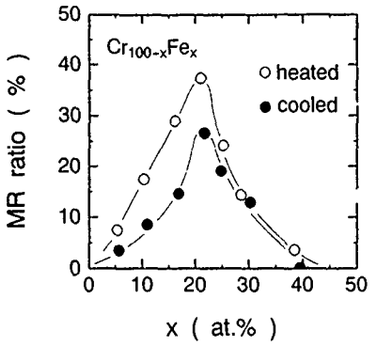

FIG. 3. Fe concentration, x, dependence of the MR ratio in $Cr_{1-x}Fe_x$ alloy films sputtered on the heated (open circles) and cooled (closed circles) substrates.

III. RESULTS AND DISCUSSION

Figures 1(a) and 1(b) show bright field images and their corresponding selected area diffraction patterns (SADP) of h-$Cr_{83.9}Fe_{16.1}$ and c-$Cr_{83.1}Fe_{16.9}$, respectively. The SADPs indicate that the films consist of a bcc phase. The average grain size is 200 nm for h-$Cr_{83.9}Fe_{16.1}$ and 70 nm for c-$Cr_{83.1}Fe_{16.9}$, respectively, indicating that cooling by liquid nitrogen reduces the grain size remarkably. For the h-$Cr_{83.9}Fe_{16.1}$ sample, small specks can be seen within a grain. The size of the specks is approximately 2 nm and these distribute homogeneously within the grain. Such specks are seen in many grains, although the appearance of the image varies depending on the orientation of the grains. This specklike contrast is probably due to the presence of Fe-rich ferromagnetic isostructural particles. The formation of these particles is considered to be a result of the phase separation which progressed during the film growth on the heated substrate.

Typical examples of MR and M-H curves are shown in Figs. 2(a)–2(c). The MR curves represent the normalized resistivity, $\Delta\rho/\rho_{max}$, as a function of applied magnetic field H. In the M-H curves, the values of magnetization are calculated per Fe volume. The results of two specimens with a similar composition but grown at different temperatures are displayed in the same figure. Negative MR is observed for all the samples. Interestingly, the maximum value of MR as large as 37.3% is observed in h-$Cr_{79.0}Fe_{21.0}$. However, MR does not saturate even at 14 T for all the samples. At the Fe concentrations of $x<10$ at. %, the resistivity for the films grown on the cooled substrate decreases almost linearly as a function of the magnetic field. On the other hand, the resistivity drops more steeply in the low field region for the films grown on the heated substrate. As the concentration of Fe increases, the discrepancy between the MR curves for the heated and cooled substrates diminishes and both are almost the same at $x>25$ at. %. A similar tendency is seen for the M-H curves. The magnetization for the heated substrate saturates more easily than that for the cooled substrate in the low x region, and the saturation of the magnetization for the cooled substrate becomes easier with increasing x. The concentration dependence of the MR ratio, $[\rho_{max}-\rho(H=14\ T)]/\rho_{max}$, is shown in Fig. 3. The MR ratio has a maximum around $x=20$ at. % for both heated and cooled substrates, similarly to other systems such as Ag-Fe.[5] However, the MR ratio for the cooled substrate is smaller than that for the heated substrate at $x<25$ at. %, and no difference is seen at $x>25$ at. %.

The negative MR behavior observed in samples grown on cooled substrates is considered to be equivalent to that reported for various spin glasses.[11–13] We have also prepared homogeneous bulk Cr-Fe alloys by the solution treatment, and confirmed a similar MR behavior.[14] In the spin glass state, single Fe atoms and/or small Fe clusters with a few Fe atoms distribute in a Cr matrix randomly. The magnetization vectors of the Fe atoms and clusters lie in different directions. Therefore, the MR and the magnetization do not saturate easily. By heating substrate phase separation may progress during the film growth. In this case, large ferromagnetic Fe particles, the average size of which is estimated to be 2 nm, are formed as shown in Fig. 1(a). Consequently, the MR and the magnetization for the heated substrate changes more steeply in low fields than those for the cooled substrate; the MR ratio for the heated substrate is larger than that for the cooled substrate. However, Figs. 2 and 3 indicate that the shape of the MR curve and the magnitude of the MR ratio do not depend on the substrate temperature at $x>25$ at. %. The reason for this is considered to be as follows: In a concentrated region, even if Fe atoms are randomly distributed in the Cr matrix, the density of Fe atoms is so high that a considerable amount of Fe atoms couple ferromagnetically to form a magnetic cluster.[15] The size of the magnetic clusters may be comparable to that of Fe particles precipitated by heating the substrate. Consequently, the difference between the MRs for the heated and cooled substrates disappears in the concentrated region. The fact that the MR has a maximum around $x=20$ at. % also suggests that ferromagnetic coupling of Fe atoms becomes dominant when x becomes larger than 20–25 at. %. In fact, by neutron diffraction, Burke *et al.*[15] showed that the onset of ferromagnetism was around 19 at. % Fe in bulk Cr-Fe alloys.

It should be noted that the MR does not saturate even at 14 T for any samples, irrespective of Fe concentrations and the substrate temperatures, while the magnetization reaches saturation at 5.5 T for $x>25$ at. % as shown in Fig. 2. We consider that this is due to spin glass behavior of Fe atoms contained in the Cr matrix. The values of magnetization are much smaller than that of pure bcc Fe, suggesting the phase separation is incomplete. Therefore, a large amount of Fe atoms is considered to be dissolved, forming a supersaturated solid solution in the Cr matrix. Regarding the absolute magnitude of the saturated MR it has been pointed out both theoretically and experimentally that the MR is larger as the size of magnetic clusters is smaller at a certain concentration of a magnetic element.[16–18] This may suggest that the saturated MR could be largest in the spin glass state. The unsaturated behavior of MR was also observed for other heterogeneous alloys.[4,6] We would like to remark here that the magnitudes of MR in heterogeneous alloys are not necessarily meaningful values because it varies depending on the magnetic field under which the MR is measured.

IV. CONCLUSION

We have investigated the GMR behavior of sputtered $Cr_{1-x}Fe_x$ heterogeneous alloy films. The MR ratio shows a maximum around $x=20$ at. % both for the heated and cooled substrates. However, the MR ratio for the cooled substrate is smaller than that for the heated substrate at $x<25$ at. %, and the discrepancy diminishes with increasing x. This suggests that in dilute regions, the samples sputtered on cooled substrates behave like spin glass, while in concentrated regions, ferromagnetic interaction becomes dominant even in the homogeneous solid solution.

Origin of giant magnetoresistance effect in granular thin films

Atsushi Maeda, Minoru Kume, Satoru Oikawa, and Kazuhiko Kuroki
New Materials Research Center, Sanyo Electric Co., Ltd., 1-1 Dainichi-higashimachi, Moriguchi, Osaka 570, Japan

Though the demagnetization process of granular Co-Ag films became steep by adding permalloy layer, slow saturation in the magnetoresistance (MR) curves was maintained. In addition, the MR characteristics of granular Fe-Ag films prepared under a magnetic field, in which strong magnetic anisotropy was induced, were isotropic. The disagreement between the MR and magnetic characteristics implies that ferromagnetic granules are not responsible for the giant MR (GMR) effect. The MR ratio of the granular Fe-Ag films considerably increased at thicknesses less than 20 nm. In such ultrathin films, the features of the MR curves corresponded well with those of the magnetization curves with slow saturation and no hysteresis. These results suggest that the GMR effect in the granular systems is attributable to superparamagnetism.

I. INTRODUCTION

Giant magnetoresistance (GMR) effect in the Fe/Cr multilayer[1] has stimulated a great deal of investigation of the magnetotransport properties in the various multilayered and sandwiched materials. Since the interlayer diffusion strongly influences the physical properties of such structures, the origin of the GMR effect is believed to be an interfacial spin-dependent scattering.[2–5] Recently, it has been observed that the GMR effect is also present in granular materials comprising mutually insoluble magnetic and nonmagnetic metals and/or alloys.[6,7] These results demonstrated that the GMR effect is not restricted to multilayered structures and that additional opportunities exist for technological applications. However, the transport phenomena in the granular systems are not much understood. So far a few models have been used for an explanation of the GMR effect.[8,9] Though magnetization of the granular films is saturated at low fields, the MR curves show a slow saturation.[10] We consider that such disagreement between the MR and magnetic characteristics is a key in the understanding of the mechanisms for the GMR effect in the granular systems.

In the present study, based on the experimental results for Fe-Ag films prepared under a magnetic field, ferromagnetic granules are pointed out to be not responsible for the GMR effect in the granular systems. Detailed thickness dependence study suggests that the GMR effect is dominated by fine granules with superparamagnetic characteristics.

II. EXPERIMENT

To study the effects of the applied field, the Fe-Ag films were prepared by rf sputtering under a magnetic field H_{ex}=130 Oe. The thickness dependence was studied on the granular Fe-Ag films that were prepared under zero field. The details for the preparation have been described previously.[11] An electron probe microanalyzer (JEOL JXA-840) was used for the elemental analyses. Magnetization (M) and hysteresis loops were measured using a vibrating sample magnetometer (TOEI VSM-3S). The MR was measured at room temperature, about 293 K, in a four-terminal geometry with an in-plane direct current (J) between 0.01 and 1 mA. A magnetic field (H) up to 1.5 T was applied parallel to the current. In the present study, the MR ratio is displayed as follows:

$$\Delta \mathrm{MR} = \Delta R/R(1.5), \tag{1}$$

where ΔR is the MR change, $R_{\max} - R(1.5)$, and $R(1.5)$ is the MR at H=1.5 T.

III. RESULTS AND DISCUSSION

Very recently, we have indicated that the Co-Ag/permalloy double-layered structure possesses a steep magnetization change.[10] This occurred because the ferromagnetic granules in the granular Co-Ag layer were magnetically dragged by the Permalloy layer with a soft magnetic nature. However, saturation was not observed in the MR curves of the double-layered films with a steep demagnetization process. Such disagreement between the MR and magnetic characteristics is also observed in granular Fe-Ag films prepared under a magnetic field (H_{ex}=130 Oe) which was applied parallel to the film plane. Figure 1(a) shows the M-H curves measured under the condition where the H was applied par-

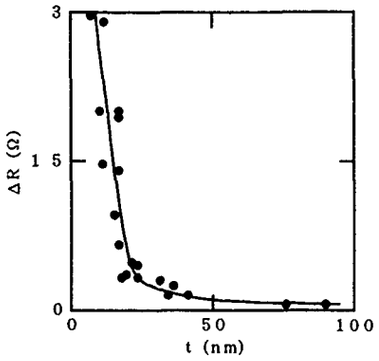

FIG. 3. MR changes of $Fe_{48}Ag_{52}$ films with various thicknesses (t).

allel ($H \| H_{ex}$) and perpendicular ($H \perp H_{ex}$) to the H_{ex} in the film plane. Here the thickness of the sample was 100 nm. It is found that magnetic anisotropy was induced in the prepared samples. This is probably because the applied field dominated the easy axis direction of the ferromagnetic granules. In contrast, the MR characteristics were independent on the arrangements between the J, H, and H_{ex}, as shown in Fig. 1(b). This indicates that the MR characteristics are maintained to be isotropic in the samples prepared under a magnetic field. These results for the Co-Ag/Permalloy double-layered films and the Fe-Ag films prepared under a magnetic field suggest that the GMR effect is not attributable to the ferromagnetic granules. In the granular systems, therefore, other magnetic components must be proposed as scattering centers. In this respect, we note small magnetic granules with superparamagnetic characteristics. Though the contribution of the superparamagnetic components are negligibly small in the magnetic properties of the granular materials, the transport properties are probably influenced by them.

The magnetic property of granules changes from ferromagnetic to superparamagnetic as the granule size decreases.[12] Therefore, the existing ratio of the superparamagnetic granules is expected to increase with decreasing the thickness of the granular films. This idea prompted us to prepare the granular "ultrathin" films. Figure 2 shows the thickness dependence of the MR ratio in $Fe_{48}Ag_{52}$ films that were prepared under zero field. Here the MR ratio is normalized relative to the MR ratio of the 90-nm-thick sample. The MR ratio considerably increased at thicknesses less than 20 nm. It is interesting that this thickness is close to the "critical diameter" of the Fe granule (25 nm), below which the Fe is theoretically estimated to be superparamagnetic.[13] Here the value of $R(1.5)$ necessarily increased with decreasing thickness. Therefore, it is noteworthy that the MR ratio increased in spite of the increase in the $R(1.5)$ value. This means that intrinsic change in the MR, which is estimated from ΔR in Eq. (1), is extremely large in the ultrathin films. From a quantitative study, it was found that the MR change is about 60 times as much as that in the "bulk" films which are thicker than 90 nm (see Fig. 3). As shown in Fig. 4, the $Fe_{48}Ag_{52}$ ultrathin films showed the M-H curves with slow saturation and no hysteresis. In addition, the features of the MR curves corresponded well with those of the M-H curves. This is in contrast to the disagreement between the MR and M-H data in the Co-Ag/Permalloy double-layered films and the Fe-Ag films prepared under a magnetic field. The above results indicate that the growth of the granules is restrained with decreasing the thickness as we expected. It is also suggested that the small granules with superparamagnetic characteristics mainly contribute to the GMR effect in the granular systems. Figure 5 shows the thickness dependence of saturation field (H_s) associated with the MR characteristics. Here the H_s is defined as the value of the magnetic field corresponding to the MR ratio at a value 80% below each MR ratio [see Fig. 5 in Ref. 11(b)]. The H_s decreased with increasing the MR ratio in the ultrathin films. Toward the application for thin-film sensor devices, it is extremely important that the MR ratio increases and H_s decreases with reducing the thickness in the granular systems.

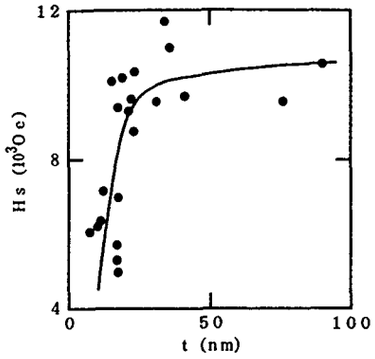

FIG. 5. H_s of $Fe_{48}Ag_{52}$ films with various thicknesses (t).

IV. SUMMARY

Though the interlayer magnetic coupling was induced in the Co-Ag/permalloy double-layered films, the MR change was maintained to be slow. In addition, the isotropic MR characteristics were observed in the granular Fe-Ag films prepared under a magnetic field. The MR ratio in the Fe-Ag system considerably increased at thicknesses less than 20 nm. In such ultrathin films, a slow saturation and no hysteresis were observed in the *M-H* curves, whose features corresponded well with those of the MR curves. These results suggest that the larger ferromagnetic particles are not as effective as the smaller superparamagnetic particles to the GMR effect in the granular systems. This is probably because of the small surface to volume ratio of the former.

Structural and magnetoresistance results on annealed sputtered ($Ni_{81}Fe_{19}$, $Ni_{66}Fe_{16}Co_{18}$)/Ag granular multilayers are presented. Structural evolution has shown that highly (111) textured, discontinuous layered structures can persist on annealing up to 400 °C. The average magnetic particle size is controlled by the annealing temperature and the initial magnetic layer thickness. No giant magnetoresistance was observed in the as-deposited films, while significant MR was found after annealing between 300 °C and 400 °C. Magnetoresistance over 30%, together with a small saturation field, was found at 4.2 K for a starting magnetic thickness of 4 Å. Increasing the magnetic layer thickness to 20 Å greatly improves the magnetic thermal stability, and leads to high magnetoresistive sensitivities of up to 0.35%/Oe in a field of 10 Oe at room temperature. The magnetization hysteresis, anisotropy, and magnetic interaction in such a granular multilayer are also discussed.

I. INTRODUCTION

Since the observation of giant magnetoresistance (GMR) first in antiferromagnetically coupled multilayers,[1,2] and later in uncoupled granular alloy films,[3,4] structural and magnetotransport properties have been intensely studied in a variety of artificially inhomogeneous structures. High negative GMR, which is essential for magnetoresistive sensor applications, is found in these system and is shown to be related to the interface spin-dependent scattering, and is associated with the reorientation of the magnetic moments in either a coupled multilayer structure or an immiscible granular alloy.[1,3] However, the magnetic fields required to achieve magnetic saturation and a significant magnetoresistive effect are generally too large to be useful in low-field device applications.

Annealed NiFe/Ag multilayers, however, have shown low-field GMR.[5–8] We have recently extended these studies by annealing NiFe/Ag multilayers containing ultrathin NiFe layers. Larger enhancements in GMR at 4.2 K were found for annealed multilayers and low saturation fields were also observed by controlling the size and shape of the magnetic precipitates.[9] In this paper, we report the magnetic layer thickness dependence of annealed (NiFe,NiFeCo)/Ag multilayers on the structural, magnetic, and transport properties.

II. EXPERIMENT

A series of ($Ni_{81}Fe_{19}$,$Ni_{66}Fe_{16}Co_{18}$)/Ag multilayers with individual magnetic layers, ranging from 4 to 20 Å and Ag layers of 20–40 Å were prepared by dc magnetron sputtering at room temperature from separate targets of $Ni_{81}Fe_{19}$, $Ni_{66}Fe_{16}Co_{18}$, and Ag onto both glass and oxidized Si substrates. The base pressure was less than 2×10^{-7} Torr. The deposition rates were typically 1.4–1.6 Å/s in 7.5 mTorr argon. The individual layer thicknesses of the magnetic alloys and Ag were adjusted to yield films of magnetic composition between 20 and 55 at. %. Total film thicknesses were 750–1200 Å. The heat treatment was carried out, either under a vacuum of better than 2×10^{-6} Torr or under a flow of 5% H_2 and 95% Ar.

The structural characterization of the samples were performed using low- and high-angle x-ray diffraction using Cu-K_α radiation and a transmission electron microscope. The film compositions, as determined by electron microprobe measurements, were found to be within 4% of the nominal values. The magnetoresistance measurements were carried out using a four-terminal geometry and a high-resolution ac bridge.[10] The current was in the plane of the film, with the magnetic field either in the film plane and perpendicular to the current (transverse ρ_T) or perpendicular to the plane (perpendicular $\rho_\perp$). Magnetic hysteresis data at 300 K were obtained using a magneto-optic Kerr effect (MOKE) magnetometer with the applied field in the plane of the film.

III. RESULTS AND DISCUSSIONS: $Ni_{81}Fe_{19}$/Ag MULTILAYERS

($Ni_{81}Fe_{19}t$/Ag20 Å)$_{30}$ multilayers with t_{NiFe}=4–20 Å were deposited on glass substrates and followed by annealing under vacuum. The low-angle x-ray reflectivity spectra reveal superlattice peaks for all the as-deposited samples, down to a bilayer thickness of Λ=24 Å (with a 4 Å layer of magnetic component), indicating a well-defined compositional modulation along the growth direction. The corresponding high-angle x-ray diffraction and electron diffraction for these samples show that the multilayer films have coherent interfaces and a highly textured structure with (111) orientations normal to the film plane. Figure 1 shows the high-angle x-ray diffraction patterns for a multilayer with t_{NiFe}=20 Å at different annealing temperatures. Highly textured Ag(111) and NiFe(111) structures can be seen in the

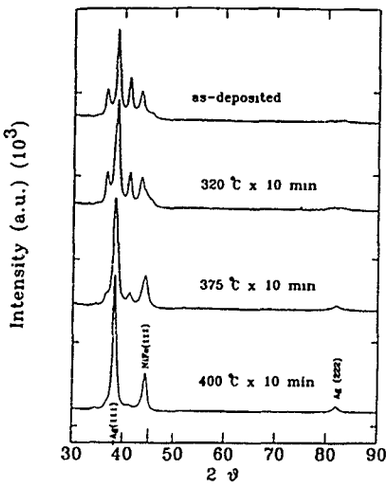

FIG. 1. High-angle x-ray data for the samples with form glass/(Ag20 Å/$Ni_{81}Fe_{19}$20 Å)$_{30}$/Ag20 Å, as-deposited and annealed at 320 °C, 375 °C, and 400 °C for 10 min.

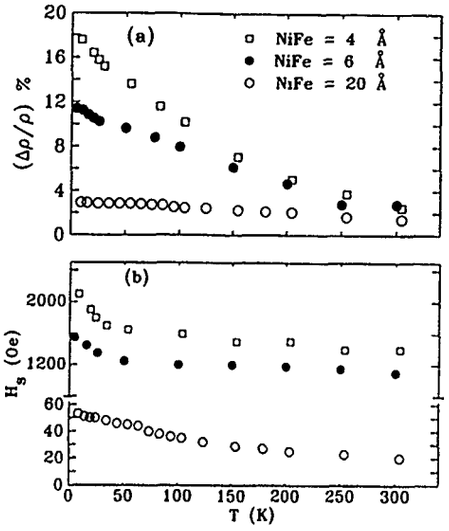

FIG. 2. Temperature dependencies of (a) $\Delta\rho/\rho$ and (b) saturation field H_S for three $Ni_{81}Fe_{19}$ samples with layer thicknesses, as indicated.

annealed samples. As illustrated in Fig. 1, superlattice coherence persists for samples annealed up to 400 °C. Further annealing above 450 °C, however, dissolved the superlattice structures, as shown by the disappearance of the satellite peaks around the two primary Bragg peaks, indicating significant interdiffusion during annealing. Similar structural changes in annealing, found from high-angle x-ray diffraction, were observed for all the NiFe thicknesses studied here. However, low-angle x-ray reflectivity data show that, except for very thin NiFe layers (4–6 Å), the compositionally modulated layer structures persist, even after annealing at 450 °C, indicating a well-spaced discontinuous multilayer structure. The average NiFe grain sizes, D, corresponding to different t_{NiFe}, estimated from the high-angle diffraction peak width, range from 60 to 250 Å for samples annealed at 450 °C, as shown in Table I. As the annealing temperature is increased, the high-angle NiFe (111) x-ray peak intensity increases and becomes sharper, indicating the growth of NiFe particles.[7]

For a wide range of NiFe thicknesses (4–20 Å) and Ag spacer 20 Å, the as-deposited multilayers show no GMR at room temperature. However, large MR was found for samples annealed between 300 and 450 °C at both 4.2 and 300 K. Data obtained at 4.2 K are shown in Table I. For the samples with ultrathin NiFe layers (~4–6 Å), which is considered as granular in nature, GMR as large as 30% was found in the samples annealed at 300 °C with a saturation field generally less than those observed in cosputtered granular films of similar compositions.[3,4] As t_{NiFe} increases to 20 Å, a substantial decrease of the GMR is observed. This result is expected, since for high NiFe concentrations, the surface to volume ratio decreases, thereby reducing the interfacial spin-dependent electron scattering.[11] However, the saturation field is greatly reduced as the magnetic layer thickness is increased. Similar behavior was found for samples annealed at 450 °C, except that the values of the GMR and H_S are lower, due to the growth of magnetic precipitates.

An important aspect of increasing t_{NiFe} is the improvement of the magnetic thermal stability. Figure 2 shows the temperature dependence of GMR and H_S. Cooling the samples down from 300 K to 4.2 K increased $\Delta\rho/\rho$ by a factor of 7 for the sample with t_{NiFe}=4 Å, but only by a factor of 2 for the sample with t_{NiFe}=20 Å. Interestingly, the MR values for these samples are comparable at 300 K. The saturation fields show behavior similar to those of GMR. A large increase of H_S for thinner NiFe samples are seen at temperatures below 50 K, compared to a relatively flat variation for the thickest NiFe sample. The strong temperature dependences of the GMR parameters for the samples with ultrathin NiFe layers were shown to be related to the superparamagnetic properties of the small magnetic precipitates.[9]

TABLE I. Dependence of magnetoresistance parameters on t_{NiFe} for samples annealed at 300 °C and 450 °C, data obtained at 4.2 K. ρ_0 and ρ_S are the resistivities at $H=0$ and $H=H_S$, respectively.

IV. LOW-FIELD GMR STRUCTURE

Although large GMR values have already been obtained in a variety of multilayers and granular alloys, the magnetic fields required are usually large. In a multilayer structure, low saturation fields are possible by choosing a structure with small antiferromagnetic coupling.[12] A recent report has shown that very low field GMR is obtained in an annealed NiFe/Ag multilayer structure, with a typical magnetic layer thickness of 20 Å.[5] The large value of the magnetoresistive sensitivity, over 0.8%/Oe, was ascribed to the balance of magnetostatic and local antiferromagnetic interaction between the plate-like islands in the annealed layer structures. We have prepared similar structures by substituting the magnetic component by a magnetically soft $Ni_{66}Fe_{16}Co_{18}$ alloy. Figure 3 shows the room temperature magnetoresistance data for multilayer with form SiO_2/Nb50 Å/Ag20 Å/NiFeCo20 Å (Ag40 Å/NiFeCo20 Å)$_4$/Ag20 Å/Nb100 Å, at a different annealing temperature. No GMR was found for the as-deposited sample, while significant GMR was observed after annealing the samples between 300 °C and 400 °C. Values of $\Delta R/R=4\%$ and $(dR/dH)/R=0.35\%$/Oe were obtained for the sample annealed at 325 °C. It appears that the large increase in $\Delta R/R$ is dominated by the increase of ΔR, as the sheet resistances generally decrease by only 10%–15% after annealing. We also note that the MR parameters, particularly the saturation field are extremely sensitive to the annealing temperature. As a consequence, the annealing temperature needed for maximum sensitivity was found to lie within a very narrow window of a few degrees around 325 °C for this particular structure.

Finally, the magnetization hysteresis was studied using a MOKE magnetometer. Figure 4 shows the room temperature MOKE hysteresis loops for the same samples indicated in Fig. 3. A typical ferromagnetic characteristic is seen for the as-deposited sample with relatively small Kerr intensity. Upon annealing at a moderate temperature below 370 °C, the hysteresis loop gradually tilts and the remanence magnetization decreases, suggesting the formation of a fractional antiferromagnetic spin configuration. Annealing above 370 °C increases both the remanence and the coercivity; correspondingly, the GMR sensitivity decreases. Although a small in-plane anisotropy was found in the as-deposited sample, the hysteresis loop difference of the in-plane magnetic easy and hard axes vanishes after annealing above 300 °C. Therefore, one could conjecture that under a minimum in-plane anisotropy, low-field GMR and high sensitivity are promoted as the results of the balance of magnetostatic interaction and local antiferromagnetic coupling.[5]

Magnetoresistance in (Fe–Co)/Ag films

A. Tsoukatos,[a] D. V. Dimitrov, A. S. Murthy, and G. C. Hadjipanayis
Department of Physics and Astronomy, University of Delaware, Newark, Delaware 19716-2570

The structural and magnetotransport properties of $(Fe_yCo_{1-y})_{100-x}Ag_x$ films were studied as a function of composition. Giant magnetoresistance (GMR) values were measured in these granular films, with the best GMR obtained for the composition $(Fe_{0.33}Co_{0.67})_{27}Ag_{73}$, with values of 29% at 30 K and 11.7% at 300 K. XRD and TEM results have shown a fcc crystal structure with a relatively homogeneous microstructure. Magnetic data for the samples with the best GMR indicate a superparamagnetic behavior. The narrow peak in thermomagnetic data and low blocking temperature suggest a small and uniform size distribution of magnetic granules. A summary of the electrical transport properties is presented, in relation to the structural, microstructural, and magnetic properties.

I. INTRODUCTION

Giant magnetoresistance has been recently observed in transition metal multilayers,[1] composite films,[2,3] and in broken multilayers.[4] The origin of GMR is attributed to spin-dependent scattering at the interfaces between magnetic and nonmagnetic regions.[5–7] The highest GMR, of the order of 150%, was observed in multilayers,[8] but the highest sensitivity, about 1.2%/Oe, was found in broken multilayers.[4] Both of these systems require very stringent preparation techniques, which make them difficult to be used for practical applications. On the other hand, granular films are much easier to prepare, but the studies, to date, showed low sensitivity and high saturation fields. This study was performed in an effort to improve the sensitivity and lower the saturation field in (Fe–Co)/Ag films by investigating the dependence of these parameters on the composition, structure, size, and density of magnetic granules.

II. EXPERIMENTAL PROCEDURES

$(Fe_yCo_{1-y})_{100-x}Ag_x$ granular films with $y=0$–0.4 and $x=30$–80 were prepared using magnetron sputtering from Fe–Co and Ag targets on water cooled substrates. Carbon coated copper grids, Al foils, kapton, and glass were used as substrates. The predeposition pressure was 3×10^{-8} Torr, and sputtering was done in a 5 mTorr Ar pressure. X-ray diffraction (XRD) and transmission electron microscope (TEM) studies were used to determine the crystal structure and microstructure of the samples. A SQUID magnetometer, with a maximum applied field of 55 kOe, was used for the magnetic and the electrical transport measurements in the temperature range of 10–300 K. The four-probe technique with the field parallel to both the current and the film surface was used for the GMR measurements.

III. RESULTS AND DISCUSSION

The XRD (Fig. 1) and TEM results (Fig. 2) have shown a fcc crystal structure with uniform microstructure (grain size ranging from 5 to 50 nm), irrespective of the Ag or Fe–Co relative composition. All the observed selected area diffraction (SAD) reflections were solely due to Ag. The absence of diffraction rings characteristic of elemental Fe or Co or some FeCo structure is reminiscent of Co(Fe)/Ag granular films. In the latter system,[9] the absence of Co(Fe) reflections was attributed to the very small size of Co(Fe) granules (1 nm), which were observed only when high resolution TEM was used.

The dependence of GMR values on composition in (Fe–Co)/Ag is shown in Fig. 3. It is seen that for a fixed ratio between Fe and Co (y), the GMR values form a well-defined bell-shaped curve. All these curves show maxima that lie in the region of 65%–70% Ag. The magnitude of GMR drops significantly when the magnetic content becomes 50%, which corresponds to the theoretical estimation for the percolation point of granular solids.[10] For the samples with a small percent of magnetic material (less than 20%), the density of magnetic granules is small, giving rise to a small scattering surface area and a large separation between the granules, leading to small GMR values. Figure 3 also shows that the GMR values for Fe–Co/Ag films are consistently lower than those of the Co/Ag films prepared under identical conditions. However, for $y=0.33$ and $x=0.73$, comparable values were observed, with a maximum $\{[R(H)-R(0)]/R(0)\}$ of 29% at 30 K and 11.7% at 300 K. The prominent feature of all Fe–Co/Ag samples was the lower magnetic

fields required for the saturation of magnetoresistance, which results in sharper GMR (H) peaks compared to their Co/Ag counterparts. This point is clearly demonstrated in Fig. 4.

The GMR vs H curves taken for samples with different magnetic content (Fig. 5) show that for a small amount of the magnetic material, the magnitude of GMR smoothly increases with increasing field. For samples with a magnetic content of about 30%, it is seen that the magnetoresistance increases and the curve appears to have a peak at around $H=0$. The magnitude of the peak becomes smaller, and the slope of the curve decreases with a further increase of the magnetic content. The peak vanishes for the sample with 63% magnetic content. Magnetization curves (Fig. 6) taken on the samples with the best GMR, at different temperatures, show small coercivity (100 Oe at 20 K and a negligible value at 300 K) and lack of saturation, even for fields up to 55 kOe [the magnetization curve at 300 K seems to achieve saturation, because of the higher signal from the diamagnetic substrate (kapton)]. These results are indicative of the superparamagnetic behavior of the samples, having a small grain size. A notable feature here, however, is that although the magnetization does not show complete saturation, the magnetization at 10 kOe is 95% of the magnetization at 55 kOe. This is in contrast to the Co/Ag samples with the same percentage of magnetic material, which never approached saturation, even for fields as high as 55 kOe.[11]

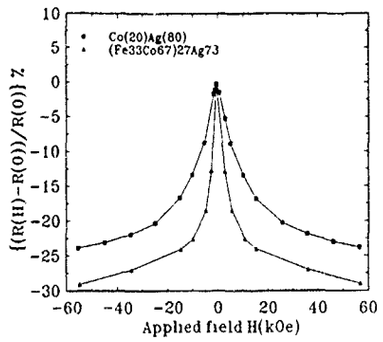

FIG. 4. Field dependence of GMR at 30 K.

The thermomagnetic data for the samples showing the highest GMR values (Fig. 7) confirm their superparamagnetic behavior. The low blocking temperature, of the order of 25 K, is suggestive of a very small size of the magnetic particles, which is consistent with the absence of SAD reflections and XRD peaks. The narrow peak is indicative of the uniform size distribution of magnetic particles.

IV. CONCLUSIONS

We observed high values of GMR in Fe–Co/Ag granular films with values of 29% at 30 K and 11.7% at 300 K. The GMR saturating fields are lower than those in Co/Ag. The

origin of GMR in these structures seems to be due to the spin-dependent scattering from the surfaces of the Fe–Co clusters. The percentage of the magnetic content and relative Fe and Co composition play a significant role in the magnitude of GMR and the saturation field.

In this paper AgNiFe alloy films were examined both before and after annealing. Characterization of the samples and examination of interaction effects was carried out by measuring the temperature decay of remanence, initial susceptibility, and magnetoresistance. The temperature decay of remanence reveals that annealing widens the distribution of energy barriers, which is indicative of grain growth. The behavior of the initial susceptibility as a function of temperature is analogous to that found in spin glasses. From these measurements, it is believed that interaction effects in these systems are small.

I. INTRODUCTION

Recently, there has been a growing interest in giant magnetoresistance (GMR) materials, which are being considered for applications such as sensors and read/write heads in recording systems. Materials that exhibit GMR may be multilayers or alloys. In granular alloy films such as AgNiFe, the giant magnetoresistance arises from spin-dependent electron scattering within and at the boundaries of the grains contained within the Ag matrix. The size of these precipitates and the interactions between them affects the orientation of the spins, and hence the magnitude of the magnetoresistance.

In disordered magnetic materials, the first step in their characterization is the measurement of the energy barrier distribution. This measurement is made by cooling the sample in the zero field to the lowest temperature, where all the moments are blocked and unable to fluctuate over their energy barriers (ΔE). Then the saturation remanence of the magnetic compound is measured as a function of temperature, this variation is given by[1]

$$\tilde{M}_r(T)=\tilde{M}_r(0)\int_{y_{\rm crit}}^{\infty} f(y)dy, \tag{1}$$

where $\tilde{M}_r=M_r/M_s$ is the reduced remanence relative to the saturation magnetization of the system, $y=\Delta E/\overline{\Delta E}$ is the reduced energy barrier relative to the average barrier $\overline{\Delta E}$ and $f(y)$ is the distribution function of reduced energy barriers, which, in this formalism we assume to be independent of T. $y_{\rm crit}$ is the reduced critical barrier above which the moments are unable to fluctuate on a given time scale. Using this criterion of the critical barrier, $y_{\rm crit}$ is given by

$$y_{\rm crit}=\frac{\Delta E_{\rm crit}}{\overline{\Delta E}}=\frac{T}{T_B}, \tag{2}$$

where $\Delta E_{\rm crit}=kT\ln(t_m f_0)$, t_m is the measuring time and f_0 is a frequency factor associated with these fluctuations. $\tilde{T}_B$ is the average blocking temperature of the system, at which fluctuations are taking place over the average barrier. According to Eq. (1), the differential of the temperature decay of remanence curve shows directly the distribution of energy barriers $f(\Delta E/\overline{\Delta E})\equiv f(T_B/\overline{T_B})$.

A second useful measurement is the variation of initial susceptibility with temperature. For a zero field cooled process this behavior is well known and gives a peak at a temperature $T=T_g$.[2] If the distribution of energy barriers originates from a distribution of precipitate sizes, then well above T_g and over a limited range of temperature, the initial susceptibility, χ_i is given by[3]

$$\chi_i(T)=\frac{bC_0}{T+T_{0\,\rm tot}}, \tag{3}$$

where $T_{0\,\rm tot}=T_{0\,\rm Bi}-T_{0i}$ is the total ordering temperature over that limited range of temperature. T_{0i} represents the contribution of interactions to $T_{0\,\rm tot}$ and $T_{0\,\rm Bi}=\gamma T_{B\,\rm eff}$ represents the correction for the blocking effects that arise, due to the fact that there is a distribution of blocking temperatures. Equation (3) was derived by fitting the tail of the distribution function to $f(y)=\alpha y^{-3}$ in the limited range of temperature examined, where $\gamma=\alpha/b$ and $b=\exp(-\sigma_y^2/2)$ and σ_y is the standard deviation of $f(y)$, since a lognormal distribution of energy barriers is assumed.

According to this analysis of the temperature variation of the initial susceptibility, and with the help of the energy barrier distribution data obtained via the decay of remanence measurement, the interaction effects in the AgNiFe alloy films can be examined.

II. EXPERIMENT

The films examined consisted of silver, which formed the bulk of the material, together with nickel and iron, the ferromagnetic components that form precipitates in the silver matrix. The size of these grains, and hence the GMR, may be controlled after deposition by annealing of the film, which causes growth of the grains.

The films were produced by rf sputtering onto glass substrates in 8 mTorr argon pressure from a base pressure of better than 2×10^{-7} Torr. The films were between 200–300 nm thick and the deposition time was 1 min. The film compositions were varied by changing the configuration of the sputtering target. Films were generally 78 ± 5 atomic percent silver, with the rest consisting of nickel and iron in a range of proportions. Annealing was carried out at three different temperatures: 600 °C, 650 °C, and 750 °C under vacuum, using halogen bulbs as heaters.

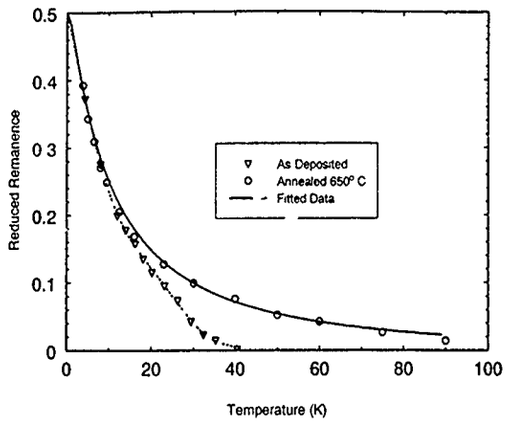

FIG. 1. Temperature decay of remanence data for the as-deposited and annealed films.

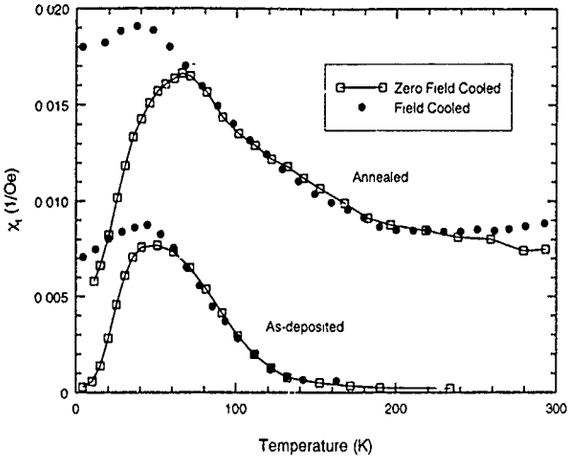

FIG. 3. Initial susceptibility, χ_i, for as-deposited and annealed samples after cooling in zero and 50 Oe fields.

Magnetic measurements were made with a PAR4500 VSM. Measurements of the initial susceptibility were made after zero field cooling using applied fields of ±50 Oe over a temperature range from room temperature to 4 K. The samples were cooled in zero field. Further susceptibility measurements were made at $T>T_g$ while cooling the sample in a 50 Oe field. Temperature decay of remanence measurements were made over the same temperature range, measurements of the remanence were made after saturating in a ±1.2 T field. Magnetoresistance was measured using a four point probe.

III. RESULTS AND DISCUSSION

Figure 1 shows the measured temperature decay of remanence curves for two films of composition 78.9% Ag, 11.3% Fe, and 9.7% Ni before and after annealing at 650 °C. We see that the value of $\bar{M}_r(0)$ can be extrapolated to 0.5, i.e., the Stoner–Wolfarth value for a system with randomly oriented easy axes.[4] Analysis of this data according to Eq. (1) gives the energy barrier distribution. Figure 2 shows the distribution of energy barriers or the distribution of blocking temperatures obtained from the decay of remanence curves.

The energy barrier distribution for the as-deposited sample shows that there is some degree of bimodality that disappears when the sample is annealed. The data also shows that the distribution becomes broader after annealing, which may be due to precipitate growth arising from coagulation of neighboring precipitates or alloying. The analysis of the decay of the remanence curve for the annealed sample gives a value of $\bar{T}_B=10$ K and $\sigma_y=1.3$, however, it is difficult to fit the curve for the as-deposited sample, since a bimodal distribution is present.

Figure 3 shows the temperature variation of reduced initial susceptibility: $\bar{\chi}_i(T)=\chi_i(T)/M_s(T)$, where $M_s(T)$ is the saturation magnetization. Curves are shown for cooling in the zero applied field and cooling in a 50 Oe field. The samples exhibit typical spin-glass behavior. From the figure, the values of initial susceptibility for the annealed sample are larger than those of the as-deposited sample, and also the position of the peak in the zero field cooled curve is shifted to a higher temperature. This behavior can be attributed to

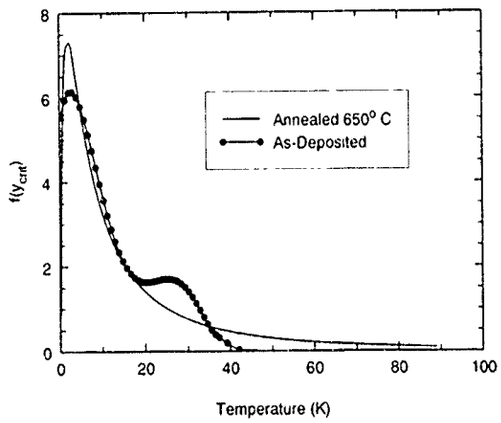

FIG. 2. The energy barrier distributions, $f(y_{crit})$, for the as-deposited and annealed films.

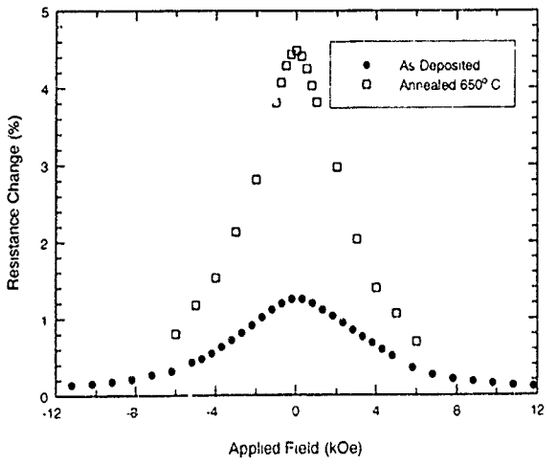

FIG. 4. Magnetoresistance for the two films.

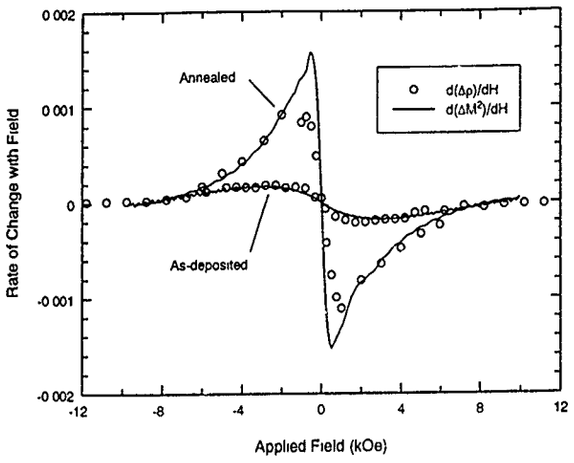

FIG. 5. Comparison of $d(\Delta\rho)/dH$ and $d(\Delta M^2)/dH$ for the annealed and as-deposited films.

the fact that the precipitates are larger in the annealed sample.

Analysis of χ_i^{-1} versus temperature for the annealed sample according to Eq. (3) gives a total ordering temperature of $T_{0\,\mathrm{tot}}=-50$ K. Using the data for the energy barrier distribution obtained for this sample, we calculate a value for $T_{0\,\mathrm{Bi}}$ of -55 K. Subtracting this from $T_{0\,\mathrm{tot}}$ gives a value for T_{0i} of 5 K that arises due to interaction effects. This value of T_{0i} indicates that the interaction effects in this sample are small.

Figure 4 shows the GMR curves measured at room temperature before and after annealing. We see that the GMR effects in the annealed sample with the larger precipitates are greater than in the as-deposited film, and $\Delta\rho$ increases from 1.3% to 4.7% as the sample is annealed to 650 °C.

Since neither samples exhibit remanence or coercivity at room temperature, we may compare the field dependence of $\Delta\rho(H)$ and $\Delta\bar{M}^2(H)$, where $\Delta\bar{M}^2=[\bar{M}(\infty)-\bar{M}(H)]^2$. This comparison is based on the model of Gittleman *et al.*,[5] describing the relationship between the magnetoresistance and the magnetization of the system. Figure 5 shows the rate of change of $\Delta\rho(H)$ and $\Delta\bar{M}^2(H)$ for both samples examined. The data clearly shows that the rate of change of $\Delta\rho(H)$ is greater for the annealed sample. This data also shows that for the as-deposited sample, the variation of $d[\Delta\rho(H)]/dH$ and $d[\Delta\bar{M}^2(H)]/dH$ is similar, whereas for the annealed sample the $d[\Delta\rho(H)]/dH$ curve deviates from the $d[\Delta\bar{M}^2(H)]/dH$ curve; this is particularly apparent at low fields. This result can be explained in terms of recent calculations,[6] in which, due to interaction effects, the $\Delta\rho(H)$ curve does not follow the $\Delta\bar{M}^2(H)$ curve at low fields. This is because the magnetoresistance is influenced by the short range correlation between neighboring precipitates, whereas the behavior of $\Delta\bar{M}^2$ is an average over the whole system. The data for the annealed sample shown in Fig. 5 shows that the deviation of the $d[\Delta\rho(H)]/dH$ curve from the $d[\Delta\bar{M}^2(H)]/dH$ curve is not large, which again suggests that interaction effects are small in this sample. This result is consistent with the magnitude of the ordering temperature $T_{0i}=5$ K, obtained from the initial susceptibility data.

IV. CONCLUSIONS

In this paper, a method of examining and characterizing interaction effects has been presented. The temperature decay of remanence is found to give useful information about the energy barrier distribution that can be used to examine interaction effects, in conjunction with initial susceptibility measurements. From the examination of the initial susceptibility data and a comparison of the resistivity and magnetization curves of the annealed sample, the effects of interactions are found to be small. These effects are believed to play a significant role in the increase in the GMR effect as the sample is annealed.

Nonferromagnetic atoms present at Ni/Cu and Permalloy/Cu interfaces in sputtered spin valve magnetoresistive layered structures have been shown to cause reduced magnetoresistance. Here we show that a model in which the moments on the Ni atoms in the interfacial region of Ni/Cu are reduced substantially by interdiffusion with Cu is consistent with the experimental results. In contrast, we believe that moments persist at the permalloy/Cu interface, which first principle total energy calculations suggest will be disordered at finite temperatures. These reduced or disordered moments are expected to significantly reduce the GMR.

I. INTRODUCTION

It is clear from experiments[1–4] that an understanding of the chemical, physical, and magnetic structure of the interfaces in magnetic multilayers is an important part of understanding the giant magnetoresistance (GMR) effect in these systems. Here we report on experiments and calculations aimed at elucidating the magnetic structure of these interfaces.

For some time, the moment as a function of the total amount of magnetic material deposited in Cu/Permalloy/Cu and Cu/Ni/Cu sandwiches, as well as Ni/Cu and Permalloy/Cu and other spin valves, has been measured,[1–3,5] and the moment found to be less than expected from the amount of Ni and Fe deposited. In particular, for nickel thicknesses less than T_{nf} (thickness nonferromagnetic) no moment was observed, but with a further increase in thickness, the moment increased linearly with a slope given by the bulk magnetization. This showed that a nonmagnetic region is formed at the interface, and that away from the interface relatively undisturbed ferromagnetic material is present. The thickness T_{nf} corresponded to roughly one atomic layer of $Ni_{0.8}Fe_{0.2}$ per interface for the "as deposited" sample and increased to approximately four atomic layers after annealing at 320 °C. For Ni/Cu, the missing moment was equivalent to approximately 2.5 atomic layers of bulk Ni. A direct correlation of T_{nf} with loss in GMR was observed, and was interpreted as arising from spin-independent scattering caused by the nonferromagnetic atoms near the interface. This scattering reduces the number of majority carrier electrons that can traverse the interface unhindered and penetrate into the ferromagnetic layer.[1,3,5]

The need to understand the magnetic structure of GMR interfaces takes on added importance in light of experiments in which atoms of third elements added to the interface greatly modify the GMR amplitude;[6] in particular, small amounts of Co at the Permalloy/Cu interface greatly increase the GMR effect.[4] Also, first principles calculations[7] predict an extremely large GMR effect for multilayer systems, such as Permalloy/Cu/Permalloy or Co/Cu/Co. This large calculated GMR arises, because the majority spin potentials (and majority d-wave phase shifts) of fcc Ni, Fe, and Co are all similar and close to that of Cu. As a consequence of this matching of potentials, interfaces in these materials that have no imperfections other than a substitutional intermixing of the constituent atoms are predicted to scatter majority spin electrons only weakly, whereas the scattering of the minority spin electrons at the interfaces (and in the bulk for Permalloy) is predicted to be very strong. The GMR arises in part because these majority carriers that carry most of the current do not scatter strongly at either interface for the case of ferromagnetic layer alignment, but scatter strongly off of one of the interfaces in the antiferromagnetic case. Another contribution to the GMR arises because of the difference in ferromagnet spin up and spin down mean-free paths, so that majority carriers that traverse the interface unhindered can travel a large distance before scattering, but minority carriers continue to be strongly scattered throughout the ferromagnetic layer.[8] In this paper, we attempt to present a coherent picture of the disorder present at the Cu/Ni and Cu/Permalloy interfaces and its effect on the GMR amplitude.

II. DIFFUSION MODEL OF NI/CU CONCENTRATION PROFILES

Ni differs from Fe and Co, in that it loses its moment as a substitutional impurity in Cu. At low temperature, the solid solution moment per atom is observed both experimentally[9] and theoretically[10] to decrease from its value of $0.6\mu_B$ in pure Ni at about $1\mu_B$ per atomic fraction Cu. This decrease is due both to the dilution of Ni by Cu and to the decrease of the Ni moment, which vanishes at around 60% Cu. At room temperature the moment decreases faster, vanishing at about 30% Cu.

We shall investigate a model in which Cu atoms migrate into the magnetic layer, where they reduce the nearby moments. To model interfaces with different amounts of intermixing, and to make connection to the annealing data, we consider initially abrupt interfaces that we allow to interdiffuse for increasing amounts of time, resulting in more intermixing. For Ni/Cu, the atoms are of similar size, and the equilibrium phase above 322 °C is a slightly clustering solid solution. Therefore, it is reasonable to assume that hopping

 0021-8979/94/76(10)/6805/3/$6 00 © 1994 American Institute of Physics

probabilities are species independent. Thus, the concentration on a layer should obey a one-dimensional diffusion equation of the form

$$\frac{dc_k}{dt}=\sigma_D\left(-c_k+\frac{1}{2}\left(c_{k+1}+c_{k-1}\right)\right), \tag{1}$$

where c_k is the concentration of Cu on the kth plane and σ_D is the number of out of plane jumps per second per site. This equation is easily solved in terms of the dimensionless time, $\tau=\sigma_D t$, for an initially perfect periodic multilayer consisting of n_{Cu} planes of Cu followed by n_{Ni} planes of Ni. Unfortunately σ_D is not available, and since the experimental deposition and annealing includes several successive temperatures, the mapping from τ to t is not even linear. However, the mapping should be independent of n_{Cu} and n_{Ni}. This allows us to qualitatively compare our calculated loss in moment and interfacial width with those obtained from magnetometry and x-ray reflectance.[11] Specifically, we calculate the concentration profile $c_k(\tau)$ as a function of τ for a periodic structure initially consisting of 25 [111] planes of Cu followed by n_{Ni} planes of Ni. As τ increases, mixing occurs and the concentration profile evolves.

We are interested in fcc [111] layers, where each atom has six neighbors in its plane and three neighbors in each of the two neighboring planes. To obtain a rough picture of the dependence of the moment on the thickness of the Ni layer, n_{Ni}, we approximate the moment on a Ni atom by the average Ni moment in a random alloy, with the same average number of Ni nearest neighbors as the Ni atom under consideration. With this assumption, the total moment can be determined as a function of intermixing, calculated from Eq. (1) for different numbers of Ni planes. In Fig. 1(a), we show the total moment per unit cell of a multilayer consisting of 25 Cu planes followed by n_{Ni} planes calculated as a function of τ using the room temperature data for the moment as a function of concentration.

These results show that, depending on τ (i.e., intermixing), when only a few Ni layers are present, there is no moment, but that as Ni layers are added, a point is reached when the moment appears; the moment then increases almost linearly. In Fig. 1(b), the net moment versus the number of Ni layers is plotted for $\tau=5$, along with room temperature (RT) measurements. The value, $\tau=5$, was chosen to give the best agreement with the measurements. Based on this qualitative agreement with experiment, we propose that our simple diffusion model provides a plausible description of the concentration profile, and may be the explanation for the missing moment at Cu/Ni interfaces. The intermixed region is predicted to be somewhat larger than the number of layers corresponding to the missing moment, in general agreement with x-ray measurements.[11]

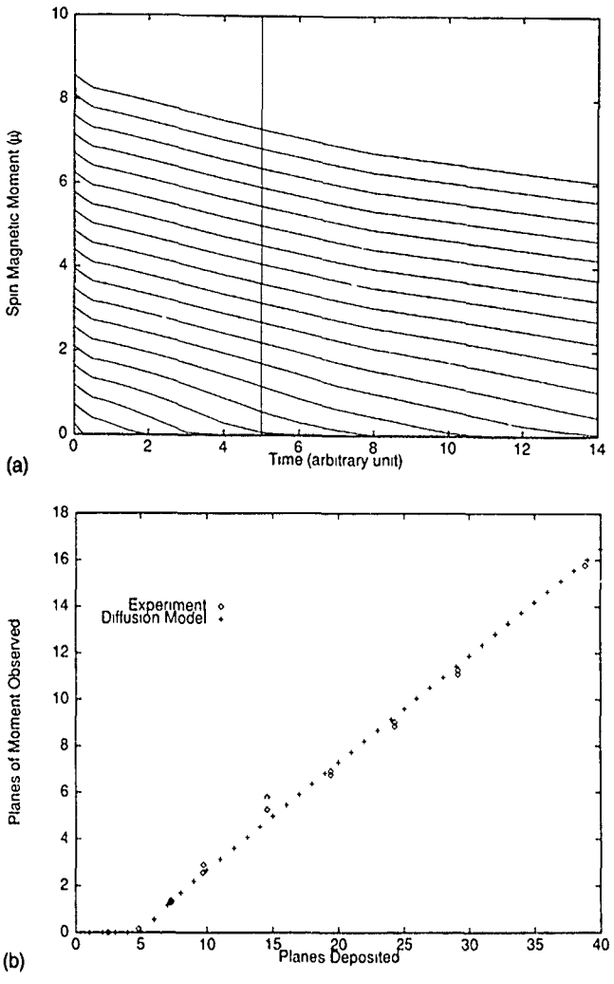

FIG. 1. (a) The total spin magnetic moment as calculated in the model is shown as a function of τ for various n_{Ni}. The number of Ni planes goes from 2 in the lower left corner to 20 at the top. (b) Magnetization (expressed in terms of an equivalent number of planes with bulk moments) vs the number of planes deposited. Calculated and experimental results are shown for Cu/Ni/Cu sandwiches.

III. PERMALLOY/CU INTERFACES

In the case of Permalloy ($Fe_{0.2}Ni_{0.8}$)/Cu interfaces, the situation is more complicated. Fe, which contributes as much to the total moment of Permalloy as Ni, is unlikely to have its moment reduced by mixing at the interface, since the moment of an Fe atom as an impurity in Cu is greater than that of an Fe atom in bulk Fe. This picture is confirmed by our calculation of the moments in Permalloy/Cu/Permalloy sandwiches with interfacial mixing, as shown in Table I. We find that the moment on Fe actually increases slightly for atoms in the nominally Cu layer, while the Ni moment decreases. Thus, although it may be possible to model the missing moment at Permalloy/Cu interfaces similarly to our treatment of the Ni/Cu interfaces, an alternative or additional explanation for the missing moment at Permalloy/Cu inter-

TABLE I. Calculated moments on Ni and Fe near Permalloy Cu interfaces. It is assumed that three layers have interdiffused with a simple linear diffusion profile.

System	Relative energy (mHa)	Ni moment (μ_B)	Fe moment (μ_B)
Ferromagnetic Ni0.8Fe0.2	0.00	0.570	2 59
Disordered local moment Ni0.8Fe0.2	1.70	0.050	2.55
Ferromagnetic Ni0.4Fe0.1Cu0.5	0.00	0.292	2.54
Disordered local moment Ni0.4Fe0.1Cu0.5	0.33	0.023	2.51

faces is that as an Fe atom becomes increasingly surrounded by Cu and very weakly magnetic Ni, its moment becomes increasingly decoupled from the moments of its neighboring magnetic atoms, i.e., the exchange interaction is substantially weakened and the spins disorder.

In order to test this hypothesis, we calculate the total energy of Ni, Permalloy, and a hypothetical Permalloy–Cu alloy, both in the ferromagnetic state and in a state with disordered local moments.[12] These calculations provide a rough idea of the relative energy cost for disordering the moments in the presence of the exchange coupling, which attempts to align them ferromagnetically. These calculations were performed using the local density approximation and the layer Korringa–Kohn–Rostoker coherent potential approximation technique.[13] Details of the calculations will be published elsewhere.

For bulk Permalloy, we find (Table II) that the ferromagnetic state is stable with respect to a state in which the moments are completely disordered by 1.7 mHa (1 mHa =0.0272 eV or 1 mHa/k_B=316 K). For a hypothetical Permalloy–Cu alloy, such as might form at the interface between Permalloy and Cu, we find that the exchange forces holding the moments in ferromagnetic alignment are much weaker. The energy difference ($\approx\frac{1}{3}$ mHa$\approx$100 K) between the ferromagnetic state and the disordered local moment state is smaller by a factor of 5 for the alloy.

It is unlikely that a sharp ferromagnetic transition will be observed from any disordered moments near the interfaces, since we expect that in most samples there will be a continuum of environments and local concentrations. We expect that even at zero temperature these very small exchange forces may be overcome by local perturbations due to strains, local fluctuations in concentration, crystal fields, etc. This is consistent with the temperature variation of T_{nf} observed for annealed Permalloy/Cu spin valves, where only about 10% of the moment lost at RT was recovered when cooling to 4 K.[3] The presence of disordered local moments and of decreased local moments near the interface is expected to cause a large reduction in the GMR effect, because it spoils the very close matching between the majority spin potentials and leads to greatly increased scattering.

The increased GMR observed[4] when Co is added to the Permalloy/Cu interface may also be explained in terms of the reduction of disorder in the moments at the interface. Since cobalt and Cu are mutually insoluble below 500 °C, cobalt may impede the mixing of the Permalloy and Cu near the interface. Probably more important, however, is the ability of cobalt to maintain its ferromagnetic alignment, even in the presence of dilution by Cu. To test this idea, we performed total energy calculations for an equiconcentration fcc cobalt–Cu alloy in its ferromagnetic state and in the disordered local moment state. The ferromagnetic state was more stable by 2.1 mHa. Thus, we predict that the ferromagnetic exchange interaction in fcc cobalt, even when diluted by 50% Cu, is stronger than in Permalloy with no dilution.

A theory of the electrical conductivity of homogeneous random alloys based on the Korringa—Kohn—Rostoker coherent potential approximation (KKR-CPA) is generalized to treat an inhomogeneous alloy in which the concentrations of the constituent atoms can vary from site to site. A special case of such a system is an epitaxial multilayer system. We develop the theory for such systems and show how it can be implemented by using the layer Korringa—Kohn—Rostoker technique to calculate the electronic structure. Applications to magnetic multilayers and to the calculation of the giant magnetoresistance are discussed.

I. INTRODUCTION

Recently, there has been great interest in the transport properties of layered magnetic materials because of the discovery of a new form of magnetoresistance,[1,2] which may have important practical applications. The transport properties of layered materials have been the subject of several theoretical investigations already. Fuchs,[3] and later Sondheimer,[4] obtained a solution to the semiclassical Boltzmann equation with boundary conditions appropriate to a thin film. Barnás and co-workers[5] extended this approach to the case in which the film has several layers with differing scattering rates. Levy and co-workers[6–10] used the more rigorous Kubo–Greenwood theory,[11,12] which avoids certain conceptual difficulties associated with the semiclassical approach. The work described in this paper also starts from the Kubo–Greenwood linear response formula, but it is based on quantities calculable from first principles electronic structure theory. We do not assume that the scattering is weak or that the electron wave functions are those of free electrons. The only necessary inputs to our calculations are the atomic numbers and concentrations of the atoms in each layer.

Our approach is based on the Korringa–Kohn–Rostoker coherent potential theory for transport in homogeneous random alloys.[13] We first generalize this theory so that it can be applied to the case in which the concentrations of the constituent atoms can vary from site to site, then we treat the particular case of layered systems. Finally, we show how this theory can be implemented using the layer Korringa–Kohn–Rostoker technique.[14]

II. CONDUCTIVITY OF INHOMOGENEOUS ALLOYS

We define the nonlocal conductivity $\sigma^s_{\mu\nu}(\mathbf{r},\mathbf{r}')$ as the linear response of the current of electrons of spin s at point $\mathbf{r}$ in direction μ to the local applied field at point $\mathbf{r}'$ in direction ν,

$$J^s_\mu(\mathbf{r}) = \int d\mathbf{r}' \sum_\nu \sigma^s_{\mu\nu}(\mathbf{r},\mathbf{r}') E^s_\nu(\mathbf{r}'). \tag{1}$$

Here, "local applied field" means the change in the local electrostatic field that arises due to the application of a potential difference across the sample. For an inhomogeneous system, this may differ from the average applied field and it may be different for different spins.[8]

For a homogeneous random alloy, the current and applied field can be assumed to be uniform, so that one can define a single conductivity that is also uniform, $J^s_\mu = \Sigma_\nu \sigma^s_{\mu\nu} E_\nu$. This is the conductivity that is given by the Kubo–Greenwood formula[11,12]

$$\sigma^s_{\mu\nu} = \frac{\pi\hbar}{N\Omega} \left\langle \sum_{\alpha,\alpha'} \langle\alpha|j_\mu|\alpha'\rangle\langle\alpha'|j_\nu|\alpha\rangle \delta(\epsilon_F - \epsilon_\alpha) \times \delta(\epsilon_F - \epsilon_{\alpha'}) \right\rangle, \tag{2}$$

where j_μ is the current operator, $j_\mu \equiv (-i\hbar e/m_e)\partial/\partial r_\mu$, Ω is the volume per atom, and N is the number of atoms. The quantum states $|\alpha\rangle$ in Eq. (2) represent the exact eigenfunctions of a particular configuration of the random potential, and the large angle brackets indicate an average over configurations.

In order to define a nonlocal site-dependent conductivity, $\sigma^{ij,s}_{\mu\nu}$, we define the current density at site i for spin s as the average of the current density over the atomic cell at that site, $J^{i,s}_\mu = \Omega_i^{-1} \int_{\Omega_i} d\mathbf{r}\, J^s_\mu(\mathbf{r})$. We also assume that the local field, $E^s_\nu(\mathbf{r})$, is constant over each atomic cell. Thus, we write Ohm's law in a discrete form, in which the current at site i is related to the local electric field at site j through the two-point conductivity function, σ^{ij},

$$J^{i,s}_\mu = \sum_{j\nu} \sigma^{ij,s}_{\mu\nu} E^{j,s}_\nu. \tag{3}$$

The superscript s on the local field indicates that it can be spin dependent, as has been emphasized by Camblong *et al.*[8] The local field will be determined *after* the nonlocal conductivity is determined by the requirement of current continuity in the steady state, $\Sigma_\mu \partial J^s_\mu(\mathbf{r})/\partial r_\mu = 0$.

The intersite conductivity, $\sigma^{ij,s}_{\mu\nu}$, is given by Eq. (2), with the matrix element integrals $\langle\alpha|j_\mu|\alpha'\rangle$ and $\langle\alpha'|j_\nu|\alpha\rangle$ restricted to sites i and j, respectively, and can be seen to depend on

 0021-8979/94/76(10)/6808/3/$6 00 © 1994 American Institute of Physics

the *imaginary part* of Green's function, $\Sigma_\alpha|\alpha\rangle\langle\alpha|\delta(\epsilon_F-\epsilon_\alpha)$. It can be written in terms of the Green's function, $G(\mathbf{r},\mathbf{r}';\epsilon_F)$, by writing

$$\sigma_{\mu\nu}^{ij,s}=\frac{1}{4}\sum_{p,p'=\pm 1}(pp')\tilde{\sigma}_{\mu\nu}^{ij,s}(\epsilon_F+i\eta p,\epsilon_F+i\eta p'), \quad (4)$$

where η is infinitesimal, and where

$$\tilde{\sigma}_{\mu\nu}^{ij,s}(z_1,z_2)=\frac{-\hbar}{\pi\Omega_i}\int_{\Omega_i}d\mathbf{r}\int_{\Omega_j}d\mathbf{r}'\; j_\mu(\mathbf{r})G^s(\mathbf{r},\mathbf{r}';z_1)j_\nu(\mathbf{r}') \times G^s(\mathbf{r}',\mathbf{r};z_2). \quad (5)$$

Following Ref. 13, we write Green's function in terms of the scattering path operator of multiple scattering theory, $\tau_{LL'}^{ij,s}$, and the local solution to the Schrödinger equation on site i, $Z_L^{i,s}(\mathbf{r},z)$,

$$\frac{\hbar^2}{2m_e}G^s(\mathbf{r}_i,\mathbf{r}_j')=\sum_{L_1L_2}Z_{L_1}^{i,s}(\mathbf{r}_i)\tau_{L_1L_2}^{ij,s}Z_{L_2}^{j,s}(\mathbf{r}_j')+\text{S.T.} \quad (6)$$

The scattering path operator τ is a "representation" of Green's function within the angular momentum space, and depends on the atomic t matrices, $t_L^{i,s}$, calculated from the self-consistent atomic potentials, and on the structure constants, which depend only upon the positions of the atoms. The singular term in the Green function (S.T.), which involves the irregular solution to the local Schrödinger equation, can be omitted from the calculation of the conductivity because it does not contribute to Eq. (4). Thus, we write the conductivity in the form

$$\tilde{\sigma}_{\mu\nu}^{ij,s}(z_1,z_2)=\frac{-4m_e^2}{\pi\hbar^3\Omega_i}\sum_{L_1L_2L_3L_4} \times\langle M_{L_4L_1}^{i\mu,s}(z_2,z_1)\tau_{L_1L_2}^{ij,s}(z_1) \times M_{L_2L_3}^{j\mu,s}(z_1,z_2)\tau_{L_3L_4}^{ji,s}(z_2)\rangle, \quad (7)$$

where the dipole matrix element is given as

$$M_{L_1L_2}^{i\mu,s}(z_1,z_2)=\frac{-ie\hbar}{m_e}\int_{\Omega_i}d\mathbf{r}\; Z_{L_1}^{i,s}(\mathbf{r},z_1)\nabla_\mu Z_{L_2}^{i,s}(\mathbf{r},z_2). \quad (8)$$

So far, we have not made any serious approximations in evaluating the linear response to the applied field. Under certain circumstances, it may be computationally feasible to evaluate Eq. (7) directly, however, in this paper we use the coherent potential approximation (CPA) to put this equation into a more tractable form. The CPA is a technique for "self-consistently" averaging over the atomic configurations. The individual atomic t matrices, t_α^i are replaced in the CPA by "coherent" t matrices, t_c^i. The self-consistency condition for determining these "coherent" t matrices is $\Sigma_\alpha c_j^\alpha x^{\alpha j}=0$. Here $x^{\alpha j}$ describes the scattering caused by replacing a coherent t matrix by one for an atom of type α at site j, and is given by $x^{\alpha j}=\Delta m^{\alpha j}\,D^{\alpha j}$, where $\Delta m^{\alpha j}$ is the difference between the inverse of the coherent t matrix and the t matrix for an atom of type α on site j, $\Delta m^{\alpha j}=(t_c^j)^{-1}-(t_\alpha^j)^{-1}$, and $D^{\alpha j}$ is given by $D^{\alpha j}=(1-\tau_c^{jj}\,\Delta m^{\alpha j})^{-1}$.

We follow Rcf. 13 to average the two particle Green's function and obtain an expression for the conductivity of the form

$$\tilde{\sigma}_{\mu\nu}^{ij}=\frac{-4m_e^2}{\pi\hbar^3\Omega_i}\sum_{L_4L_1}\tilde{M}_{L_4L_1}^{i\mu}\mathscr{L}_{L_1L_4}^{ij\nu}, \quad (9)$$

where the function $\mathscr{L}$ is given by

$$\mathscr{L}_{L'L''}^{j\nu}=\sum_{L_1L_2}\tau_{L'L_1}^{cij}\tilde{M}_{L_1L_2}^{j\nu}\tau_{L_2L'}^{cji} +\sum_{L_i}\sum_{k\alpha}c_k^\alpha\tau_{LL_1}^{cik}x_{L_1L_2}^{\alpha k}\mathscr{L}_{L_2L_3}^{kj\nu}x_{L_3L_4}^{\alpha k}\tau_{L_4L'}^{ck\imath}, \quad (10)$$

where the second term is the vertex correction, and $\tilde{M}_{LL'}^{i\mu}$ is a particular average over the matrix elements for the various types of atoms that may occupy site i,

$$\tilde{M}^{i\mu}=\sum_\alpha c_i^\alpha\tilde{D}^{i\alpha}M^{i\alpha\mu}D^{i\alpha}. \quad (11)$$

Equations (9)–(11) are the generalization of the KKR-CPA theory of transport to an inhomogeneous alloy. The generalization from the results of Ref. 13 is straightforward because the CPA self-consistency condition is a single site condition and therefore can be applied independently on each site. For a general inhomogeneous alloy, this theory would be difficult to implement, because it would be hard to calculate the scattering path operators τ_c^{ij}. However, for a layered system that retains a two-dimensional periodicity, implementation is feasible, as we describe in the next section.

III. APPLICATION TO LAYERED SYSTEMS

In this section we consider a special case where the concentration of the alloy can vary from layer to layer, but is uniform within each layer. The CPA average is performed on the atomic sites to produce an effective layered system that has a two-dimensional periodicity. We use a notation in which a site labeled by i in Sec. II and representing any lattice site in the three-dimensional crystal acquires two labels: $i\rightarrow Ii$, where the upper case I distinguishes different *atomic* layers, and the lower case i labels a site within layer I. The probability of site Ii being occupied by an atom of type α depends only on the layer index, I. Thus, suppressing the angular momentum, Cartesian, and spin indices, we can write Eq. (9) as $\tilde{\sigma}^{IiJj}=(-4m_e^2/\pi\hbar^3\Omega_i)\tilde{M}^{Ii}\mathscr{L}^{IiJj}$. The interlayer conductivity can then be written in the form $\tilde{\sigma}^{IJ}=N_I^{-1}\Sigma_{ij}\tilde{\sigma}^{IiJj}$, where N_I is the number of atoms per layer.

Because of the two-dimensional periodicity (after the CPA average), we can relate the scattering path operator that connects any two sites τ_c^{IiJj} to a scattering path operator that connects layers through an integral over the two-dimensional Brillouin zone, of area Ω_z,

$$\tau_c^{IiJj}=\Omega_z^{-1}\int_{\Omega_z}d^2q\;\tau_c^{IJ}(\mathbf{q})e^{i\mathbf{q}\cdot(\mathbf{R}_i-\mathbf{R}_j)}. \quad (12)$$

These layer scattering path operators τ_c^{IJ} can be calculated using the layer KKR formalism.[14]

The final expression for the conductivity is expressed in terms of matrices indexed by the layer numbers, $\tilde{\sigma}^{IJ}=(-4m_e^2/\pi\hbar^3\Omega_t)\tilde{M}^I\mathscr{L}^{IJ}$, where

$$\mathscr{L}^{IJ}=\Omega_z^{-1}\int_{\Omega_z} d^2q\ \tau_c^{IJ}(\mathbf{q})\tilde{M}^J\tau_c^{JI}(\mathbf{q}) + \sum_{K,\alpha} c_K^\alpha\Omega_z^{-1}\int_{\Omega_z} d^2q\ \tau_c^{IK}(\mathbf{q})x_K^\alpha\mathscr{L}^{KJ}x_K^\alpha\tau_c^{KI}(\mathbf{q}). \tag{13}$$

The local fields can be determined after σ^{IJs} is obtained, by using $J^{Is}=\Sigma_K\sigma^{IKs}E^{Ks}$, and the condition that the current for each spin must be continuous in the steady state. Two geometries are commonly discussed. If the field is applied parallel to the layers, sometimes referred to as "CIP" for "current in the plane," the local fields will be uniform by symmetry and equal to the average applied field. Thus, the overall conductivity will be given by $\sigma=t^{-1}\Sigma_{IKs}t_I\sigma^{IKs}$, where t_I is the thickness of layer I and t is the total film thickness. If the field is applied perpendicular to the layers, $J^{I,s}$, will be independent of I for each spin. Thus, $J^s=\Sigma_K\sigma^{IKs}E^{KS}$, and the local fields can be obtained by inverting σ^{IKs},

$$E^{Is}=\sum_K[(\sigma^s)^{-1}]^{IK}J^s=\sum_K\rho_s^{IK}J^s. \tag{14}$$

This allows the current to be expressed in terms of the voltage difference across the sample, ΔV, as $J^s=\Delta V/\Sigma_{IK}t_I\rho_s^{IK}$. In this case, the resistivity for each spin (neglecting spin-flip scattering) is given by $\rho_s=t^{-1}\Sigma_{IK}t_I\rho_s^{IK}$, and the conductivities of the two spin channels should be added to obtain the overall conductivity.

The giant magnetoresistance effect is observed in layered films in which ferromagnetic layers alternate with nonmagnetic spacer layers. If the moments on neighboring ferromagnetic layers are brought into alignment by the application of a magnetic field, the electrical resistance of the film may decrease. This giant magnetoresistance systems can be calculated directly using the results derived in this paper by calculating the conductivity for the case in which alternate ferromagnetic layers are aligned parallel or antiparallel. Calculations that we have performed for cobalt—copper—cobalt sandwiches using the formalism of this paper implemented within the layer-KKR technique in the "CIP" arrangement show that the major contributions to the magnetoresistance arise from terms, σ^{IJ}, in which I and J are atomic layers adjacent to the ferromagnetic–spacer interfaces, and are on opposite sides of the spacer layer. Details of these calculations will be published elsewhere.

In this article the effects of dipolar and exchange interactions on the magnetoresistance curves in granular solids has been calculated using a generalized 3-*d* Monte Carlo model. This model allows the final configuration of magnetic moments to be calculated as a function of concentration, temperature, and magnetic field. The results show that interaction effects give rise to a finite resistivity in small magnetic fields. The magnitude of this finite magnetoresistance is found to increase with increasing concentration. Thus the maximum change in MR with field is found to be lowered by the interaction effects.

I. INTRODUCTION

The magnetoresistance phenomena have recently received major attention due to its potential application in magnetic sensors and recording heads. The first attempt to obtain a simple description for the magnetoresistance was made by Gittleman *et al.*[1] who showed that the change in resistivity with magnetic field is directly proportional to the moment to moment correlation of the neighboring grains averaged over all configurations

$$\rho(H) \propto \frac{\langle \boldsymbol{\mu}_i \cdot \boldsymbol{\mu}_j \rangle}{\mu^2}, \tag{1}$$

where $\boldsymbol{\mu}_i$ and $\boldsymbol{\mu}_j$ are the magnetic moments of the ith and jth neighboring grains, respectively.

For systems which contain uniform, noninteracting superparamagnetic particles (i.e., all the moments fluctuate thermally) the statistical average of $\langle \boldsymbol{\mu}_i \cdot \boldsymbol{\mu}_j \rangle / \mu^2$ along the field direction gives

$$\langle \boldsymbol{\mu}_i \cdot \boldsymbol{\mu}_j \rangle = \mu^2 [L(b)]^2 = \bar{M}^2, \tag{2}$$

where $\bar{M}[=M/M_s = L(b)]$ is the reduced magnetization of the system, $L(b)$ is the Langevin function with $b = \mu H / k_B T$, where H is the field acting on the grain, k_B is Boltzmann's constant, and T is the absolute temperature. In Ref. 1 interaction effects were represented by a mean-field term which was added to the applied field (H_a), i.e., $H \rightarrow H_a + \lambda M$. However, this way of representing interaction effects has always been criticized particularly when the problem is related to inhomogeneous systems and hence the strength of the interaction field is not directly proportional to M.

In general and particularly at low temperatures, the magnetoresistance curves exhibit hysteresis effects and plots of $\Delta\rho(H) = \rho(\infty) - \rho(H)$ as a function of field, give a peak near the coercivity, where $\rho(\infty)$ is the maximum resistivity in a saturating field.[2,3] In the case where no hysteresis is observed Eq. (2) has been adapted to analyze the MR curves and estimate the average volume of the cluster in Co-Ag granular systems.[4] In other Co-Ag systems the MR data are observed not to follow the $\bar{M}^2$ law particularly in the region of low fields which was attributed to different magnetic phases within the sample.[5] However in Ref. 5 and at low temperatures where hysteresis is observed, the value of $\Delta\rho(H = H_c)$ i.e., $\Delta\rho_{\max}$ was observed to be different from the value obtained at zero field (i.e., starting from a demagnetized state). This effect was attributed to interaction effects between the so-called active magnetic regions.

Thus, in order to provide an unambiguous explanation for the interaction effects on the behavior of MR in granular or quasigranular systems we have used a generalized 3-*d* Monte Carlo model in which the quantity $\langle \boldsymbol{\mu}_1 \cdot \boldsymbol{\mu}_2 \rangle$ can be examined directly as a function of temperature, field, and other variables.

II. MODEL

The model consists of a cubic cell in which the positions of the particles are generated randomly. The particle sizes were generated according to a log-normal distribution function and fitted randomly within the cell without their positions being overlapped. Anisotropy effects were also considered and the particles easy axes were generated randomly. According to this arrangement the axis system for any particle within the cell is described in Fig. 1 where the total energy of the ith particle is

$$E = KV_i \sin^2 \alpha - \boldsymbol{\mu}_i \cdot \mathbf{H}_T, \tag{3}$$

where K is the anisotropy constant (uniaxial) and $\mu_i = I_{sb} V$ is the magnetic moment of the particle, with I_{sb} the saturation magnetization of the bulk material, and V the particle volume. $\mathbf{H}_T(H_T, \theta_{HT}, \phi_{HT})$ is the total field that particle i experiences which is the vector sum of the applied field and the dipolar and exchange fields arising from neighboring particles j

$$\mathbf{H}_T = H_a \hat{z} + \sum_{i \neq j} \left[\frac{3(\boldsymbol{\mu}_j \cdot \mathbf{r}_{ij}) \mathbf{r}_{ij}}{d_{ij}^5} - \frac{\boldsymbol{\mu}_j}{d_{ij}^3} \right] + c^* \sum_{i \neq j} \boldsymbol{\mu}_j, \tag{4}$$

where the applied field (H_a) is chosen to be along the z axis. The second term of Eq. (4) represents the vector sum of the total dipolar fields arising from neighboring particles while the third term represents the vector sum of the exchange fields with C^* being the average exchange coupling between the grains whose surfaces lie within a distance comparable to the interatomic spacing ($\approx$10 Å). The range of the dipolar field is chosen to be at a distance of $3D_m$ from the particle under investigation where D_m is the median diameter of the particles. This range is chosen because the dipolar field aris-

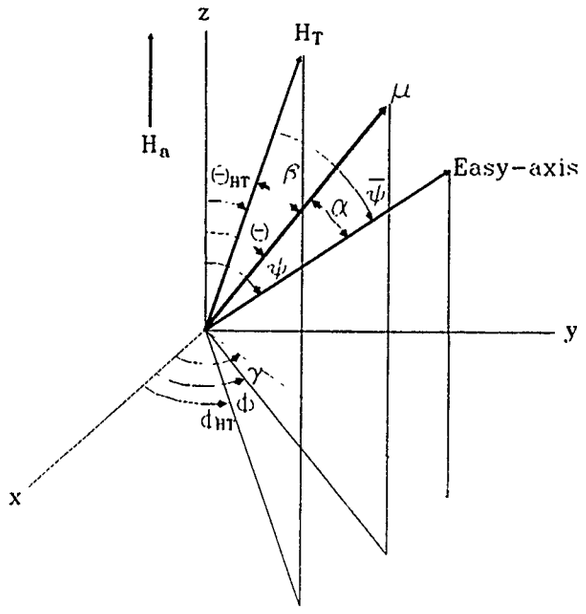

FIG. 1. Axis system for a particle within the cell.

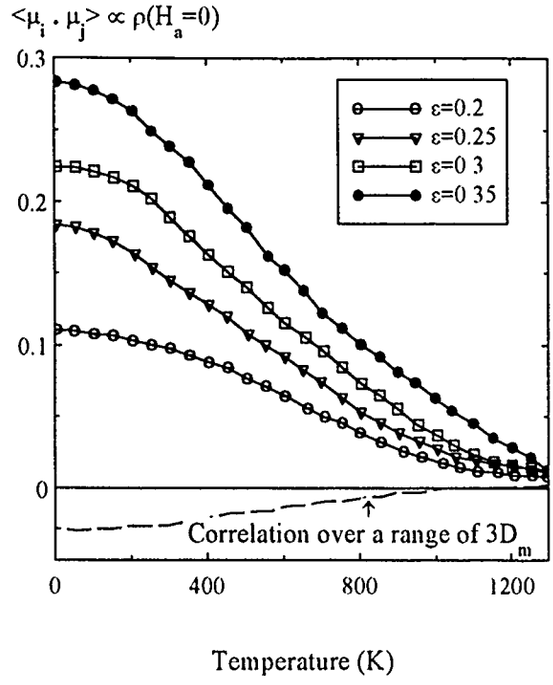

FIG. 2. The calculated short-range correlation of moments during the thermal demagnetization process.

ing from other particles located outside this range becomes very small (<4%). The calculation is based on the energy minimization of Eq. (3) where the final configuration of moments is obtained after several hundred iterations for θ and ϕ. Therefore, the magnetoresistance is calculated as $\rho \propto \langle \hat{\mu}_i, \hat{\mu}_j \rangle$ where the correlation range is taken over the neighboring particles, i.e., the short-range correlation. More details of this model and how the calculation is performed for both superparamagnetic and blocked particles are to be published elsewhere.[6]

III. RESULTS AND DISCUSSION

All the calculations were made using a primary cell which contained 400 particles. The particles generated were chosen to have a median diameter of $D_m=60$ Å with a standard deviation of $\sigma=0.15$ and an effective anisotropy constant of $K=2\times10^6$ erg/cc. These parameters were obtained for a fine particle system containing cobalt particles in previous experimental work.[7] For this system the MR curves were calculated as a function of concentration. One advantage of this study is that the distribution of particle sizes was invariant with particle concentration, thus any changes in the behavior was due entirely to interaction effects. However, in real alloy films the distribution will not be invariant with concentration and an extended report on this matter is in preparation.[6] In these calculations a value of $C^*=0.05$ was used in order to keep the exchange interaction effects small and the total interaction effect will then be dominated by dipolar interactions.

Before starting the calculation of the MR curve, the initial configuration of the magnetic moments (i.e., the demagnetized state) was achieved by thermal demagnetization. This technique produces demagnetized states which are equivalent to those obtained via an ac demagnetizing technique.[8] Thus the demagnetized state was achieved by taking the system to the Curie temperature and then cooling down slowly in zero applied field. Figure 2 shows the temperature variation of the short-range correlation of moments during the thermal demagnetization process. These data show that there is a finite positive correlation which increases with concentration due to the increase in the interaction strength within

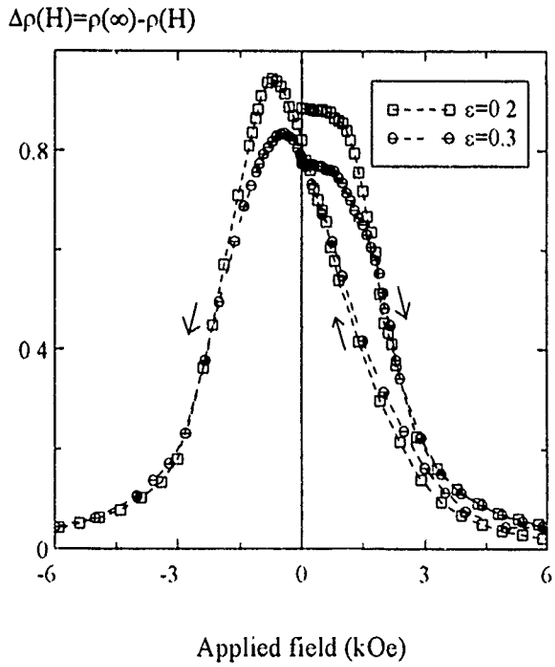

FIG 3. Calculated MR curves at $T=5$ K for Co particles

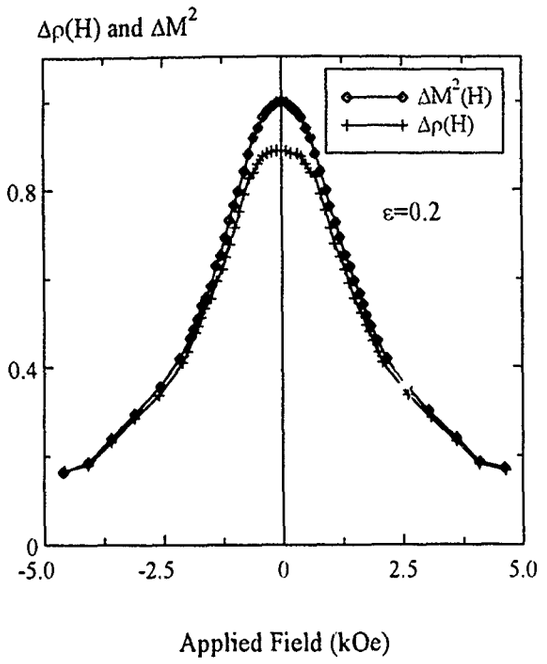

FIG. 4. Calculated room-temperature MR curves for Co particles.

the system. This result suggests that the moments have formed a vortex structure where the correlation over a short-range compared to the particle diameter is positive, whereas if this range is extended further a negative correlation is obtained (see the dotted line in Fig. 2 which represents the correlation of moments over a range of $3D_m$ where D_m is the average diameter of the system.

Figure 3 shows the calculated MR loops at $T=5$ K for concentrations $\epsilon=0.2$ and 0.3, starting from the demagnetized state and increasing the field to positive saturation and then to negative saturation. These data for $\Delta\rho(H)$ are typical and show that the value of $\Delta\rho(H=0)$ is lower than that for $\Delta\rho(H)_{\max}$ due to the fact that there is a finite positive correlation of moments in the demagnetized state. Also, these data show that as the concentration increases $\Delta\rho(H)_{\max}$ decreases which indicates that interaction effects in random systems depress the MR values and then decrease the maximum change in magnetoresistance for the system. Figure 3 also shows that due to interaction effects the peak in the $\Delta\rho(H)$ curve is shifted to lower fields and becomes more rounded.

Figure 4 shows the MR curves at room temperature ($T=300$ K) for the sample with $\epsilon=0.2$. In this case all the particles are superparamagnetic and the system exhibits no remanence and coercivity. Also on the same figure $\Delta\bar{M}^2$ data are shown where $\Delta\bar{M}^2=\bar{M}^2(\infty)-\bar{M}^2(H)$ and $\bar{M}$ is the reduced magnetization of the system. It is clear from the data that the $\Delta\rho(H)$ curve starts to deviate from the $\Delta\bar{M}^2$ curve as the field is reduced and at low fields the $\Delta\rho(H)$ exhibits a flat region which is lower than $\Delta\bar{M}^2$. This result can be understood since $\Delta\bar{M}^2$ is a measure of the average correlation over the whole system whereas the $\Delta\rho(H)$ data give the degree of short range correlation between the neighboring particles. At low fields the short-range correlation is insensitive to field changes and only gives small changes in the magnetoresistance. These results also shows that even at room temperature the short-range correlation is still significant which indicates that interaction effects in random systems decrease the values of $\Delta\rho(H)_{\max}$.

IV. CONCLUSIONS

In this article the effects of interactions on the behavior of GMR in idealized granular systems is examined using a generalized 3-*d* Monte Carlo model. Calculations of the short-range correlation of moments as a function of field are partially consistent with the observed MR curves in random systems. These calculations show that due to interaction effects the $\Delta\rho(H=0)$ is different from that for $\Delta\rho(H)_{\max}$. Also, when there is no hysteresis the $\Delta\rho(H)$ does not follow an M^2 law due to the fact that MR depends on the short-range order whereas the magnetization is an average over the whole system.

We report the observation of the GMR effect in spinodally decomposed Cu–20Ni–20Fe thin films. A $\Delta R/R$ value as high as 6.5% was observed at room temperature. In contrast to the commonly observed temperature-dependent behavior of $\Delta R/R$ increasing at low temperature; thin film shows a decrease in $\Delta R/R$ at 4.2 K. The dependence of the GMR effect on various deposition parameters, such as substrate temperature has been studied. The observed giant magnetoresistance behavior in Cu–20Ni–20Fe films is most likely related to the field-induced decrease in electron scattering in a pseudosuperparamagnetic material, as well as the spin-dependent scattering at the two-phase interface and in the ferromagnetic phase.

Giant magnetoresistance (GMR) type ferromagnetic/nonmagnetic superlattice structure was first discovered in a Fe/Cr system,[1] and later in other systems, including Co/Cu, Fe/Cu, Co/Ag, etc.[2,3] Recently, negative magnetoresistance in granular alloys, consisting of ferromagnetic particles dispersed in a nonmagnetic matrix, was also found in Cu–Co thin films,[4,5] as well as in other thin film systems, for example, Ag–Co, Cu–Fe, and Au–Co.[5–7] While many combinations of ferromagnetic–nonmagnetic phases are possible in granular alloys, the systems that exhibit the GMR effect are restricted to those that are essentially not soluble to each other in the solid state.

In our previous reports, giant negative magnetoresistance was created in spinodally decomposed Cu–Ni–Fe bulk alloys with artificial layer-like structures, in both the ferromagnetic–nonmagnetic and ferromagnetic–ferromagnetic two-phase states.[8,9] The superlattice-like structure with a size scale of 10–30 A was obtained, either by anisotropic deformation or by proper heat treatment of spinodally decomposed Cu–20Ni–20Fe alloys. In this study, the creation of the ultrafine and spinodally decomposed microstructure of Cu–20Ni–20Fe thin films by triode magnetron sputtering is reported, and the giant magnetoresistance and magnetization results are presented.

The Cu–20Ni–20Fe (wt.%) alloy thin films were prepared by dc magnetron triode sputtering from a 57 mm diam target. The films with a thickness of 1000–5000 Å were sputtered onto Si(100) single crystal substrate under various sputtering conditions. The substrate temperatures during sputtering were changed from 77 to 500 K. Various accelerating bias voltages, applied between the target and the substrate, ranging from 75 to 250 V were used in the sputtering.

The film thickness was determined by Rutherford Backscattering Spectrometry (RBS). The crystal structure and texture of the deposited films were investigated by x-ray diffraction (XRD) using K_α (Cu) radiation. The magnetoresistance (MR) measurement were made using the conventional four-point probe method with a magnetic field applied in the film plane. The measurements were carried out at various temperatures (4.2 K–295 K) and fields up to 60 KOe. The magnetic properties were studied by using a vibrating sample magnetometer. The microstructure of thin films was studied by high resolution transmission electron microscopy (TEM) using JEOL 4000 microscope operated at 400 kV, after sample thinning by ion milling at 77 K.

The Cu–20Ni–20Fe film was first deposited onto a substrate at a temperature of 77 K with an Ar accelerating bias of 200 V and under a pressure of 4 mTorr. Figure 1 shows the room temperature and 4.2 K magnetoresistance (MR) ratio versus the applied magnetic field for this film. The MR ratio was defined here as $\Delta\rho_m/\rho_s$ or $\Delta R_m/R_s$, where ρ_s (or R_s) is the electrical resistivity or resistance near the saturation field. The electrical resistivity of the film in zero field is about 24 $\mu\Omega$ cm at room temperature and 14 $\mu\Omega$ cm at 4.2 K. As the field strength is increased, the electrical resistivity of the film decreases continuously. The as-deposited sample exhibits a negative room temperature magnetoresistance ratio of about 6.5% at H=60 KOe. The MR ratio versus H curve is not saturated at the maximum applied field, and hence the maximum magnetoresistance ratio attainable must

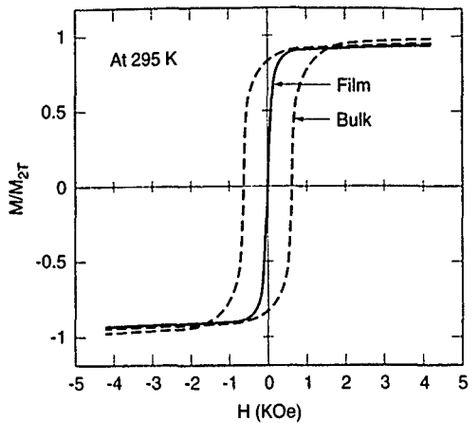

FIG. 2. M–H loops for the as-deposited film and bulk Cu–20Ni–20Fe alloy.

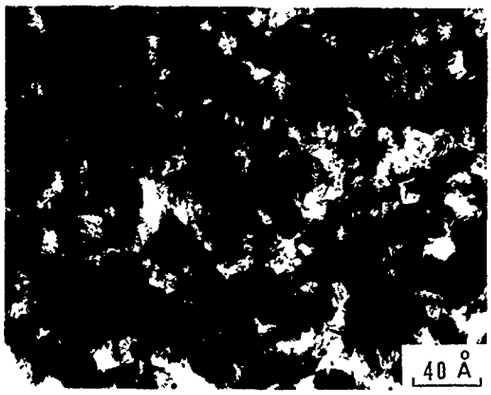

FIG. 3. Spinodally decomposed microstructure in the as-deposited Cu–Ni–Fe film.

be higher than 6.5% measured at the field of 6 T. The magnetoresistance ratio of the sample in Fig. 1 was also measured with magnetic fields up to 2 T, applied perpendicular to the film surface. When the demagnetizing field is taken into consideration, essentially the same magnetoresistance behavior as for the in-plane field orientation was observed. Thus, the possibility of significant anisotropic magnetoresistance contribution is eliminated.

Shown in Fig. 2 is the M–H magnetization hysteresis loop at room temperature, measured with the maximum field of 2 T for the as-deposited film. The M–H loop for the bulk Cu–20Ni–20Fe alloy sample is also shown as a dotted curve for comparison. The as-deposited film exhibits a relatively small hysteresis with a relatively lower coercivity (Hc) of less than ~20 Oe, a remanence ratio (M_r/M_s) of ~0.2, and a saturation (M_s) of 130 emu/cm^3, which suggests a film microstructure with very fine particle size of the ferromagnetic phase, almost close to the superparamagnetic regime. However, the bulk sample with particle size of ~500 Å has a coercivity of 620 Oe, a remanence ratio of 0.87, and saturation of 200 emu/cm^3. Essentially, similar M–H behavior is observed at 4.2 K, except with slightly larger hysteretic behavior for both samples.

The x-ray diffraction study indicates that the main diffraction peak in the XRD pattern of this as-deposited film are, respectively, (111), (200), and (220) in the order of integral intensity for both the Cu-rich and the (Fe, Ni)-rich phases, as their lattice parameters are very close to each other and the peaks overlap due to the slight shift and broadening of the peaks. This suggests that polycrystalline structure exists in this as-deposited Cu–20Ni–20Fe film, and the composition fluctuation and phase separation in it is small, as indicated by diffraction peaks without significant splitting. Figure 3 shows the decomposition structure with a ~30 Å size composition modulation in the as-deposited Cu–Ni–Fe film. The Moire fringes in the TEM image suggests that the (Fe, Ni)-rich phase (the darker phase in Fig. 3) has a lattice parameter slightly different from that of Cu-rich matrix. The relative volume of the two phases is approximately 50% each. The particle size in the present film is comparable to the layer thickness, and the interlayer spacing between the ferromagnetic layers in GMR-type superlattice films, which is on the order of 10–30 A. Thus, the observed giant magnetoresistance in the as-deposited Cu–Ni–Fe film is attributed to the extremely fine-scale spinodally decomposed structure, the presence of which is further confirmed by magnetization measurement, as well as by XRD and TEM. The bulk spinodally decomposed Cu–20Ni–20Fe alloy (Cunife 1, a common permanent magnet material) with a particle size of ~500 Å was found to exhibit a magnetoresistance ratio of only about 0.6% at room temperature, with fields up to 6 T in our previous report.[8] Here we show that the promotion of the magnetoresistance effect in the spinodally decomposed Cu–Ni–Fe alloy could be achieved through microstructure modification by a sputtering process, in addition to the anisotropic deformation or heat treatment methods reported in the previous papers.

Upon cooling from room temperature to 4.2 K, the film exhibits a decrease of electrical resistivity by a factor of 1.7 (from 24 to 14 $\mu\Omega$ cm). In contrast to the resistivity, the $\Delta\rho_m$, defined as $(\rho_0-\rho_s)$, decreases by a factor of 3.3 (from 1.4 to 0.4 $\mu\Omega$ cm). The net result is that the room temperature MR ratio is higher than that at 4.2 K as shown in Fig. 4, which is opposite to the commonly observed tendency of MR ratio increasing at lower temperatures.

Comparing the MR ratio versus H curve to the M–H curve, the saturation field for the M–H curve appears to be

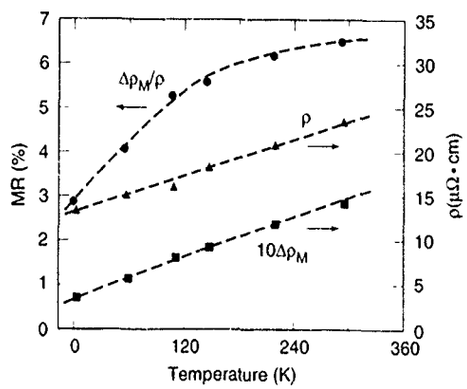

FIG. 4. MR ratio and resistivity vs temperature.

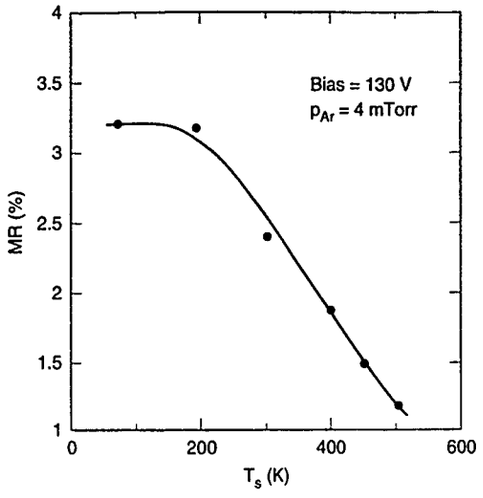

FIG. 5. Substrate temperature dependence of the MR ratio (for H=2 T) for the Cu–20Ni–20Fe film.

significantly lower than that for the corresponding magnetoresistance curve (Fig. 1). Although the exact mechanisms not fully understood are still obscure, the GMR behavior is believed to be related to the spin-dependent scattering, which is reduced when the angle between the magnetization of adjacent layers of magnetic grains (domains) is decreased. It is thus expected that the GMR and magnetization will be directly related.

However, in view of the much lower saturation field for the M–H curve than that for the magnetoresistance curve, as well as the abnormal temperature dependence of MR, it is speculated that the GMR mechanism in the present film may be qualitatively different from the general feature described by previous investigators. Similar to the as-deformed Cu–Ni–Fe alloy wire, the observed MR, as well as its temperature dependence, could be explained in terms of the mechanism proposed by Dieny *et al.*[10] The magnetic excitations in the nearly superparamagnetic film, which is supported by the M–H curve data, as well as the XRD and TEM observation, lead to strong, but not necessarily spin-dependent, electron scattering. Such excitations are reduced by an applied field, and lead to the observed MR behavior. At lower temperatures, they are significantly reduced, and hence the field-related decreasing of resistivity becomes smaller than at higher temperatures. This gives the negative temperature dependence of the MR ratio for the film. However, the contribution of spin-dependent scattering at the two-phase interface and in the ferromagnetic phase to the GMR phenomenon could not be ruled out in this study. Further studies are necessary to verify the exact role of various mechanisms involved.

Figure 5 describes the substrate temperature (T_s) dependence of the MR ratio measured at room temperature in Cu–20Ni–20Fe thin film samples, prepared with an accelerating bias of 130 V and under Ar pressure of 4 mTorr. The MR ratio versus T_s curve shows a strong dependence of MR ratio on T_s. It increases from 1.2% to 3.2% after the substrate temperature is lowered down to 200 K or below. The measurement at room temperature indicates that higher coercivity, magnetization (at H=2 T) and remanence magnetization ratio (M_r/M_s) are obtained for the films deposited at higher T_s. For example, the magnetization for the film deposited at 500 K is ~380 emu/cm^3 at room temperature, which is about 2.5 times that for the film deposited at 77 K. In general, the films deposited at higher temperatures show more significant hysteresis behavior of M–H loops.

Higher substrate temperatures tend to increase the particle size (or wavelength in a spinodally decomposed structure) and compositional segregation. The Cu–20Ni–20Fe film deposited at low T_s below 300 K is composed of small particles (clusters) with comparatively smaller compositional variation, and gives small coercivity and a remanence magnetization ratio, which indicates a superparamagnetic-like behavior at the measurement temperatures. For the substrates at higher T_s, the larger driving force for the sputtered particles to diffuse and coalesce in the film enhances the particle growth, and phase separation. It is noteworthy that the energy (and mobility) of the impinging atoms on substrate surface during sputter deposition is much higher than that of bulk materials at nominally the same temperature as T_s. The magnetoresistance ratio (measured at H=2 T) is substantially reduced from 3.2% for the film with T_s=77 K to 1.2% for the film with T_s=500 K. This is most likely due to the particle coarsening at higher T_s, which will raise the superparamagnetic blocking temperature (T_b) for the (Fe, Ni)-rich clusters and reduce the degree of superparamagnetic fluctuation.

Relaxation of magnetoresistance and magnetization in granular $Cu_{90}Co_{10}$ obtained from rapidly quenched ribbons

P. Allia, C. Beatrice,[a] M. Knobel,[a] P. Tiberto,[a] and F. Vinai[a]
Dipartimento di Fisica, Politecnico di Torino, I-10129 Torino, Italy

Bulk granular $Cu_{90}Co_{10}$ systems displaying a negative giant magnetoresistance (GMR) were produced by submitting melt-spun ribbons to conventional annealing and dc joule heating in order to induce diverse microstructures. Room-temperature GMR values up to 9% at 20 kOe were found in samples produced using both kinds of thermal treatments. An evolution from a superparamagnetic towards a ferromagnetic behavior has been observed in samples submitted to different heat treatments. A long-time, nearly logarithmic relaxation of the magnetic remanence has been measured after fast removal of a magnetic field of 10 kOe. The progressive randomization of the magnetic moments also gives rise to a corresponding increase in the zero-field electrical resistance.

I. INTRODUCTION

A strong negative magnetoresistance has been observed in certain granular magnetic materials where clusters of a ferromagnetic metal such as Co or Fe are dissolved in a metallic matrix such as Cu or Ag.[1,2] Although the interest for these granular magnetic systems is obviously enhanced by the possible applications of the giant magnetoresistance effect (GMR), a great research effort is being focused on a number of open problems concerning their fundamental properties.[3,4] The magnetoresistance behavior of these heterogeneous alloys was first observed in deposited thin films.[5,6] Melt-spinning techniques have been successfully exploited to produce bulk metastable solid solutions where superparamagnetic and ferromagnetic clusters may be developed by effect of suitable annealing treatments.[7,8]

The technique of joule heating under a direct electrical current, where the temperature of a metallic ribbon strip is dramatically increased by the joule effect, has recently proven to be a most effective method to produce nanostructured ferromagnets starting from compositionally homogeneous, melt-spun ribbons.[9]

In this article, we report on the magnetic and transport properties of a set of CuCo granular bulk systems obtained by submitting the rapidly quenched alloy either to conventional annealings, or to dc joule heating under different currents for the same time. The latter technique allows one to easily produce materials with GMR comparable to the ones found in conventionally annealed materials. The superparamagnetic component of the considered granular magnetic materials is particularly evidenced by a significant relaxation of the magnetic remanence. In correspondence of this gradual reduction in the magnetic order, the zero-field electrical resistance of the samples is observed to steadily increase with time.

II. EXPERIMENT

A rapidly quenched $Cu_{90}Co_{10}$ alloy was obtained in ribbon form by planar flow casting in controlled atmosphere on a CuZr drum. Strips cut from the ribbon (width 5×10^{-3} m, thickness 5×10^{-5} m) were submitted either to furnace annealing in Ar atmosphere at T_a=440 and 500 °C for 1 h, or to dc joule heating *in vacuo*. The latter treatment was performed by clipping the samples between copper electrodes (electrode distance 1×10^{-1} m), and subsequently applying an electrical current I of constant intensity for 60 s. The electrical resistance R was continuously monitored by measuring the voltage drop across a standard resistor, in order to detect thermal and structural changes occurring in the samples.[10] A detailed description of the technique is given elsewhere.[11]

Room-temperature measurements of magnetization curves and magnetoresistance were performed on both as-quenched and annealed ribbon strips. The magnetic moment of each sample was measured as a function of the applied field H by means of a vibrating sample magnetometer (LDJ/VSM model 9500) up to H=10 kOe. The field behavior of the electrical resistance was measured up to H=20 kOe in the same magnetometer through a conventional four-contact technique. The magnetic field was applied either in the ribbon's plane, perpendicular to the bias current (transverse configuration), or normally to the ribbon plane (perpendicular configuration).

III. RESULTS AND DISCUSSION

Hysteresis loops give information about the development of Co clusters. The values of magnetic remanence (M_r) and coercivity (H_c) of selected samples are reported in Table I along with the saturation magnetization M_s determined by

TABLE I. Magnetic hysteresis parameters of various granular $Cu_{90}Co_{10}$ samples. Treatment times: joule heating 60 s; furnace annealing: 3600 s. The GMR ratio is defined in the text.

Treatment	H_c (Oe)	M_r (emu/g)	M_s (emu/g)	GMR (%)
As-quenched	42	0.12	7.7	−1.7
7 A (2.8×10^7 A/m^2)	141	0.53	10.0	−6.3
8 A (3.2×10^7 A/m^2)	185	1.4	10.9	−5.5
9.25 A (3.7×10^7 A/m^2)	198	1.4	15.2	−6.2

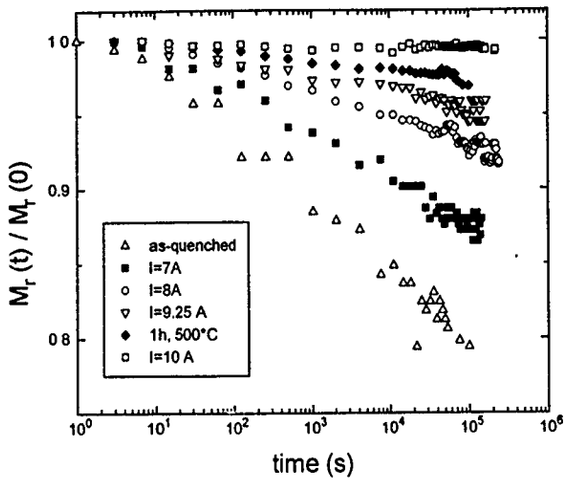

FIG. 1. Time behavior of the reduced magnetic remanence $M_r(t)/M_r(0)$ in joule heated and conventionally annealed $Cu_{90}Co_{10}$ samples.

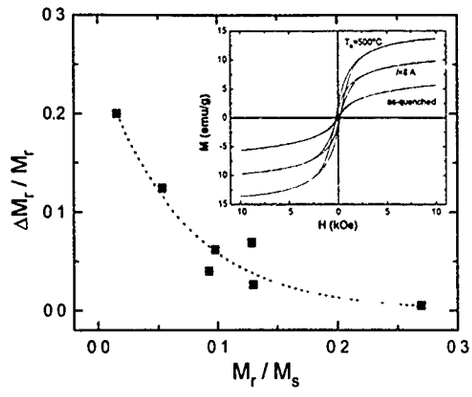

FIG. 2. Intensity of the remanence relaxation, $\Delta M_r/M_r \equiv [M_r(0) - M_r(10^5\ \text{s})]/M_r(0)$, as a function of the ratio M_r/M_s for the samples of Fig. 1. Inset: selected hysteresis loops up to $H=10$ kOe.

extrapolation of the experimental curves to $H \rightarrow \infty$ through a multiple-Langevin function fit. This fitting procedure allows one to assign values of the cluster radii ranging between 2 and 6 nm. The values of M_r and H_c of the as-quenched sample show that the starting material is not an ideal solid solution, although the size of quenched-in clusters is so small that the system nearly behaves as a superparamagnet. Table I shows that all annealing treatments induce a growth of H_c with increasing either the current density or the annealing temperature. Usually, the value of H_c may be taken as a measure of the average size of the ferromagnetic clusters once the value of the magnetic anisotropy constant of the precipitates is known.[12] This is however not the case for granular systems produced by high heating rates, where both the crystalline structure and the shape of the Co clusters are still unknown. The evolution of the product KV (V being the average cluster volume) with changing the annealing parameters is responsible for the magnetic behavior of this set of samples. A particularly large value of KV is possibly responsible for the peculiar magnetic and transport properties of the sample submitted to 4×10^7 A/m^2 joule heating.

A significant isothermal relaxation of the magnetic remanence was observed in all samples. This effect was measured by first applying to each sample a high magnetic field (10 kOe) for a fixed time (1 h), and subsequently measuring the time behavior of the magnetic moment in the range $1-10^6$ s after sudden removal of the field (stabilized in ≈5 s). The relaxation of $M_r/M_r(0)$ is reported in Fig. 1 for different samples. The curve for the specimen treated at $T_a=440$ °C is not shown because it is identical to the one observed in the sample submitted to joule heating at $I=8$ A. The relaxation kinetics is roughly of logarithmic type in all samples. However, the intensity of relaxation is strongly influenced by the thermal treatment, being highest in the as-quenched material, where Co clusters are very small and finely dispersed in the Cu matrix.[13] In this case the magnetic field is effective in orienting the magnetic moments, which are progressively randomized by thermal fluctuation when the field is removed. The increase in the average cluster size brings about both an increase in the ferromagnetic character of the hysteresis loops (Table I) and a reduction in the relaxation intensity, as evidenced in Fig. 2, where $M_r(0)-M_r(10^5\ \text{s})/M_r(0)$ is reported as a function of the ratio M_r/M_s for the considered set of samples.

The magnetoresistance (MR) ratio is defined here as $[R(H)-R_{max}]/R_{max}$, where R_{max} is the maximum resistance value obtained in each hysteresis loop. For as-quenched samples the MR value obtained for a maximum field of 20 kOe is about 1.7%. After a proper furnace annealing or joule-heating treatment, the room-temperature MR ratio can reach values as high as 9%, comparable to the highest GMR values obtained in granular solids.[1,2] Figure 3 shows two representative GMR curves, obtained for a conventionally annealed sample (curve a, $T_a=440$ °C) and for a current-heated ribbon (curve b, $I=6\,A$). The differences between the curves of Fig. 3 mainly arise from a different experimental procedure. Curve a was measured by waiting until complete stabilization of the resistance value was obtained for each value of H (≈15 s per point). Curve b was instead obtained during a continuous hysteresis loop (total time 5 min). The curves do not saturate up to 20 kOe, indicating the presence, in both samples, of a superparamagnetic phase responsible for the

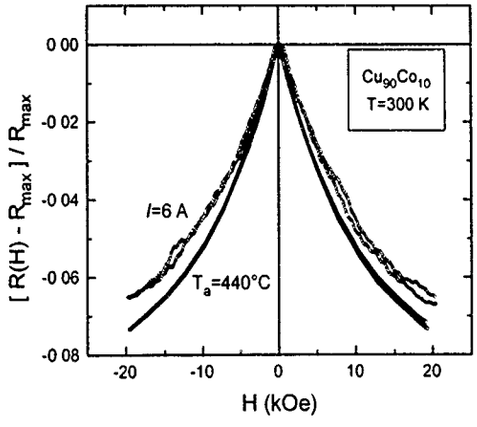

FIG. 3. Room-temperature giant magnetoresistance in a conventionally annealed and a joule-heated sample of granular $Cu_{90}Co_{10}$.

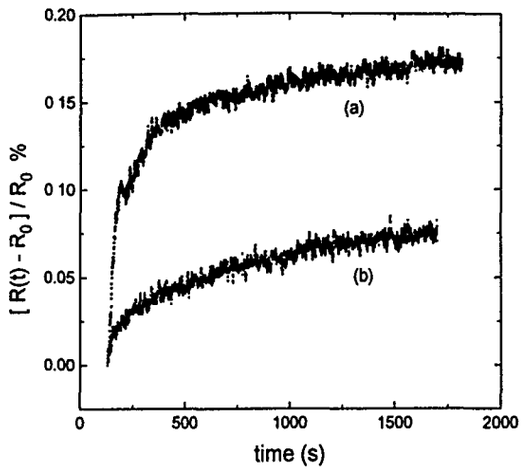

FIG. 4. Time behavior of the zero-field electrical resistance after applying a transversal (curve a) or perpendicular (curve b) field of 20 kOe for 120 s on a joule-heated sample (I=6 A, 60 s).

giant MR effect. In agreement with Wecker *et al.*,[7] we also verified that the $R(H)$ data obtained in a loop are always different from the ones obtained on the virgin curve.

Owing to the close relation existing between the magnetoresistance and the magnetic order within the material, a change in the electrical resistance should be measured along with the relaxation of M_r. In order to study this effect, we tried to follow the same procedure adopted for the remanence relaxation. However, we noticed that the resistance values are extremely sensitive to very small variations in temperature and/or magnetic history of the sample (the temperature coefficient of resistivity being as high as 9×10^{-4} K^{-1} in this granular material), and therefore extrinsic thermal effects dominate over the true relaxation of R. In order to overcome this difficulty, we applied a field of 20 kOe for 2 min only. The ratio $[R(t)-R_0]/R_0$, where R_0 is measured after suddenly removing the field, is reported in Fig. 4 as a function of the measurement time for a joule-heated sample (I=6 A) in both the transverse (curve a) and perpendicular (curve b) field configurations. Although the effect is very small, the gradual randomization of the magnetic moments induces an increase in the conduction-electron scattering and in the electrical resistance, as expected. The relaxation of R is about two orders of magnitude lower than the relaxation of M_r, as one should expect considering that the effect of a change in the magnetic order must have only a minor effect on the overall sample resistance. Owing to the reduced magnitude of the observed effect, the differences found between the two measurement configurations can have several origins, including anisotropic magnetoresistance,[1] ordinary magnetoresistance of Cu, or even the lack of complete sphericity of the clusters, as proposed by Xiao *et al.*[5]

In conclusion, the present results confirm that the joule-heating technique can be adopted as a reliable, fast, and easy-to-use treatment to produce granular magnetic materials. In fact, this treatment allows one to produce a variety of microstructures in the $Cu_{90}Co_{10}$ system, dependent on the value of the joule-heating current, and characterized by very small clusters displaying a magnetic behavior gradually evolving from the nearly superparamagnetic to a more ferromagnetic character. By properly choosing the treatment conditions, not only very similar MR curves, but also nearly identical magnetic parameters may be obtained through conventional annealing and joule heating, indicating that the same microstructures are generated independently of the rate of heating involved in the thermal treatments. Finally, the observed relaxations in both M_r and R, although detrimental to perspective applications of granular magnetic systems, are intrinsically very interesting and worthy of more detailed investigation in the near future.

The magnetic and magnetotransport properties of granular $Cu_{85}Fe_{15}$ prepared by mechanical alloying have been investigated. The sample was prepared by grinding fine powders of copper and iron in a high energy ball mill. Zero field cooled and field cooled susceptibilities showed a behavior that is typical of a superparamagnet. The blocking temperature T_B of 20 K was determined from ac susceptibility. The magnetoresistance reached 5.5% at 4.5 K in a field of 5 T. It was increased to 7.6% after the sample was annealed at 300 °C for 20 min. The hysteresis loop was measured for both magnetization and magnetoresistance. There was a clear correlation between the two. The magnetoresistance is due to the scattering associated with iron nanoparticles present in the samples and its dependence on particle size is discussed.

INTRODUCTION

The discovery of negative giant magnetoresistance (GMR) in Fe-Cr magnetic multilayers by Baibich *et al.*[1] and the subsequent finding that GMR occurs in many other multilayer ultrathin magnetic film systems[2–5] have attracted much attention. Recently, GMR was also found in granular structures where metallic ferromagnetic nanoparticles are dispersed in a nonmagnetic metal matrix.[6,7] Not only have these discoveries provided new opportunities for studying the fundamental issues of spin-dependent electrical transport phenomena but they may also have an enormous impact on the information storage technologies due to the potential device applications of these materials in magnetic read heads.[8] The fact that GMR also exists in some granular systems has provided opportunities to explore other preparation methods which are capable of producing the granular systems and are less expensive and more reliable than, for example, the commonly used sputtering techniques. Wecker *et al.*[9] have applied the melt-spinning method to produce bulk Cu-Co alloys by rapid solidification. For the optimally annealed samples the GMR was found to be 36% at 30 K. Ounadjela *et al.* have studied GMR in the Ag-Co granular system prepared by mechanical alloying.[10] GMR of 7.7% at 5 K was observed in their bulk mechanically alloyed $Ag_{70}Co_{30}$ sample. In this article, we report the magnetic and magnetoresistive properties of granular $Cu_{85}Fe_{15}$ prepared by mechanical alloying.

EXPERIMENTAL DETAILS

$Cu_{85}Fe_{15}$ was prepared by mechanical alloying using a high energy Spex 8000 mixer/mill. The starting materials were fine powders of copper and iron of 99.9% purity. Stoichiometric amounts of the powders were sealed in a grinding vial made of hardened steel under argon atmosphere. Also sealed in the vial were two hardened steel balls. The weight ratio of ball to sample was approximately 2:1. After 30 h of grinding, the product was shiny, almost colorless and in the form of small spherical dots. A SCINTAG x-ray powder diffractometer with Cu $K\alpha$ radiation was used for x-ray diffraction examinations. The sample was cold pressed into pellets, and some of those were annealed at low temperatures (T=300 and 550 °C) for 20 min in order to study the effects of such annealing on the interested physical properties.

The magnetic susceptibility of the mechanically alloyed sample was measured as a function of temperature under both zero field cooled (ZFC) and field cooled (FC) conditions, and measured with an ac field using a Quantum Design SQUID susceptometer (Model MPMS-5S). The blocking temperature of the superparamagnetic iron nanoparticles embedded in the copper matrix was determined from the data. Magnetization (M vs H) and hysteresis loop of the sample were examined at 4.5 K. Magnetoresistance measurements were carried out, using a four-point technique, at both room temperature and low temperatures as a function of applied field. Magnetoresistive hysteresis was also studied and compared with the magnetic hysteresis.

RESULTS AND DISCUSSION

The x-ray diffraction pattern of the $Cu_{85}Fe_{15}$ sample which was mechanically alloyed for 30 h showed only broad peaks from fcc copper. No peak from bcc α iron was observable. The diffraction peaks of the mechanically alloyed sample were slightly shifted toward lower angles relative to those of pure copper. This indicated an increase in the lattice constant a of the mechanically alloyed sample as compared to that of pure copper, which implies that a certain amount of iron has been dissolved in the fcc copper matrix. This result is consistent with the finding that mechanical alloying induces fcc solid solution $Cu_{1-x}Fe_x$ for $x<0.6$.[11–13] However, as will be discussed later, magnetic measurements indicated that our sample also contained undissolved iron particles. The reason that peaks from the iron were absent in the x-ray pattern is probably attributed to the extremely small sizes of the iron particles.

Figure 1 shows the magnetic susceptibility of the 30 h mechanically alloyed $Cu_{85}Fe_{15}$ measured under both field-cooled (FC) and zero-field-cooled (ZFC) conditions. What is obvious is the irreversibility indicated by the deviation be-

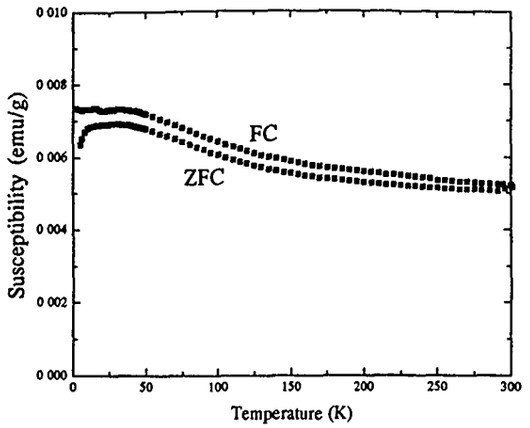

FIG. 1. dc magnetic susceptibilities of the as-mechanically alloyed $Cu_{85}Fe_{15}$ measured under both ZFC and FC conditions The measuring field is 2000 Oe.

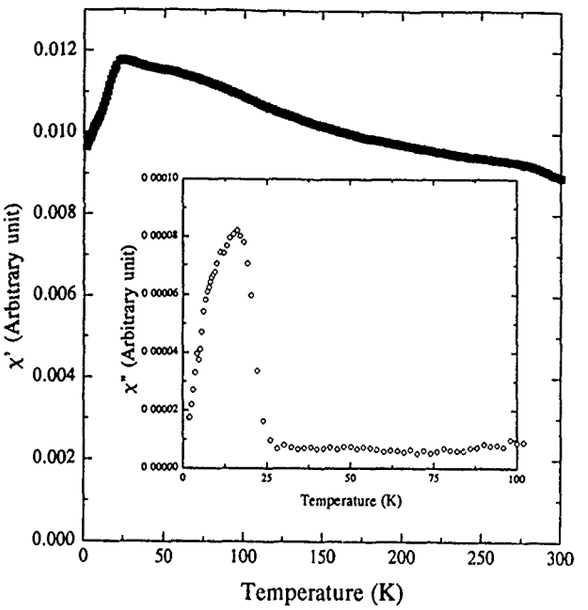

FIG. 2. The real part of the ac susceptibility χ' of the as-mechanically alloyed sample and imaginary part of the ac susceptibility χ'' (inset). Only the low-temperature portion of the χ'' is shown.

tween FC and ZFC susceptibilities. There is a broad maximum in the ZFC susceptibility at 20–30 K. This maximum can be caused by either a spin-glass-type transition or superparamagnetic iron particles. For a spin-glass transition, the peak in the ZFC susceptibility is normally very sharp and all irreversibility effects disappear just above the freezing temperature. On the other hand, in a superparamagnet, the maximum is broad and irreversibility persists well above the blocking temperature.[14] Therefore, we believe the observed irreversibility and broad maximum in the ZFC susceptibility of our sample is caused by an assembly of superparamagnetic iron particles dispersed in the copper matrix. In addition, the absolute value of susceptibility is quite high even at room temperature, which suggests that there is a wide distribution of particle size with blocking temperatures ranging from very low temperature to above room temperature. Figure 2 shows the real part of the ac ($f=32$ Hz) susceptibility χ' of the same sample. The inset shows the imaginary part χ'' in the low-temperature region. The average blocking temperature T_B determined from the peak in the ac susceptibility χ' is 20 K. As seen, χ'' shows a corresponding loss peak near the same temperature.

The magnetoresistance was measured as a function of applied field up to 5 T at 4.5, 77, and 300 K, respectively. Figure 3 shows such magnetoresistance, defined as $[\rho_{(H)}-\rho_{(0)}]/\rho_{(0)}$, versus applied field plots. The magnetoresistance reaches 5.5% at 4.5 K in a field of 5 T. It is reduced to 3.8% at 77 K and less than 0.2% at 300 K. The observed magnetoresistance shows no indication of saturation in a field of 5 T at all temperatures.

The as-mechanically alloyed sample was subsequently annealed for 20 min at 300 and 550 °C, respectively. Figure 4 is the magnetoresistance versus field plots at 4.5 K for samples annealed at these temperatures. The as-mechanically alloyed sample is also shown for comparison. The heat treatment at 300 °C results in an increase in magnetoresistance to 7.6% from 5.5% of the not-annealed sample. This is attributed to the precipitation of additional iron particles from the copper matrix, which contribute to the spin-dependent scattering process. As the annealing temperature is further increased to 550 °C, the sizes of the iron particles grow and become sufficiently large such that the GMR decreases significantly. The effects of annealing at the mentioned temperatures on the particle size have been well documented, for example, see Ref. 15.

Shown in Fig. 5 are the hysteresis loops for magnetization and magnetoresistance measured at 4.5 K. Only data below $H=3500$ Oe are shown. A clear correlation between the two hysteresis loops exists. The coercivity H_c (at which magnetization becomes zero) is about 500 Oe, and as can be seen, it is also the field at which magnetoresistance becomes zero.

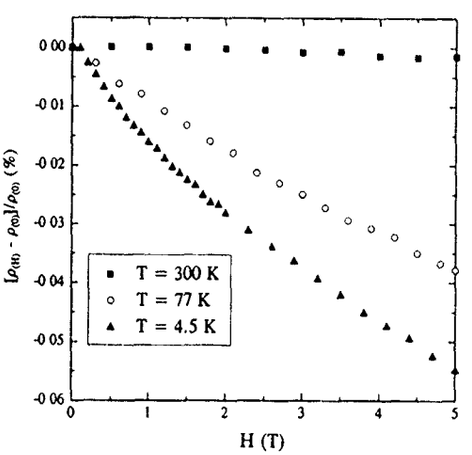

FIG. 3 Magnetoresistance of the as-mechanically alloyed sample vs applied field measured at 4 5, 77, and 300 K.

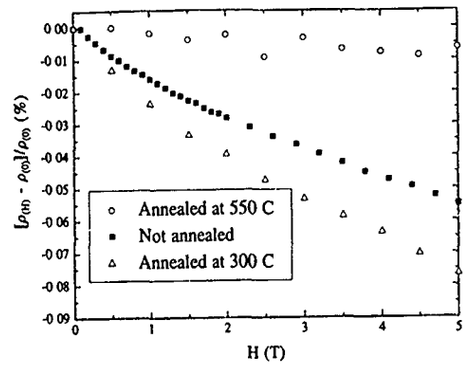

FIG. 4. Magnetoresistance as a function of applied field at 4.5 K for the as-mechanically alloyed sample and subsequently annealed at 300 and 550 °C samples.

CONCLUSIONS

The magnetic and magnetoresistive properties of granular $Cu_{85}Fe_{15}$ prepared by mechanical alloying have been studied. The presence of magnetic iron nanoparticles in the as-mechanically alloyed sample is demonstrated by both zero-field-cooled and field-cooled susceptibilities. The superparamagnetic behavior is also shown in its ac susceptibility from which a blocking temperature T_B of 20 K is derived. There is a clear correlation between the hysteresis loops of magnetization and magnetoresistance. The magnetoresistance is 5.5% at 4.5 K in a field of 5 T. It is increased to 7.6% after the sample was annealed at 300 °C for 20 min. The effect of such heat treatment is to let more iron particles precipitate out of the copper matrix. Further annealing at higher temperature has a deteriorating effect on the magnetoresistance. The largest magnetoresistance of 7.6% found in our sample is smaller than reported elsewhere using other preparation methods.[6,7] Improvement should be possible by optimizing parameters like grinding time, composition, and annealing temperature. As mentioned earlier, x-ray diffraction data indicate that a part of iron is dissolved in the fcc copper matrix in the as-mechanically alloyed sample, therefore the actual composition of the granular portion of the sample which contributes to GMR is not $Cu_{85}Fe_{15}$ but probably contains less iron. It is interesting to note that another granular system prepared by mechanical alloying $Ag_{70}Co_{30}$ exhibits MGR of 7.7% at 5 K, which is almost identical to the value found in our sample.

Granular giant magnetoresistive materials and their ferromagnetic resonances (abstract)

M. Rubinstein, B. N. Das, N. C. Koon, D. B. Chrisey, and J. Horwitz
U.S. Naval Research Laboratory, Washington, DC 20375-5000

Ferromagnetic resonance (FMR) can reveal important information on the size and shape of the ferromagnetic particles which are dispersed in granular giant magnetoresistive (GMR) materials. We have investigated the FMR spectra of three different types of granular GMR material, each with different properties: (1) melt-spun ribbons of $Fe_5Co_{15}Cu_{80}$ and $Co_{20}Cu_{80}$, (2) thin films of $Co_{20}Cu_{80}$ produced by pulsed laser deposition, and (3) a granular multilayer film of [Cu(50 Å)/Fe(10 Å)]×50. We interpret the linewidth of these materials in as simple a manner as possible, as a "powder pattern" of noninteracting ferromagnetic particles. The linewidth of the melt-spun ribbons is caused by a completely random distribution of crystalline anisotropy axes. The linewidth of these samples is strongly dependent upon the annealing temperature: the linewidth of the as-spun sample is 2.5 kOe (appropriate for single-domain particles) while the linewidth of a melt-spun sample annealed at 900 °C for 15 min is 3.8 kOe (appropriate for larger, multidomain particles). The linewidth of the granular multilayer is attributed to a restricted distribution of shape anisotropies, as expected from a discontinuous multilayer, and is only 0.98 kOe with the magnetic field in the plane of the film.[1]

Magnetoresistance of granular Cu-(Co,Fe) and Cu-Co-B (abstract)

R. v. Helmolt
Siemens AG, Research Laboratories, 91052 Erlangen, Germany and Institute of Physics, University of Augsburg, 86159 Augsburg, Germany

J. Wecker
Siemens AG, Research Laboratories, 91052 Erlangen, Germany

K. Samwer
Institute of Physics, University of Augsburg, 86159 Augsburg, Germany

Giant magnetoresistance (GMR) is known to occur in alloys consisting of superparamagnetic precipitates in a metallic matrix. This had been demonstrated for the first time for Cu-Co prepared as co-sputtered thin films[1] and later for rapidly quenched alloys.[2] For Cu-Fe no GMR has been reported even in multilayer systems. In order to study the transition from Cu-Co to Cu-Fe in more detail we prepared quasibinary $Cu_{90}Co_{10-x}Fe_x$ ribbons by conventional melt spinning followed by an annealing treatment to precipitate Co-Fe clusters in the Cu matrix. The particle sizes of the ferromagnetic phase have been determined by fitting the magnetization and magnetoresistance curves with a Langevin function. The saturation magnetization increases with increasing Fe content x for $x \leqslant 4$ as expected from the Slater–Pauling curve. However, a strong decrease of the magnetization is observed at high Fe contents. The GMR effect continuously decreases with increasing Fe content and for $x > 0.7$ no GMR is observed, similar to Cu-Fe multilayers. Small B additions were added to Cu-Co in order to improve the homogeneity of the as-quenched ribbons. For these samples the magnetoresistance is suppressed even by small B additions below 3 at. %. This is different from the Au-Co system, where B additions of up to 20% enhance the GMR effect.[3]

Evolution of recombination in a solid HDDR processed $Nd_{14}Fe_{79}B_7$ alloy

I. R. Harris
School of Metallurgy and Materials, The University of Birmingham, Birmingham, United Kingdom

A high-resolution scanning electron microscope was used to study the microstructural changes occurring during the desorption and recombination stages in a cast $Nd_{14}Fe_{79}B_7$ alloy HDDR processed at 780 °C. Phase identification was based on backscattered electron contrast. In the early stages of desorption, the disproportionated structure in the matrix coarsens to produce a mixture of Nd-rich (NdH_2 and/or Nd) and Fe-rich (αFe and/or Fe_2B) clusters. At the center of the specimen, regions of recombined multicrystalline $Nd_2Fe_{14}B$ phase are observed associated with Nd- and Fe-rich clusters. When desorption of hydrogen is almost complete, the microstructure consists of a $Nd_2Fe_{14}B$ matrix with a few remaining Nd- and Fe-rich clusters. The subsequent completion of recombination results in a multigrained $Nd_2Fe_{14}B$ structure, some grains being separated by Nd-rich material. The magnetic properties of the $Nd_{14}Fe_{79}B_7$ alloy have been measured at significant stages during the desorption/recombination process at 600 °C, the stages being deduced from electrical resistivity measurements. Initially, the material is noncoercive with a high magnetization at 1100 kA/m, reflecting the high proportion of αFe in the sample. As recombination proceeds, the magnetization drops and the coercivity increases as the fine-grained $Nd_2Fe_{14}B$ develops and the αFe disappears.

I. INTRODUCTION

The Hydrogenation–Disproportionation–Desorption and Recombination process (HDDR)[1,2] transforms a coarse-grained ingot (cast or homogenised) into a friable, powdered material with submicrometer grain size. The first stage results in the hydrogenation and decrepitation of the ingot (HD process).[3] The disproportionation reaction occurs at elevated temperature and produces an intimate mixture[2,4] of αFe, Nd hydride, and Fe_2B. Recombination occurs on hydrogen desorption at high temperature. The main potential of these coercive powders is to produce polymer bonded[1] and hot pressed[5] magnets.

It is possible to disproportionate solid blocks of Nd-Fe-B based alloys without decrepitating them by using very high heating rates under hydrogen[6] or introducing hydrogen at high temperature.[7] It has been observed that, in $Nd_{16}Fe_{76}B_8$, the disproportionation process begins at the grain boundaries at the Nd hydride/$Nd_2Fe_{14}B$ interface and then progresses into the matrix phase.[8,9] The block does not decrepitate as in the HD process. The process is referred to as "solid HDDR" and can be usefully employed to study the development of the HDDR microstructure because of the modified reaction kinetics.

II. EXPERIMENTAL PROCEDURE

Differential thermal analysis (DTA) was carried out in order to determine the starting temperatures of disproportionation in a hydrogen atmosphere and recombination under vacuum. The solid HDDR was carried out at 780 °C in an initial hydrogen pressure of 1 bar. Hydrogen was evacuated, and the samples held under vacuum for 20, 40, and 70 min at 780 °C. Finally, the samples were quenched in order to fix the recombined structure. The observations were carried out with a high-resolution field-emission scanning electron microscope (Hitachi 4000) using the backscattered electron mode.

An electrical resistivity monitoring method[8] was used to follow the average state of three samples during recombination at 600 °C under vacuum, after disproportionation at 700 °C in an initial hydrogen pressure of 0.7 bar. These low temperatures were chosen in order to slow the reaction and study only the transformations occurring in the matrix phase by avoiding the desorption and melting of the intergranular Nd-rich phase.[10] Intrinsic coercivity and magnetization at 1100 kA/m were measured with a vibrating sample magnetometer (VSM).

III. RESULTS AND DISCUSSION

A. Determination of the desorption temperature

Figure 1 represents the DTA graph showing the desorption of hydrogen from the disproportionated material with increasing temperature. The first peak starting at ≈100 °C corresponds to the transformation from NdH_{2+x} to NdH_2 that takes place within the disproportionated matrix and Nd-rich intergranular phase. The two peaks, starting at ≈600 °C, represent first, desorption of hydrogen from the disproportionated matrix and also recombination and second, from the Nd-rich grain-boundary phase.[11]

B. Microstructures of samples desorbed at 780 °C

During solid hydrogenation and disproportionation, a disproportionated front moves from the edges towards the

 0021-8979/94/76(10)/6825/3/$6.00 © 1994 American Institute of Physics

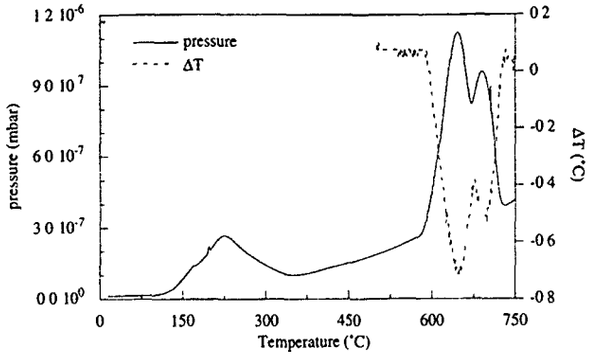

FIG. 1. ΔT and pressure traces vs temperature of the hydrogen desorption of the disproportionated $Nd_{14}Fe_{79}B_7$ material.

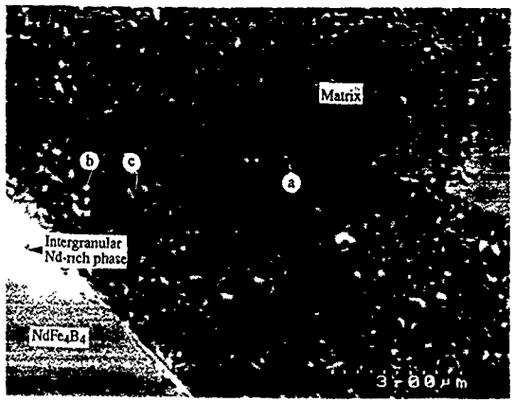

FIG. 2. Backscattered electron picture of a $Nd_{14}Fe_{79}B_7$ sample desorbed at 780 °C for 20 min. (a) colonies of lamellae, (b) Nd-rich cluster, (c) Fe-rich cluster.

center of the specimen. Because of the hydrogen diffusion during absorption and desorption, the microstructure of a solid disproportionated and recombined sample, at a given temperature and initial hydrogen pressure, depends on the region observed in the specimen and also the position considered in the original $Nd_2Fe_{14}B$ grains. The evolution of the microstructure with time, during the solid HDDR process, also depends upon the total volume of the specimen. Times given in the present work must therefore be considered in the light of these factors. It should also be noted that at $T \geqslant 655$ °C, the Nd-rich material melts as soon as the transformation of NdH_2 into metal Nd occurs.[12]

In the specimen, desorbed for 20 min, the distribution of the original grain boundaries, most of which contain $NdFe_4B_4$ and Nd-rich phases, has not been altered by this process and appears to be the same as in the cast material. Residual free-iron dendrites, present in the cast state, could also be observed. The colony-type structure,[8,9] observed in the matrix of disproportionated samples, has coarsened as shown in Fig. 2. The microstructure of the matrix, between the edges and the center of the sample, consists of small colonies of (a) lamellae, which are broader than those of a fully disproportionated matrix, indicating that coarsening has occurred, thus lowering the total interfacial energy. This microstructure corresponds to the stage where the desorption reaction is dominant. At the center of the specimen, the recombination of the $Nd_2Fe_{14}B$ phase has begun and Fig. 3 illustrates the formation of (d) the recombined, multicrystalline $Nd_2Fe_{14}B$ phase from the surrounding (e) Nd-rich and (f) Fe-rich particles. This microstructure is only located at the center of the sample occupying a very small volume fraction of the total volume. The specific identification of αFe and Fe_2B has not been possible so far by SEM studies.

Figure 4 shows the microstructure of a sample desorbed for 40 min. The structure is different from that shown in Fig. 2, as the matrix consists now of (g) a multicrystalline $Nd_2Fe_{14}B$ phase but still contains some remaining (h) Nd-rich and (i) Fe-rich clusters. This microstructure is similar to that of the $Nd_2Fe_{14}B$ region shown in Fig. 3 and was also observed by Nakayama and Takeshita.[13] The scale of clear regions indicates multicrystalline $Nd_2Fe_{14}B$ phase but individual crystallites cannot be imaged. Powder x-ray-diffraction analysis revealed that this sample consists predominantly of the $Nd_2Fe_{14}B$ phase.

Fully recombined samples were obtained after 70 min of desorption. This microstructure consists of submicrometer grains, some of which are delineated because they are surrounded by Nd-rich phase.

C. Desorption and recombination at 600 °C

Figure 5 represents the variation of normalized electrical resistivity [$\rho(0)$=resistivity at 600 °C before desorption] and hydrogen pressure with desorption time at 600 °C. Approximately three different stages could be identified during recombination, although in the bulk samples the various stages will overlap. When the temperature is lower than the melting point of Nd metal and the Nd-rich phase, it is possible to follow the recombination as a completely solid-state reaction occurring exclusively in the matrix phase and thus much less dependent upon the state and proportion of the intergranular Nd-rich phase. Thus, during desorption and recombination at 600 °C, the Nd-rich phase remains in the hydrided state. In the first stage (stage I in Fig. 5), the desorption of hydrogen

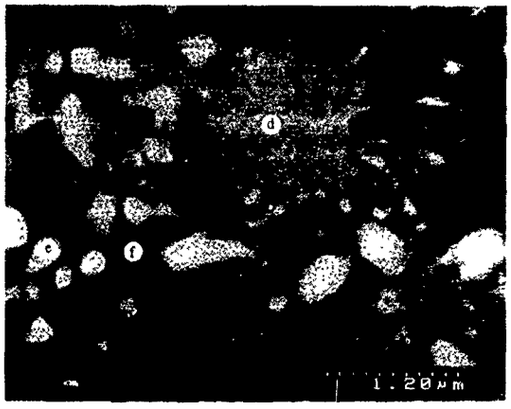

FIG. 3. Backscattered electron picture of a $Nd_{14}Fe_{79}B_7$ sample desorbed at 780 °C for 20 min. (d) region of recombined $Nd_2Fe_{14}B$, (e) Nd-rich cluster, (f) Fe-rich cluster

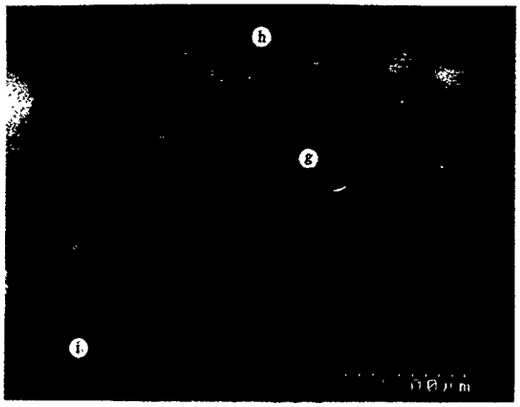

FIG. 4. Backscattered electron picture of a $Nd_{14}Fe_{79}B_7$ sample desorbed at 780 °C for 40 min. (g) $Nd_2Fe_{14}B$ phase, (h) Nd-rich cluster, (i) Fe-rich cluster.

from NdH_2, within the disproportionated structure, is the dominant reaction and is responsible for the resistivity drop as this reaction transforms semiconducting NdH_2 into metallic Nd.[7] The subsequent increase in resistivity (stage II in Fig. 5) is due to the consumption of αFe as the recombination reaction proceeds. In order to study the mechanism of the recombination reaction, samples were obtained by quenching in vacuum at three stages (A, B, and C in Fig. 5) of the desorption and recombination process (stage II in Fig. 5). Their magnetic properties were measured and compared with those of a specimen fully disproportionated at 700 °C.

Figure 6 shows the demagnetization traces of the fully disproportionated specimen and the partially and fully desorbed samples. It can be seen that the magnetization of the fully disproportionated material at 1100 kA/m is the highest and its coercivity is the lowest, as expected from the presence of αFe and the absence of the $Nd_2Fe_{14}B$ phase. These results are in accordance with those reported by Book *et al.*[14]

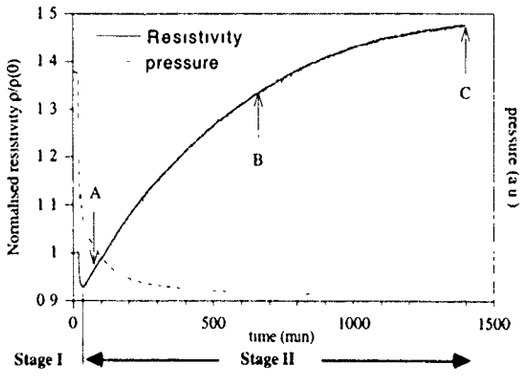

FIG. 5. Electrical resistivity and pressure vs desorption time at 600 °C for a $Nd_{14}Fe_{79}B_7$ alloy Stage I: desorption of hydrogen from the matrix is the dominant reaction, stage II recombination is dominant and consists of three substages, A, B, and C.

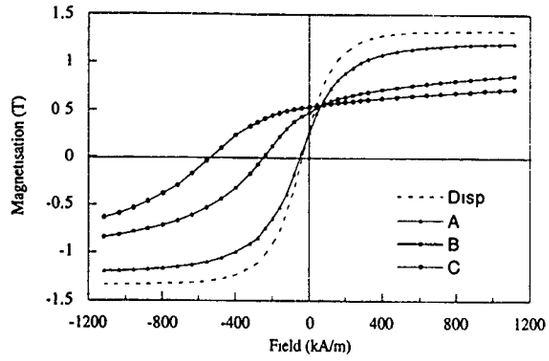

FIG. 6. VSM traces of disproportionated (Disp) and partially desorbed (A,B,C) $Nd_{14}Fe_{79}B_7$ samples.

At stage A, when the specimen is partially desorbed and recombined, the coercivity has not been modified significantly and the magnetization has decreased but is still high compared to that of the fully recombined sample. This indicates that the recombined $Nd_2Fe_{14}B$ phase coexists with αFe. The second curve represents the demagnetization curve of a sample quenched at stage B, when the specimen is almost desorbed but still partially recombined. The coercivity has improved and the magnetization at 1100 kA/m has decreased significantly, thus indicating that the proportion of recombined phase is much larger compared to stage A. At stage C, when the sample is fully desorbed and recombined, the coercivity has improved considerably, whereas the magnetization at 1100 kA/m has decreased slightly compared to that of the previous sample. This indicates that the remaining αFe was removed between stages B and C. The microstructures of all these specimens are currently under investigation and will be reported at a later date.[15]

Effects of HDDR treatment conditions on magnetic properties of Nd-Fe-B anisotropic powders

H. Nakamura, R. Suefuji, S. Sugimoto, M. Okada, and M. Homma
Department of Materials Science, Faculty of Engineering, Tohoku University, Sendai 980, Japan

It is reported that Nd-Fe-B magnetic powders prepared by utilizing the HDDR (hydrogenation, disproportionation, desorption, and recombination) phenomena exhibit high coercivity, and the addition of Co, Ga, and Zr induces magnetic anisotropy in these powders. HDDR phenomena are caused by the heat treatment in hydrogen (H treatment) and subsequently in vacuum (V treatment). Present works describe the effects of V-treatment conditions on magnetic properties of $Nd_{12.6}Fe_{bal}Co_xB_{6.0}$ (x=0–17.4) alloys. The powders V-treated at lower temperature show lower remanence and no noticeable magnetic anisotropy. V treatment at higher temperature enhances remanence and increases the differences of remanence between the powders aligned with and without magnetic field. Higher values are obtained in Co added alloys. This result suggests that a selective grain growth of $Nd_2Fe_{14}B$ grains during V treatment plays an important role for the inducement of magnetic anisotropy in HDDR-treated powders. The temperature for complete recombination reaction under evacuating condition decreases with increasing Co content. It can be said that Co addition enhances recombination reaction and results in acceleration of grain growth.

I. INTRODUCTION

Hydrogenation, disproportionation, desorption, and recombination (HDDR) phenomena[1,2] in Nd-Fe-B alloys are caused by the heat treatment in hydrogen (H treatment) and further treatment in vacuum (V treatment). $Nd_2Fe_{14}B$ compound disproportionates into a mixture of NdH_2, α-Fe, and Fe_2B at an elevated temperature of around 800 °C in H treatment. Removal of hydrogen in the mixture by subsequent V treatment reforms the $Nd_2Fe_{14}B$ compound with homogeneous and fine grains of about 0.3 μm in diameter, which is close to the single domain size of $Nd_2Fe_{14}B$. This results in high coercivity in HDDR-treated Nd-Fe-B powders.

Since it has been reported that Co, Ga, Zr, and Nb addition induces magnetic anisotropy through this phenomena,[3] Nd-Fe-B powders produced by utilizing HDDR phenomena have been candidates as powders for high performance bonded magnets. But the mechanism for inducement of magnetic anisotropy is still unclear. One of the proposed mechanisms has been reported, in which the role of Co is to depress the disproportionation reaction during H treatment especially at high temperature. The origin of anisotropy is due to the undecomposed fine particles which inherit a crystallographic relationship with newly formed grains.[4] These works are only concerned with H treatment conditions on magnetic properties and microstructure. But the magnetic anisotropy might be varied not only with H treatment but with V treatment. Then the purpose of this study is to investigate the effects of V-treatment temperatures on magnetic anisotropy in $Nd_{12.6}Fe_{81.4-x}Co_xB_{6.0}$ (x=0–17.4) alloys.

II. EXPERIMENTAL PROCEDURE

The diagram of the experimental procedure is shown in Fig. 1(a). The compositions of studied alloys were $Nd_{12.6}Fe_{81.4-x}Co_xB_{6.0}$ (x=0,5.8,11.6,17.4). The alloys were induction-melted from high-purity elements under an Ar atmosphere and then were homogenized at 1100 °C for 20 h. The homogenized ingots were ground into powders of <63 μm and pressed into compacts. These compacts were used for investigating the hydrogen absorption and desorption characteristics, which were measured by monitoring the difference between the flow rate in front and in the rear of the furnace (called ΔQ hereafter). Details on ΔQ measurement are described elsewhere.[5] H treatment and further V treatment (referred to as HV treatment) was performed on crushed ingots and sintered bodies which were magnetically anisotropic. The process of HV treatment is schematically illustrated in Fig. 1(b) and details of HV treatment are described elsewhere.[5] H treatment was carried out at 850 °C for 2 h which was the same condition as used in Ref. 1. Subsequent V treatment was made at 700–950 °C for 1 h.

HV-treated samples were ground into powders of <63 μm by hand milling. These powders were mixed with molten paraffin and were solidified with or without applying a magnetic field of 12 kOe. Magnetic properties were measured by a vibrating sample magnetometer with the maximum applied field of 15 kOe after applying a pulsed field of 50 kOe to the sample.

X-ray diffractions with Fe $K\alpha$ radiation were carried out.

III. RESULTS AND DISCUSSION

The characteristics of hydrogen absorption and desorption of $Nd_{12.6}Fe_{81.4-x}Co_xB_{6.0}$ (x=0,11.6,17.4) on heating at a rate of 400 °C/h are shown in Fig. 2. It consists of two

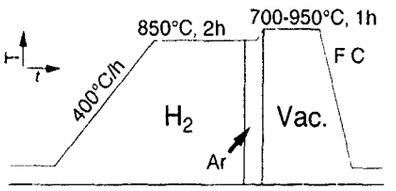

FIG. 1 (a) Diagram of experimental procedure and (b) schematic illustration of the process of HV treatment

 0021-8979/94/76(10)/6828/3/$6.00 © 1994 American Institute of Physics

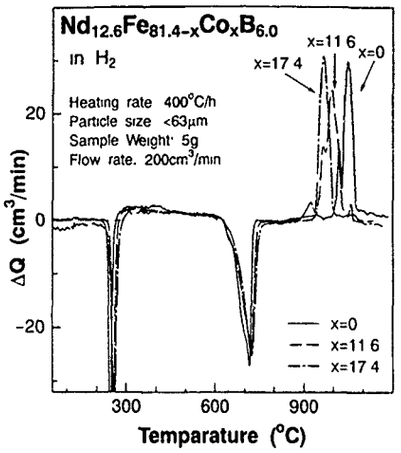

FIG. 2. Hydrogen absorption and desorption characteristics of $Nd_{12.6}Fe_{81.4-x}Co_xB_{6.0}$ (x=0,11.6,17.4) on heating at a rate of 400 °C/h.

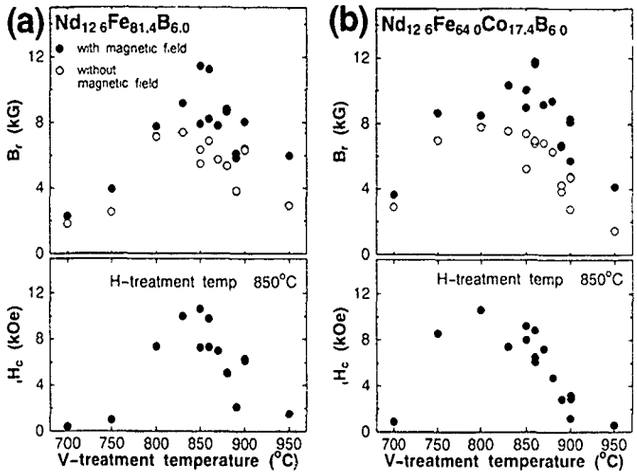

FIG. 3. V-treatment temperature dependence in magnetic properties of HV-treated $Nd_{12.6}Fe_{81.4-x}Co_xB_{6.0}$ where (a) x=0, (b) 17.4. (Dotted line indicates half values of saturation magnetization of each homogenized alloy)

absorption peaks and two desorption peaks. X-ray-diffraction analysis reveals that the characteristics of hydrogen absorption and desorption correspond to the phase changes during the heat treatment in hydrogen, and that the peaks indicate the reaction as follows: Absorption peaks at around 250 °C correspond to interstitial hydrogen uptake to form $Nd_2(Fe,Co)_{14}BH_x$, and the desorption peaks covering 250–650 °C indicate hydrogen atoms leaving the interstitial site. Hydrogen absorption peaks at around 700 °C, corresponding to a disproportionation reaction into a mixture of NdH_2, α-(Fe,Co), and $(Fe,Co)_2B$ phases. The desorption peaks observed above 900 °C correspond to the recombination reactions to the original compound. The results described above are in good agreement with the reported ones by Harris[6] and Takeshita.[7] The shape of the peaks corresponding to the disproportionation reaction is narrow in both alloys with and without Co. Co added alloys show the recombination reaction at lower temperature. It can be considered that the disproportionation reactions are very drastic in the both alloys. It can also be said that the Co contained disproportionated mixture is less stable under an atmospheric pressure of hydrogen, and tends to form $Nd_2(Fe,Co)_{14}B$ compounds at lower temperature.

Figure 3 shows the V-treatment temperature dependence in magnetic properties of HV-treated $Nd_{12.6}Fe_{81.4-x}Co_xB_{6.0}$. Coercivities increase with increasing V-treatment temperature and exhibit maximum values at 850 and 800 °C in the alloys without and with Co, respectively. Co added alloys show higher coercivity at lower V-treatment temperature than the alloys without Co. In both alloys, remanence increases with increasing temperature and shows highest values at 850–860 °C, which then decreases at above 880 °C. The alloys aligned with a magnetic field exhibit higher remanence than the half values of saturation magnetization of each homogenized alloy, which correspond to the remanence of isotropic alloys and are shown by the dotted lines in Fig. 3, in the temperature range between 800 and 900 °C. The differences of remanence between the alloys aligned with and without a magnetic field become larger at above 800 °C. Judging from the magnetic properties shown in Fig. 3, the inducement of anisotropic aspect proceeds by the V treatment above 800 °C.

Figure 4 shows x-ray-diffraction patterns of $Nd_{12.6}Fe_{81.4-x}Co_xB_{6.0}$ (x=0, 11.6, 17.4) alloys V-treated at 700 °C, which is a relatively low temperature of V treatment. X-ray reflections from NdH_2 and α-Fe phases are dominant in $Nd_{12.6}Fe_{81.4}B_{6.0}$ powders. The intensity of reflections from the $Nd_2(Fe,Co)_{14}B$ phase increases with increasing Co content. It can be said that Co added alloys tend to form $Nd_2(Fe,Co)_{14}B$ compound under evacuation condition. This results in higher coercivity at lower temperature in Co added alloys.

Figure 5 shows x-ray-diffraction patterns of HV-treated $Nd_{12.6}Fe_{81.4}B_{6.0}$ powders which were pressed with a magnetic field of 12 kOe. The x-ray-diffraction pattern of the

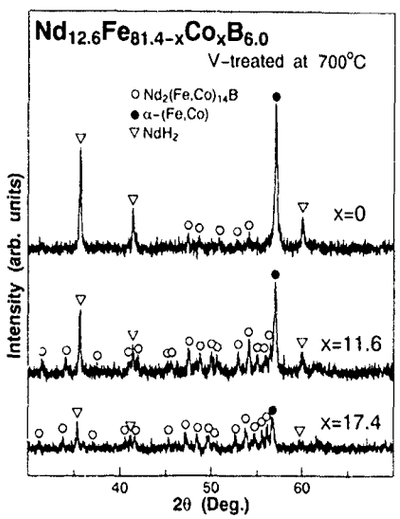

FIG. 4. X-ray-diffraction patterns of $Nd_{12.6}Fe_{81.4-x}Co_xB_{6.0}$ (x=0,11.6,17.4) V-treated at 700 °C.

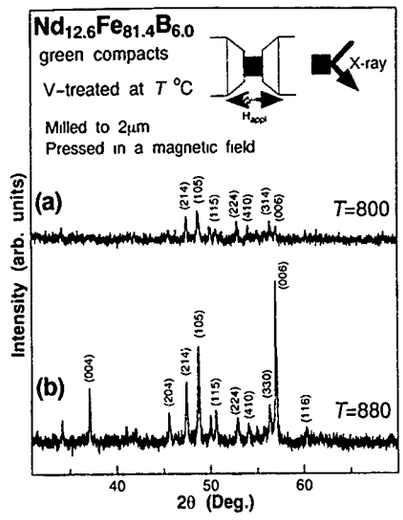

FIG. 5. X-ray-diffraction patterns of $Nd_{12.6}Fe_{81.4}B_{6.0}$ V-treated at (a) 800 and (b) 880 °C, which were milled to 2 μm and then pressed in a magnetic field.

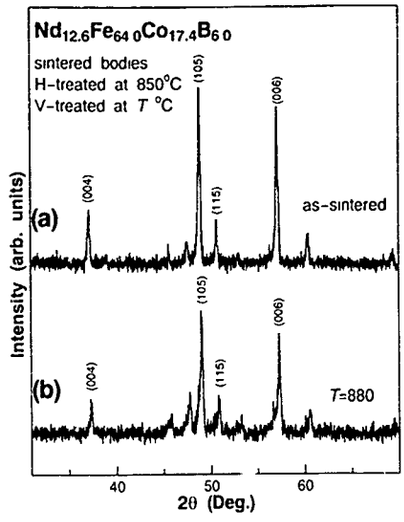

FIG. 6. X-ray-diffraction patterns of $Nd_{12.6}Fe_{64.0}Co_{17.4}B_{6.0}$ sintered bodies (a) before HV treatment, and (b) after V treatment at 880 °C.

V-treated green compact at 800 °C, where remanence equals to the value of isotropic alloy and exhibits no difference between the alloys aligned with and without magnetic field, shows isotropic characteristics. But the V-treated one at 880 °C exhibits intensive reflection from (006) which indicates alignment of grains in the powders. This feature is closely related to the difference in remanence at higher temperature shown in Fig. 3 and it would be due to grain alignment.

In order to investigate the texture change during V treatment, x-ray diffraction was performed on anisotropic sintered bodies after HV treatment. X-ray-diffraction patterns of $Nd_{12.6}Fe_{64}Co_{17.4}B_{6.0}$ sintered bodies (a) before HV treatment and (b) after V treatment at 880 °C are shown in Fig. 6. The diffraction pattern of an as-sintered sample shows an anisotropic characteristic since intensive reflections from (006) and (105) are observed in Fig. 6(a). High intensities of reflections from (006) and (105) are also observed in the sample after V treatment at 880 °C shown in Fig. 6(b). It is considered that the V-treated powders at higher temperatures tend to form the same texture as the original samples before HV treatment.

Taking account of the results shown in Fig. 5, it can be said that magnetic anisotropy in HV-treated powders is induced by high-temperature V treatment. It suggests that inducement of magnetic anisotropy proceeds through a selective grain growth of $Nd_2Fe_{14}B$ grains. Uehara *et al.* concluded that residual $Nd_2Fe_{14}B$ grains among the disproportionated mixture after H treatment are the nuclei of recombination during V treatment and Co makes this tendency noticeable.[4] Since the disproportionation reaction is very drastic and no difference can be observed in hydrogen absorption and desorption characteristics below 900 °C in all the studied alloys from Fig. 2, it is anticipated that no residual $Nd_2Fe_{14}B$ phase exists after H treatment at 850 °C. If the oriented nucleation had been dominant, magnetic anisotropy would be induced by V treatment at lower temperatures. But in our results, shown in Fig. 3, the remanence of $Nd_{12.6}Fe_{81.4}B_{6.0}$ powders V-treated at 800 °C and solidified with a magnetic field is almost the same as that without a magnetic field. The main effect of Co addition is to enhance the recombination reaction.

The use of polytetrafluoroethylene in the production of high-density bonded Nd-Fe-B magnets

C. Tattam, A. J. Williams, J. N. Hay, and I. R. Harris
School of Metallurgy and Materials, University of Birmingham, Birmingham B15 2TT, United Kingdom

S. F. Tedstone and M. M. Ashraf
Penny and Giles Blackwood, Ltd., Blackwood, Gwent NP2 2YD, United Kingdom

Rotary forging has been used to produce high-density bonded magnets from rapidly quenched Nd-Fe-B based ribbons [MQP-D, of nominal composition 28%Nd-56%Fe-15%Co-1%B (wt %)]. Polytetrafluoroethylene (PTFE), when used as an additive (5%–15% by volume) has been found to act as an effective binder and greatly enhances the forgeability of the MQI, allowing higher forging pressures to be used. Densities of up to 98% of the fully dense composite have been achieved. The forging process can be undertaken in air at room temperature. Magnetically, the compacts are comparable to conventional epoxy resin bonded MQI, with energy products of up to 84 kJ/m^3. Equivalent volume fractions of MQI (~83.5 vol %) have been achieved in the compacts with increased PTFE content due to the displacement of pores by the PTFE. The effect of PTFE content on the mechanical strength of the compacts has been assessed and it has been found that strength increases with increasing PTFE content, consistent with the reduction in porosity.

I. INTRODUCTION

There are two principal methods used for processing Nd-Fe-B alloys into permanent magnets. The first is a conventional powder metallurgy process which is similar to that employed for the production of rare-earth cobalt magnets.[1,2] The second involves the rapid quenching of the alloy from the melt.[3,4] The ribbons that result from rapid quenching have a high coercivity which can be attributed to the extremely fine grained microstructure. Magnets can be produced using rapidly quenched material by grinding, mixing with a binder, and then pressing. Various binders have been employed for this purpose including epoxy resins,[5] and more recently, polytetrafluoroethylene (PTFE).[6]

It has been shown that high-density magnets can be produced by rotary forging MQI with or without a soft metal binder.[7,8] MQI compacts forged with no binder were found to have poor mechanical integrity. PTFE was chosen as an additive to enhance the flow of the flakes, due to its low coefficient of friction, during forging. The PTFE was subsequently found to act as an effective binder as well as allowing the forging of ribbon in air, where previously it was necessary to forge in an inert atmosphere.[8]

It has been shown[6] that densities of 6.2 g/cm^3 can be achieved by the compression moulding of anisotropic Nd-Fe-B powder (prepared by the hydrogen decrepitation of hot deformed overquenched ribbon) with 2.1 wt % PTFE at a temperature of 250 °C under an argon atmosphere. The subject of this paper is the formation by rotary forging, in air at room temperature of high-density compacts of isotropic melt spun ribbon using PTFE as a binder.

II. EXPERIMENT

Melt spun flake material was mixed with 5, 10, and 15 vol % PTFE powder using a powder blender. 15 g batches were loaded into the die cavity of a rotary forging machine (Fig. 1). The contact area between the upper tool and the workpiece rotates around the top surface, producing a shearing action. The relatively small contact area means that lower overall loads are required to produce a given compaction compared with uniaxial pressing. The forging pressure in the hydraulic ram was varied to ascertain the optimum conditions with respect to compact density. Ejection of the compacts from the die was facilitated by the presence of PTFE.

The magnetic properties were measured by demagnetizing the compacts in a permeameter. The second quadrant demagnetization loop was obtained after pulse magnetizing the sample in a field of 4.5 T. The mechanical strength of the compacts was assessed using a method based on the ball on ring test.[9] Samples were supported around the edge of their base by a ring of 15 mm diameter while a load was applied to the center of the top surface via a steel sphere of 11 mm

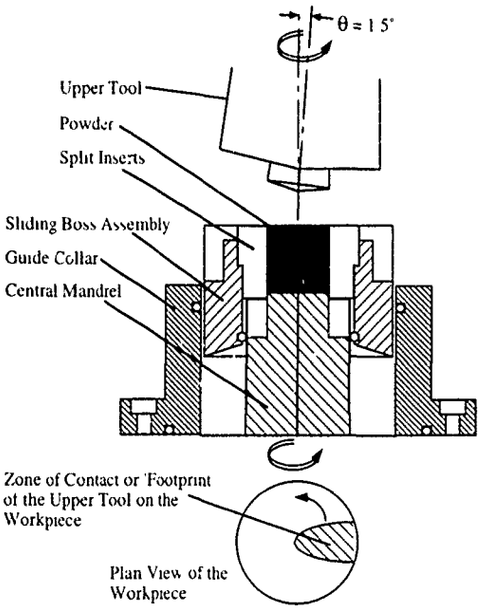

FIG. 1. A schematic representation of the rotary forging process.

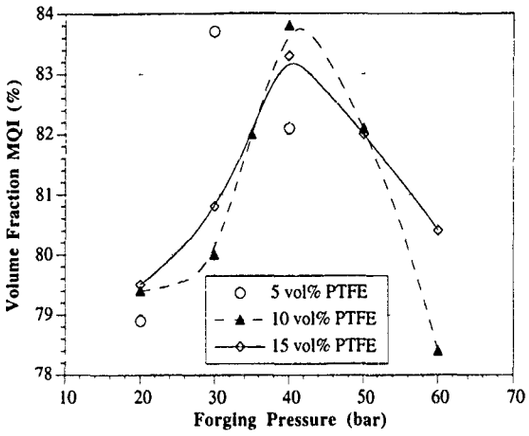

FIG 2. The effect of forging pressure on the volume fraction of MQI.

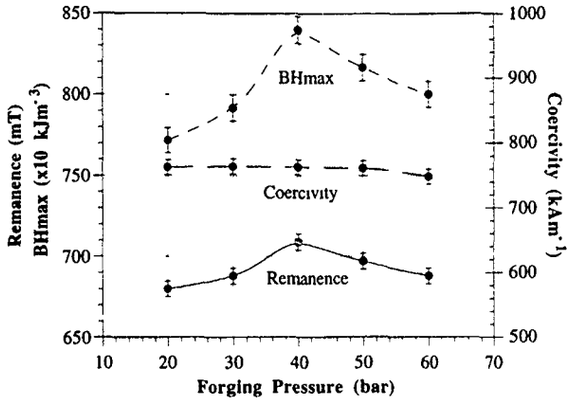

FIG. 4. The variation of magnetic properties with forging pressure for MQI+15 vol % PTFE compacts.

diameter. The cross head speed employed was 0.05 cm/min. The load required for fracture of the specimen was recorded on a chart recorder.

III. RESULTS AND DISCUSSION

The effect of varying the forging pressure on the volume fraction of MQI within the compact is shown in Fig. 2. Relative densities were determined by dividing the actual density by the theoretical maximum and converting to a percentage. The volume fraction of MQI was then calculated by multiplying the relative density by the volume fraction of MQI in the original composition. It can be seen from Fig. 2 that there is little difference in the maxima obtained for these three compositions, the largest MQI content being 83.8±0.5% for 10 vol % PTFE and the lowest being 83.3±0.5% for 15 vol % PTFE.

For all three compositions, to the left of the maxima, the lower volume fraction of MQI is due to the lower forging pressure, producing compacts of lower density and hence higher porosity. The porosity within the compacts for the three compositions as a function of forging pressure is shown in Fig. 3. At forging pressures higher than those at which the maxima in volume fraction occur, values decrease due to the onset of cracking at these pressures. The presence of cracks means that, despite the probability of there being regions of higher density within the compact, the overall density is lower than the maximum.

The traces shown in Fig. 3 are consistent with the data shown in Fig. 2. It can be seen that the higher the PTFE content, the lower the porosity. This displacement of the pores by PTFE during forging accounts for the near-equivalent volume fractions of MQI being obtainable in compacts with higher PTFE content. From these investigations it appears that the optimum forging pressure for MQI+5 vol % PTFE samples is 30 bars and for 10 and 15 vol % PTFE, 40 bars.

The effect of varying the forging pressure on the magnetic properties of MQI+15 vol % PTFE compacts is shown in Fig. 4. It can be seen that, as expected, the remanence curve follows the same trend as the volume fraction of MQI curve obtained for these compacts. Variations in the forging pressure appear to have little effect on the coercivities of the compacts. The maximum energy products are also shown and it can be seen that the highest $BH(\max)$ obtained was ~84 kJ/m^3 for samples forged at 40 bars.

A typical demagnetization loop for an MQI+15 vol % PTFE magnet is shown in Fig. 5. A curve for an epoxy bonded magnet of equivalent density is included for comparison. Both magnets have comparable remanences but it can be seen that the epoxy bonded sample has a somewhat lower coercivity. This trend has been observed in all the magnets tested, and could be due to possible modification of the ribbon microstructure during forging.[8] The energy product of the PTFE bonded magnet is slightly higher, 84±1 kJ/m^3 compared to 81±1 kJ/m^3 for the epoxy bonded magnet.

Table I shows the load required for mechanical failure of PTFE, zinc, and epoxy bonded compacts. An MQI+15 vol % PTFE compact was also produced by compression moulding at 3 tons/cm^2 but this crumbled prior to testing, exhibiting a much inferior mechanical integrity compared with that of the rotary forged compacts. The zinc bonded sample was fabricated using an identical procedure to that of

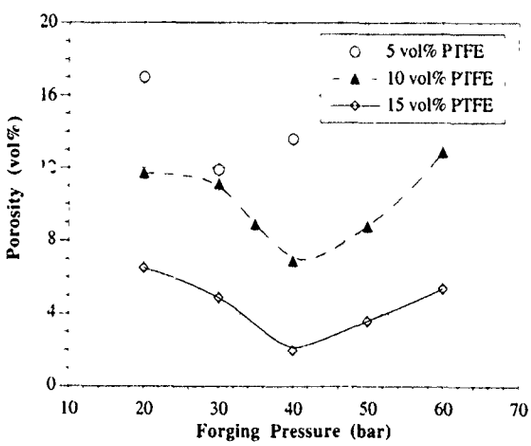

FIG. 3. The effect of forging pressure on the porosity content.

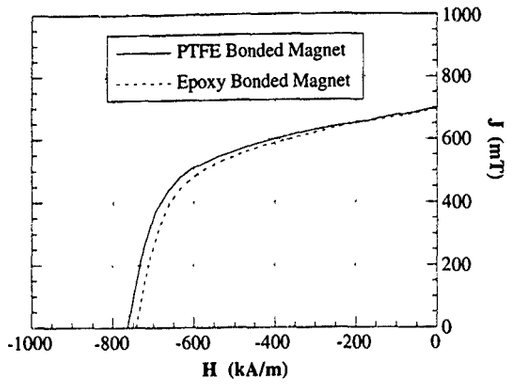

FIG. 5. Demagnetization curves for PTFE and epoxy bonded magnets.

the rotary forged PTFE bonded samples and the epoxy bonded sample was fabricated using a compression moulding technique and a low viscosity resin. All compacts tested had the same thickness.

It can be seen that the load required for fracture increases almost linearly with increasing PTFE content. Both zinc and epoxy bonded compacts required a higher load to fail; indeed the epoxy bonded sample appears to be over 6× as strong as the MQI+15 vol % PTFE sample. However. a subsequent heat treatment of the PTFE bonded samples can substantially improve their mechanical integrity.[10]

TABLE I. Load required for the fracture of various compacts.

Sample	Load to fracture/*N*
MQI+5 vol % PTFE	88
MQI+10 vol % PTFE	177
MQI+15 vol % PTFE	284
MQI+15 vol % zinc	373
Heat treated MQI+15 vol % PTFE	726
MQI+15 vol % epoxy	1766

IV. CONCLUSIONS

When PTFE is present during the rotary forging of MQI, it greatly increases the forgeability and also acts as a binder. The PTFE content can be increased without loss of MQI content due to the displacement of pores by the PTFE. Densities of up to 98% of the fully dense composite can be achieved resulting in energy products of up to 84 kJ/m^3 for the isotropic ribbon.

The mechanical testing of compacts indicates that by increasing the PTFE content the mechanical integrity increases. The non-heat-treated compacts, however, are not as strong as either zinc or epoxy bonded compacts. Heat treatment of the PTFE bonded samples improves substantially their mechanical strength.

Evidence of domain-wall pinning in W-doped (NdDy)(FeCo)B sintered magnets

T. Y. Chu
Materials Research Laboratories, Industrial Technologies Research Institute, Chutung, 310 Taiwan, Republic of China

T. S. Chin, C. H. Lin, and J. M. Yao

Addition of tungsten (1–2 at. %) is very effective in improving coercivity of (Nd,Dy)-(Fe,Co)-B sintered magnets both at room temperature and elevated temperatures in addition to improving thermal stability. Transmission electron microscopy shows that there exists a WFeB precipitate phase inside the $Nd_2Fe_{14}B$ (2-14-1) matrix grain. The WFeB phase is plateletlike, and occasionally appears to have its largest dimension running parallel to the *c* axis of the 2-14-1 matrix phase. The orientation relationship between the WFeB precipitate and the matrix is found to be $(102)_{WFeB}\|(220)_{2\text{-}14\text{-}1}$, and $[010]_{WFeB}\|[002]_{2\text{-}14\text{-}1}$. Domain walls jump from a position alongside the WFeB particles to a new position alongside others upon turning on magnetic field of the objective lens, as evidenced by Lorentz microscopy, denoting the ability of domain-wall pinning by the strain field around the WFeB precipitate. As a result, this provides extra hindrance to domain-wall motion and leads to enhanced coercivity and thermal stability, particularly at elevated temperatures.

I. INTRODUCTION

The high-temperature properties of Nd-Fe-B magnets have been found to improve dramatically by doping with some elements.[1–4] When alloying both Co and Dy in the Nd-Fe-B magnets, addition of a third element such as Al, Ga, Nb, V, or Mo has been studied extensively and was shown to be effective in improving high-temperature magnetic properties of Nd-Dy-Fe-Co-B magnets.[4–6] The Nb-rich precipitates dispersed in the matrix were suggested to be responsible for the coercivity increase of Nb-containing magnets.[7] The combined substitutions of (Nb,Ga) or (Nb,Al) for partial Fe content are effective in reducing the irreversible thermal loss and the temperature coefficient of remanence.[8] Sagawa *et al.* and Hirosawa *et al.* have shown that the addition of V or Mo is effective in improving the thermal stability of sintered Nd-Fe-B magnets, and a working temperature of over 200 °C may be possible.[5,6]

The effect of W addition on magnetic properties of Nd-Dy-Fe-Co-B magnets have been reported by us in a previous paper.[9] The observation of W-rich inclusions and precipitates in W-containing Nd-Fe-B magnets has also been reported elsewhere.[10] However, the crystallographic relationship between these precipitates and the matrix phase has never been studied. In this paper, the results of microstructure study of W-containing magnets are presented and the reason for enhanced coercivity is delineated.

II. EXPERIMENT

Alloy ingots of $Nd_{14}Dy_{1.5}Fe_{71-x}Co_6W_xB_{7.5}$ ($x=0$ or 2) were prepared by induction melting under Ar protection, then made into sintered magnets (sintering at 1090 °C for 1 h) and heat treated (at 900 °C for 2 h then 550 °C for 1 h) under Ar atmosphere by conventional powder metallurgy processes as described in the previous paper.[9] Magnetic properties of sintered specimens were isothermally measured at temperatures between 25 and 150 °C by a B-H tracer after specimens were magnetized by a 5 T pulse field. The microstructure was studied by transmission electron microscopy in a JEOL 2000 FX scanning transmission electron microscope (STEM) equipped with a LINK AN10000 energy dispersive x-ray analyzer.

III. RESULTS AND DISCUSSION

Figure 1 shows coercivity versus temperature, up to 150 °C, for the optimally heat-treated $Nd_{14}Dy_{1.5}Fe_{71-x}Co_6W_xB_{7.5}$ ($x=0$, the blank, and $x=2$) magnets. The W-containing alloy shows remarkable intrinsic coercivity (iHc) as compared to the blank alloy. Furthermore, iHc values of the W-containing alloy are twice as large as that of blank alloy even at temperatures higher than 100 °C.

It was speculated that the increased coercivity and thermal stability might be due to an intrinsic enhancement of

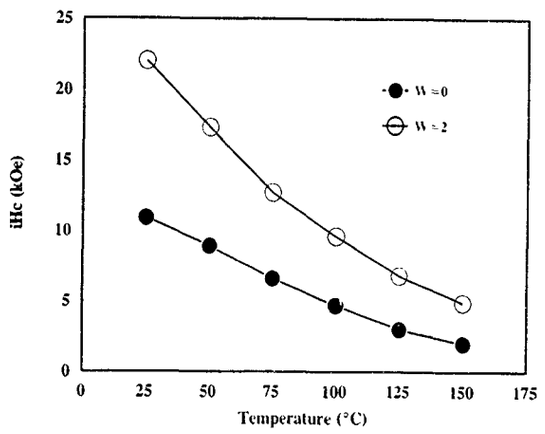

FIG. 1. Coercivity of sintered $Nd_{14}Dy_{1.5}Fe_{71-x}W_xCo_6B_{7.5}$ magnets ($x=0$, the blank alloy, and $x=2$) vs temperature.

FIG. 3. Large inclusion phase on the grain boundary (the marker=2 μm).

magnetocrystalline anisotropy field (H_A) arising from W alloying. However, experiments on H_A for both the blank and the 2% W-containing alloys showed the same value of 7.8 T. That is to say, the improvement might be due to extrinsic reasons.

It has been reported that W is not completely dissolved into the matrix 2-14-1 phase, and W-rich inclusions and precipitates exist in the W-containing magnets.[9,10] In other reports in which V- or Mo-containing Nd-Dy-Fe-Co-B alloys were studied, V_2FeB_2 or Mo_2FeB_2 phases were observed, respectively.[11,12]

Figure 2 shows the platelet precipitates dispersed inside the 2-14-1 matrix grains of W-containing magnet. Since the precipitates are generally smaller than 200 nm in thickness, the microdiffraction method, in which a focused electron probe is used to acquire the diffraction patterns, was performed in order to reduce the contribution from the surrounding 2-14-1 matrix phase. The precipitates were indexed as orthorhombic W-Fe-B (1-1-1) phase with lattice parameters $a=0.582$ nm, $b=0.316$ nm, and $c=0.681$ nm. A diffraction pattern is shown as the inset of Fig. 2. By analyzing diffraction patterns taken from the junction between the precipitate and matrix phase, it is found that there exists an orientation relationship between them, that is

$$(1\ 0\ 2)_{\mathrm{WFeB}} \| (2\ 2\ 0)_{2\text{-}14\text{-}1}. \tag{1}$$

$$[0\ 1\ 0]_{\mathrm{WFeB}} \| [0\ 0\ 2]_{2\text{-}14\text{-}1}. \tag{2}$$

Crystallographically, the platelet precipitate is found to be identical to the larger W-containing inclusions present at grain boundaries, even though their dimension is one order of magnitude larger and their morphologies are quite different from each other. The inclusions on the grain boundaries are usually equiaxed as shown in Fig. 3. These two kinds of particles are suggested to appear at different stages in the manufacturing processes. The inclusions are the broken bits of W-rich dendrite in the cast ingot as evidenced by an optical microscope. The platelets inside the matrix grains are believed to precipitate out of supersaturated W-containing matrix phase during the heat-treatment stage (900–550 °C).

It was occasionally observed that the largest dimension of these precipitates runs parallel to the c axis of the 2-14-1 phase, as identified by the electron-diffraction pattern taken from the matrix phase near the precipitate (Fig. 4). The preferred orientation of the precipitate thus results in aligning their largest dimension parallel to the domain wall, as shown in Fig. 5(a). Therefore the precipitates can very effectively act as domain-wall-pinning sites, as clearly shown by the Lorentz microscopy micrographs in Figs. 5(a) and 5(b). In the micrograph shown in Fig. 5(a), taken with the TEM specimen experiencing virtually no externally applied field, the domain wall (white line in the middle of the micrograph) is straight and sits alongside two precipitates (arrowed). The micrograph in Fig. 5(b) is taken after turning on the objective lens of the electron microscope; the domain-wall jumps left over the middle larger precipitate and bowed around the other precipitates (arrowed). Thus the dispersed platelet precipitates are effective as domain-wall-pinning sites. How-

FIG. 4. The electron-diffraction pattern taken from the matrix phase near the WFeB precipitate (the marker=200 nm).

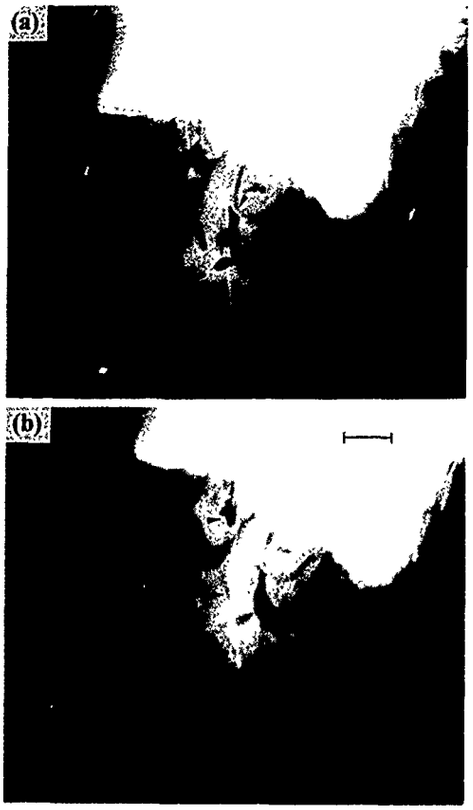

FIG. 5. Lorentz microscopy showing domain-wall motion nearby WFeB precipitates. ever, the WFeB phase, being nonmagnetic, is not able to interact with domain wall itself. It is believed that the strain field around the fine coherent precipitates inside the 2-14-1 grains are responsible for the pinning action to the domain walls.

For a sintered Nd-Fe-B magnet, it is proposed that nucleation of reverse domain prevails and the domain wall of a reverse domain, once nucleated, can sweep across the grain without difficulty.[13] The fine WFeB precipitate provides extra hindrance to domain-wall motion across the grain through the strain field around them, hence is responsible for the extremely high coercivity and thermal stability of the W-containing magnets. On the other hand, but to a lesser extent, the W-rich inclusions present on the grain-boundary regions might impede the grain growth of the 2-14-1 phase during sintering, giving rise to a fine grain structure which is also essential for high coercivity. Since the refractory WFeB phase is thermally stable at elevated temperatures, the ability of acting as domain-wall-pinning sites sustains to high temperature.

IV. CONCLUSIONS

Coercivity of (Nd,Dy)-(Fe,Co)-B sintered magnets, both at room temperature and elevated temperatures, and thermal stability can be very effectively improved by the addition of tungsten (1–2 at. %). Transmission electron microscopy studies show that there exists a WFeB precipitate phase inside the $Nd_2Fe_{14}B$ (2-14-1) matrix grain. The WFeB phase is plateletlike, and occasionally appears to have its largest dimension running parallel to the c axis of the 2-14-1 matrix phase. The orientation relationship between the WFeB precipitate and the matrix is found to be $(102)_{WFeB}\|(220)_{2\text{-}14\text{-}1}$, and $[010]_{WFeB}\|[002]_{2\text{-}14\text{-}1}$. Domain walls jump from a position alongside the WFeB particles to a new position alongside other WFeB particles upon turning on magnetic field of the objective lens, as evidenced by Lorentz microscopy, denoting the ability of domain-wall pinning by the strain field around the WFeB precipitate. Consequently, this refractory precipitate provides extra hindrance to domain-wall motion and leads to enhanced coercivity and thermal stability, particularly at elevated temperatures.

The magnetic properties of the tetragonal $ThMn_{12}$-type $R\mathrm{Co}_{10}\mathrm{Mo}_2$ compounds have been investigated by means of magnetic measurement and x-ray diffraction. It is found that the Co moment is roughly the same in all $R\mathrm{Co}_{10}\mathrm{Mo}_2$ compounds (0.9 μ_B/Co), excepting $\mathrm{CeCo}_{10}\mathrm{Mo}_2$ (0.7 μ_B/Co). It is also found that the Co sublattice displays easy c-axis magnetization. Nonaxial behavior at room temperature is observed only for $\mathrm{SmCo}_{10}\mathrm{Mo}_2$, whereas in $\mathrm{ErCo}_{10}\mathrm{Mo}_2$ a spin reorientation occurs from axial to planar magnetization upon cooling below $T_{sr}=125$ K. These results suggest that the A_2^0 term, mainly responsible for the rare-earth-sublattice anisotropy has the same sign as in the $R_2\mathrm{Fe}_{14}\mathrm{B}$ series ($A_2^0>0$). This is in contrast to other $ThMn_{12}$-type compounds ($R\mathrm{Fe}_{10}\mathrm{V}_2$, $R\mathrm{Fe}_{11}\mathrm{Ti}$) where it is generally assumed that $A_2^0<0$. The intersublattice coupling of $\mathrm{ErCo}_{10}\mathrm{Mo}_2$ has been determined by means of the high-field free-powder method.

I. INTRODUCTION

Many novel Fe-rich rare-earth-based permanent-magnet materials have comparatively low Curie temperatures and hence require Co substitution for Curie temperature enhancement. Well-known examples are $\mathrm{Nd}_2\mathrm{Fe}_{14}\mathrm{B}$, $\mathrm{SmFe}_{11}\mathrm{Ti}$, and $\mathrm{SmFe}_{10}\mathrm{Mo}_2$. In order to study the effect of Co substitution on Curie temperature, magnetization, intersublattice-coupling constant, and anisotropy field in $R\mathrm{Fe}_{10}\mathrm{Mo}_2$ compounds, we have studied the magnetic properties of the $R\mathrm{Co}_{10}\mathrm{Mo}_2$ series in pure form.

II. EXPERIMENT

The compounds of the $R\mathrm{Co}_{10}\mathrm{Mo}_2$ type were prepared by arc-melting stoichiometric mixtures of the metallic constituents of at least 99.9% purity. After arc melting, the polycrystalline specimens were wrapped in tantalum foil, sealed into evacuated quartz tubes, and annealed at 1000 °C for 4 weeks. The samples were quickly cooled to room temperature after annealing by breaking the quartz tubes under water. Subsequently, the samples were investigated by x-ray powder diffraction and found to be approximately single phase. The x-ray patterns were indexed on the basis of the $ThMn_{12}$-type of structure. For each compound, the free-powder magnetization was measured at 4.2 K as a function of applied magnetic fields up to 35 T, using the High-Field Installation at the University of Amsterdam.[1] In order to investigate the presence of spin-reorientation transitions between 4.2 K and room temperature, ac-susceptibility measurements were made on several compounds in the $R\mathrm{Co}_{10}\mathrm{Mo}_2$ series.

III. EXPERIMENTAL RESULTS

From x-ray-diffraction experiments on magnetically aligned powders, it was derived that at room temperature the easy-magnetic direction in the $R\mathrm{Co}_{10}\mathrm{Mo}_2$ compounds is parallel to the c-axis. The only exception is $\mathrm{SmCo}_{10}\mathrm{Mo}_2$ where the easy-magnetization direction is perpendicular to the c-axis. These results confirm earlier observations by Xu and Shaheen.[2]

ac-susceptibility measurements show no temperature-induced spin reorientations except in $\mathrm{ErCo}_{10}\mathrm{Mo}_2$ and $\mathrm{Er}_{0.8}\mathrm{Y}_{0.2}\mathrm{Co}_{10}\mathrm{Mo}_2$ (see Fig. 1). The sharp cusp observed for

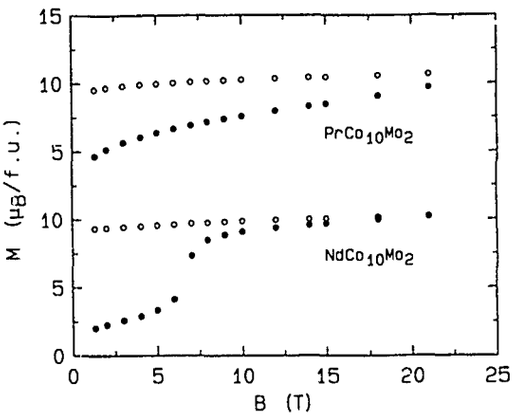

FIG. 2. Magnetic isotherms at 4.2 K measured on magnetically aligned powders of $PrCo_{10}Mo_2$ and $NdCo_{10}Mo_2$. Open circles correspond to the field parallel to the alignment direction and filled circles to perpendicular to the alignment direction.

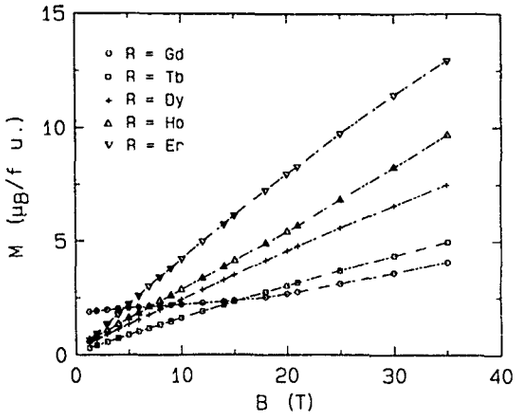

FIG. 3. Magnetic isotherms at 4.2 K of $RCo_{10}Mo_2$ compounds (R=Gd, Tb, Dy, Ho, and Er) measured on powder particles that are free to rotate in the sample holder.

both materials is taken as evidence of spin reorientations from $M \perp c$ (at low temperature) to $M \| c$ (at high temperature), at 125 K in $ErCo_{10}Mo_2$ and at 115 K in $Er_{0.8}Y_{0.2}Co_{10}Mo_2$. From the magnetic measurements on $RCo_{10}Mo_2$ compounds by Xu and Shaheen,[2] it can be derived that the moments of the light rare earths couple parallel to the Co moments and that the moments of the heavy rare earths couple antiparallel to the Co moments, as is usually observed.[3] Therefore no information on the intersublattice-coupling strength can be derived by means of the high-field free-powder (HFFP) method[4,5] for the compounds with the light-rare-earth elements. The isotherms of these compounds were therefore studied only in fields up to 20 T.

The magnetization at 4.2 K of magnetically aligned powders of $PrCo_{10}Mo_2$ and $NdCo_{10}Mo_2$ is shown in Fig. 2. The anisotropy field B_A for $PrCo_{10}Mo_2$ equals approximately 25 T. In $NdCo_{10}Mo_2$ there is a field-induced change of the magnetization direction, the critical field being equal to 6.5 T.

The saturation moments $M(0)$ at 4.2 K were derived from the free-powder magnetization curves by extrapolation to $B=0$. These values ar listed in Table I. The anisotropy in $CeCo_{10}Mo_2$ and $GdCo_{10}Mo_2$ is predominantly that of the Co sublattice since Ce is tetravalent and Gd is an S-state ion. The deviating valence of Ce follows from the lattice constants.

In order to obtain experimental information on the intersublattice-coupling strength we have studied how the low-field ferromagnetic state is affected by an applied field by measuring the magnetization of free single-crystalline powder particles of the compounds formed with the heavy rare earths in applied fields up to 35 T. Results obtained on the $RCo_{10}Mo_2$ compounds with R=Gd, Tb, Dy, Ho, and Er are shown in Fig. 3. The observation that the magnetic isotherms pass almost through the origin for the compounds with R=Tb, Dy, Ho, and Er means that the R-sublattice magnetization M_R and the Co-sublattice magnetization M_{Co} are nearly equal to each other in these materials.

In practically all R-T intermetallics previously investigated by means of the HFFP method,[5] the T-sublattice anisotropy is much smaller than the R-sublattice anisotropy. In these cases, the former can be ignored and the R-sublattice magnetization can be parallel to the easy-magnetization direction and to remain so during the bending process. The free energy is given by

$$E = E_R^{an} + E_{Co}^{an} + n_{RCo} M_R M_{Co} \cos\alpha - BM. \quad (1)$$

The magnetization M is given by $M=(M_R^2+M_{Co}^2+2M_R M_{Co}\cos\alpha)^{1/2}$.

In deriving the magnetization by minimizing the free energy, only the last two terms in Eq. (1) need to be taken into consideration. In this case, the intersublattice-coupling constant n_{RT} can be obtained straightforwardly from the magnetization in the region where the bending process from the ferrimagnetic configuration to the forced ferromagnetic state occurs ($n_{RT}=[M/B]^{-1}$).

In the $RCo_{10}Mo_2$ compounds, however, it is no longer legitimate to neglect the Co-sublattice anisotropy. If only the first-order anisotropy constants K_1^R and K_1^{Co} are taken into account, the free-energy expression reads

TABLE I. Magnetic properties of $RCo_{10}Mo_2$ compounds

Compounds	$M(0)$	M_R	M_{Co}
$YCo_{10}Mo_2$	8.5	0	8.5
$CeCo_{10}Mo_2$	6.5	0	6.5
$PrCo_{10}Mo_2$	11.2	3.2	8.0
$NdCo_{10}Mo_2$	10 6	3.2	7.4
$SmCo_{10}Mo_2$	9 5	0.7	8 8
$GdCo_{10}Mo_2$	1.9	7.0	7.0±1.9
$TbCo_{10}Mo_2$	0.1	9.0	9 0±0.1
$DyCo_{10}Mo_2$	0.3	10.0	10.0±0.3
$HoCo_{10}Mo_2$	0.3	10.0	10.0±0.3
$Er_{0.8}Y_{0.2}Co_{10}Mo_2$	1.4	7.2	7 2±1 4
$ErCo_{10}Mo_2$	0.0	9.0	9.0

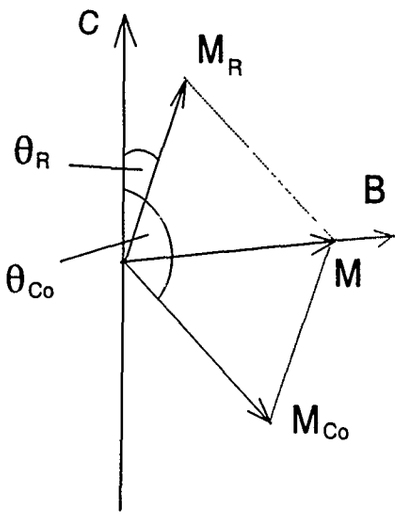

FIG. 4. Schematic representation of the orientations of M_R and M_{Co} in an external field for a free single crystal.

$$E=K_1^R \sin^2\theta+K_1^{Co} \sin^2(\theta+\alpha)+n_{RCo}M_R M_{Co} \cos \alpha-BM. \quad (2)$$

The angles θ and α are defined in Fig. 4. Due to the presence of the two anisotropy terms in Eq. (2) neither of the two sublattice magnetizations will remain oriented along the corresponding easy-axis direction during the process that the two sublattice magnetizations bend towards each other under influence of the external field. This leads to a nonlinear behavior of the magnetic isotherm.[10,11]

By minimizing the free energy given in Eq. (2), the following expression for the magnetization can be derived:

$$\frac{B}{M}=n_{AB}-\frac{2K_1^A K_1^B}{M_A M_B |K|}\cos \alpha, \quad (3)$$

with

$$|K|=[(K_1^A)^2+(K_1^B)^2+2K_1^A K_1^B \cos 2\alpha]^{1/2}.$$

By fitting the experimental magnetization curves to this expression, details about n_{RCo} and the anisotropy constants can be obtained.

As an example we analyzed the magnetization curve of $ErCo_{10}Mo_2$. The result of the fitting procedure is shown in Fig. 5. The parameters obtained ar $K_1^{Er}=-4.32\times10^{-22}$ J/f.u., $K_1^{Co}=1.13\times10^{-22}$ J/f.u., and $n_{ErCo}=3.06\times10^{23}$ T f.u./A m^2, $M_{Er}=9.0\ \mu_B$/f.u., and $M_{Co}=8.35\ \mu_B$/f.u. When expressed by means of the Hamiltonian $H=2\ J_{ErCo}\mathbf{S}_{Er}\cdot\mathbf{S}_{Co}$, the value of $-J_{ErCo}/k$ is equal to 6.7 K. One can see in Fig. 5 that the Er- and Co-sublattice moments will become parallel at about 60 T. In the bending process, the Er-sublattice moment oscillates around its easy direction (basal plane).

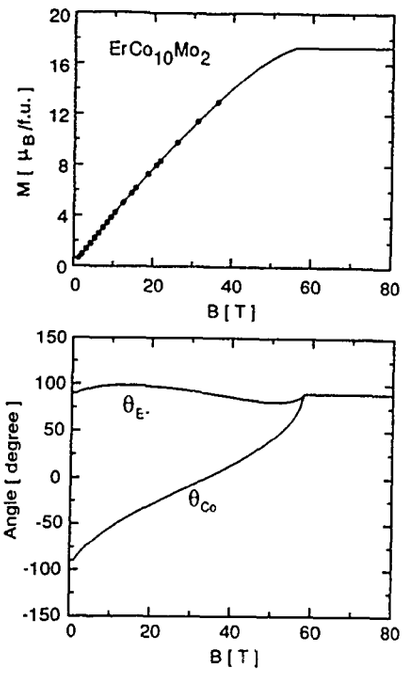

FIG. 5. (a) Comparison of the experimental and calculated magnetizations of $ErCo_{10}Mo_2$ (b) calculated field dependence of the orientations of the Er- and Co-sublattice moments.

It should be mentioned that in order to obtain the information about the magnetic coupling between R and Co sublattices for the other $RCo_{10}Mo_2$ compounds, all the magnetization curves shown in Fig. 2 should be analyzed taking into account the anisotropy of the two sublattices. This analysis which presently is carried out may be very different for the different rare-earth ions. For instance, for R=Ho, high-order anisotropy constants have to be taken into account.

Magnetic hardening by crystallization of amorphous precursors using very high heating rates

C. de Julián and J. M. González
Instituto de Ciencia de Materiales de Madrid—CSIC, c/Serrano 144, 28006 Madrid, Spain

The dependence of the treatment parameters of the coercivity of PrNdFeB samples prepared by crystallization of melt spun amorphous precursors is investigated. The crystallization treatments were carried out at high temperatures and using very high heating rates ("flash crystallization"). From the analysis of the temperature dependence of the critical field of the samples, it is concluded that this kind of crystallization treatment leads to very fine and homogeneous microstructures which result in a significant enhancement of the hard magnetic properties.

I. INTRODUCTION

The crystallization of amorphous alloys is usually described by specifying the fraction of material which is transformed either after a certain time at a given temperature (isothermal crystallization) or after a certain time when the material is heated up at a constant rate (continuous heating crystallization).[1] Nevertheless, for a given percentage of transformed material and depending on the concrete values of the treatment parameters, both the phase distribution and especially the microstructure of the crystallization product can be significantly different.[2] This is due to the different kineti 's of the elemental processes (i.e., nucleation and grain growth) involved in the crystallization and has a very interesting consequence: the possibility of optimizing the hysteretic properties of the crystallized material, which depend very sensitively on the microstructure. As it is shown in a previous work,[2] the use of high heating rates up to the treatment temperature allowed, in the case of NdDyFeB melt spun samples, optimizes the phase distribution of the crystallization product through the inhibition of the precipitation of the excess of α-Fe. Also, the accomplishment of crystallization at high temperatures favors the increase of the nucleation, which results in homogeneous microstructures.[1] In the present work, the coercivity of amorphous melt spun PrNdFeB samples crystallized by using a high heating rate and short-time anneals ("flash crystallization") is experimentally studied and correlated to the treatment parameters.

II. EXPERIMENTAL RESULTS AND DISCUSSION

Samples with nominal composition $Nd_9Pr_6Fe_{76}B_9$ were prepared by means of the single roller melt spinning technique (tangential speed of the roller, 20 m s^{-1}). According to x-ray diffraction (XRD) the as-quenched samples were amorphous. From differential scanning calorimetry (DSC) thermograms carried out at 160 °C min^{-1}, two consecutive crystallization stages, respectively, taking place at 620 and 690 °C were observed. The crystallization product consisted of a majority 2:14:1 phase.

The flash crystallization treatments were carried out by sandwiching some flakes of the amorphous precursor in between two ribbons of resistive alloy through which it was possible to flow electric current pulses (see Fig. 1). Current densities J_x, typically in the range from 1.6 to 1.9×10^3 A cm^{-2} and pulse time widths t_x, going from 1 to 12 s, were used. In order to protect the samples, and also to improve the homogeneity of the temperatures distribution, the flakes of the amorphous precursors were wrapped in a Ta foil which, in turn, was electrically isolated from the heating elements by means of mica foils. The whole setup was maintained under dynamic Ar atmosphere.

In Fig. 2 we present the time evolution of the temperature of the samples (measured by means of a low-mass thermocouple which was in good thermal contact with the Ta foil) when 16 A current pulses flow through the heating elements (cross section 0.01 cm^2) for different pulse widths t_x. The maximum temperature T_M achieved for the different treatments increased with the width of the current pulse (up to 1200 °C in the case of the 8 s, 19 A pulse). The maximum heating rate (approximately 15 000 °C min^{-1}) was achieved 2.5 s after the beginning of the pulse. The inset in this figure presents, as a function of the pulse width t_x, the total time t_{700} for which the temperature of the sample was above 700 °C (slightly above the temperature of the peak associated to the second crystallization stage as measured from DSC thermograms carried out at 160 °C min^{-1}). Since, due to the dissipation characteristics of the system, the T vs t curves of all the different treatments showed the same the initial heating regime, in the following we will use t_{700} in addition to J_x (or, equivalently, the current intensity I_x) to characterize our flash crystallization treatments.

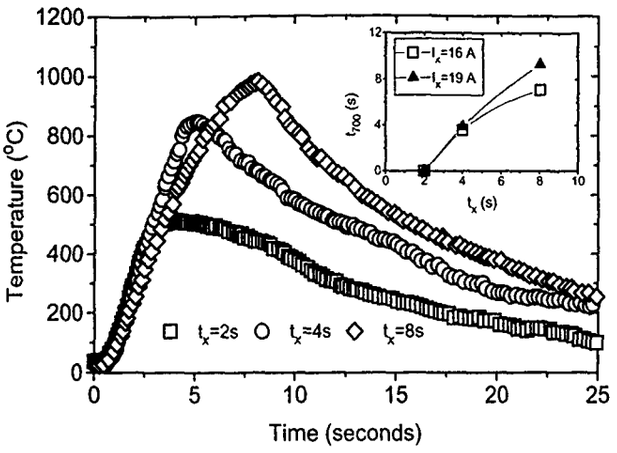

FIG. 2. Temperature of the samples vs time obtained with $I_x=16$ A and different pulse widths t_x.

The microstructure of the crystallized samples was dependent on the treatment parameters. For short-time, low intensity pulses, the samples were partially crystalline (according to the XRD) as one would expect from the increase with increasing heating rate of the crystallization processes.[3] A scanning electron micrograph (SEM) of a typical fresh fracture surface taken in the sample crystallized by using 16 A for 4 s is shown in Fig. 3(a). In it an inhomogeneous two-phase microstructure characterized by the presence of voids and domes can be observed. In contrast with this, the samples treated by means of longer pulses were fully crystallized, a homogenous microstructure [similar to that shown in Fig. 3(b)] being observed.

The study of the hysteretic properties of the samples was carried out by means of a SQUID magnetometer. Since our samples were isotropic, some reversible demagnetization occurred along the branches of the hysteresis loops corresponding to the first and second quadrants. Then, and in order to characterize the irreversible demagnetization, we considered the so-called critical field H_{crit}, defined as the demagnetization field for which the maximum susceptibility is observed. In Fig. 4 we have plotted the dependence on t_{700} of the room-temperature critical field. From this figure it is possible to observe that the critical field of the fully crystallized samples decreases with the increase of t_{700}. The deterioration of the critical field was basically related to the α-Fe segregation (which increases with T_M). Slightly lower values of the critical field than those achieved for the samples treated with $t_{700}\approx 4$ s were obtained for the samples crystallized by means of the shortest current pulses, which were only partly crystalline.[4] The optimum magnetic hardness corresponded to the samples treated with $t_{700}=4$ s, which were completely crystallized and presented a critical field of 22 kOe.

The temperature dependence of the critical field of the samples is shown in Fig. 5. We have analyzed these data in terms of the law proposed by Kromüller,[5]

$$H_{crit}=\alpha_\Psi \alpha_K H_K(T)-N_{eff}M_s(T), \qquad (1)$$

where $H_K(T)$ and $M_s(T)$ are, respectively, the anisotropy

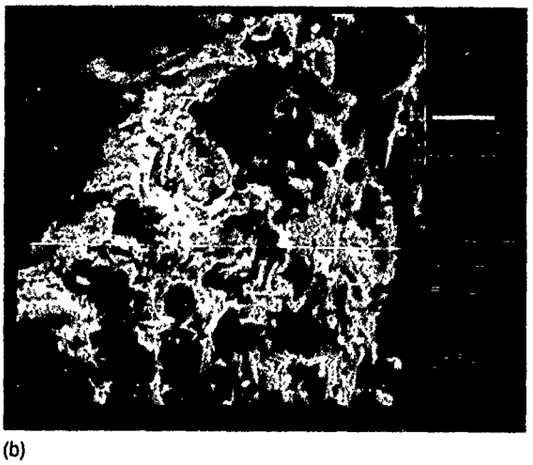

FIG. 3. (a) SEM micrograph of the fresh fracture surface of a sample treated for $t_x=4$ s with $I_x=16$ A. (b) SEM micrograph of the fresh fracture surface of a sample treated for $t_x=12$ s with $I_x=16$ A.

field and the saturation magnetization of the samples at a given temperature; α_Ψ reflects the influence on coercivity of the easy axes misalignment; α_K is related to the local reduction of anisotropy at the defects and N_{eff} gives the magnitude of the stray fields originated by the inhomogeneities in the distribution of magnetization. In samples with strong inter-

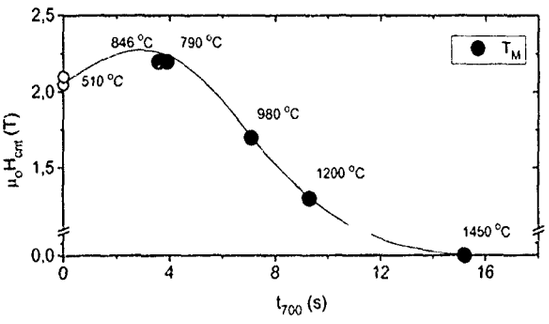

FIG. 4. Dependence of the room-temperature critical field vs t_{700} for the samples with optimum magnetic hardening.

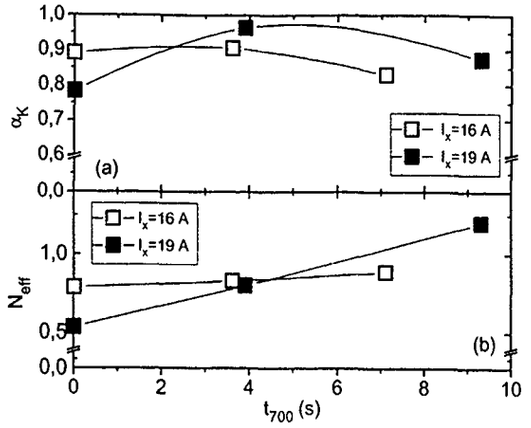

FIG. 7. (a) Variation of α_K with t_{700}. (b) Variation of N_{eff} with t_{700}.

granular coupling, tl magnetization reversal proceeds from those grains whose orientation with respect to the applied field has associated the lowest critical field. In this case α_Ψ can be replaced by its minimum value $\alpha_{\Psi min}$ which depends on the anisotropy constants as reported in Ref. 5. Considering this, from the fits of the experimental results for $H_{crit}(T)$ to Eq. (1) the parameters α_K and N_{eff} can be obtained. Figure 6 presents the results of these fits for the samples crystallized by means of I_x=19 A. These plots were carried out by taking into account the temperature dependence of the anisotropy field and magnetization of the $Nd_2Fe_{14}B_1$ and $Pr_2Fe_{14}B_1$ phases reported in Refs. 5 and 6.

The dependence of our results for α_K and N_{eff} on t_{700} is shown in Figs. 7(a) and 7(b), respectively. It is interesting to see how α_K presents a maximum value [only slightly lower than the ideal value of Eq. (1) in the case of the samples with optimum properties]. Also, and according to these results, the

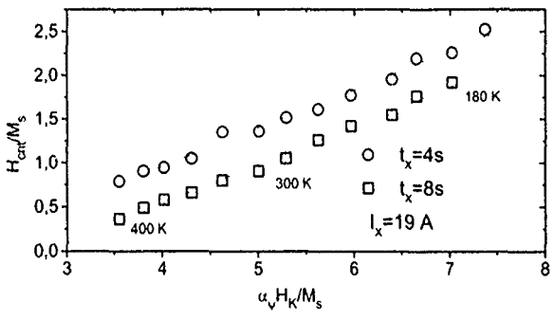

FIG. 6. Plot of the experimental $H_{crit}(T)$ data in terms of Eq. (1).

treatments carried out by using 16 A current originated larger deteriorations of the local anisotropy than those corresponding to treatments carried out by means of 19 A pulses.

Finally, N_{eff} increases with t_{700}, which reflects the progressive evolution in shape of the hard phase grains[2] from rounded original nucleus (predominant in the partly crystallized samples) to the well developed polyhedral grains with edges and corners which can be observed[2] in fully crystallized samples. Also, the inhomogeneities of the microstructure arising from the precipitation, for long t_{700} values, of α-Fe contribute to the increase of that parameter.

To summarize, we can say that optimum critical fields (larger than those achieved in as-quenched crystalline melt spun samples) can be obtained by flash crystallizing amorphous precursors using treatment times (t_{700}) of the order of a few seconds (long enough to complete the crystallization and short enough to avoid significant α-Fe segregation).

The magnetic properties of $(Y,Nd)Co_4B$, $Y(Co,Fe)_4B$, and $YCo_4(B,C)$ compounds have been investigated. The spin-reorientation temperature of YCo_4B increases with substitution of Nd for Y and Fe for Co, but decreases with the replacement of B for C. The Curie temperature of YCo_4B decreases upon substitution of Nd for Y and C for B, whereas it increases upon the introduction of Fe. The magnetic phase diagrams are given for $(Y,Nd)Co_4B$, $Y(Co,Fe)_4B$, and $YCo_4(B,C)$. The results show that the temperature range of the easy-axis anisotropy in YCo_4B is increased by C substitution, and decreased by Nd and Fe substitution. The saturation magnetization of YCo_4B increases by the introduction of Nd and Fe. Substitution of C for B changes the magnetic moment of Co only slightly. The magnetic anisotropy is increased by substitution of C for B.

I. INTRODUCTION

YCo_4B and the corresponding pseudoternary compounds crystallize in the $CeCo_4B$-type structure, which is derived from the $CaCu_5$ structure by partial substitution of B for Co in every two Co layers.[1] The structure and the magnetic properties of both Fe- and Co-based compounds of the $CeCo_4B$ type have been studied extensively in the past few years because of their potential of being used in permanent magnets.[2–8] Previous results have shown that in YCo_4B the Co-sublattice anisotropy is complex at low temperature.[5,8] In this compound, a spin-orientation occurs at about 150 K which has been attributed to a change of the easy-magnetization direction of the Co sublattice from c axis at high temperature to basal plane at low temperature. Another anomaly is observed at about 60 K, the origin of which is still unknown. In order to understand the magnetic behavior of the Co sublattice in this type of compound, we have performed a detailed study of the magnetic phase diagrams of $(Y,Nd)Co_4B$, $Y(Co,Fe)_4B$, and $YCo_4(B,C)$.

II. EXPERIMENTAL PROCEDURE

The compounds $Y_{1-x}Nd_xCo_4B$ (x=0.0,0.1,0.2,0.3), $YCo_{4-x}Fe_xB$ (x=0.0,0.1,0.2,0.3,0.4), and $YCo_4B_{1-x}C_x$ (x=0.0,0.1,0.2,0.3), were prepared by melting in an arc furnace in an argon atmosphere, followed by annealing in an atmosphere of highly purified argon at 900 °C for 2 weeks. Subsequently, the materials were quenched into ice water. X-ray-diffraction results showed that only negligible amounts of impurity phases were present.

The temperature dependence of the a.c. susceptibility was measured on bulk samples in the temperature range from 4.2 to 600 K. The high-field magnetization was measured at 4.2 K in the high-field facility at the University of Amsterdam on magnetically aligned samples. These samples were prepared by mixing fine powder of the compound with epoxy resin and letting the mixture subsequently solidify in a field of about 1 T.

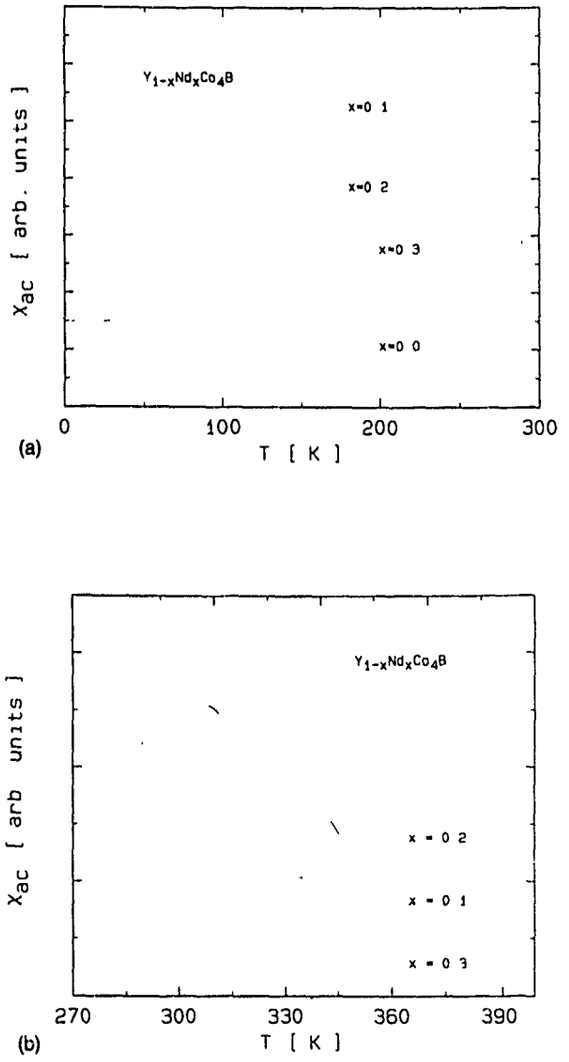

FIG. 1. Temperature dependence of the a.c. susceptibility of $Y_{1-x}Nd_xCo_4B$ compounds between (a) 4 2 and 300 K, and (b) 270 and 400 K.

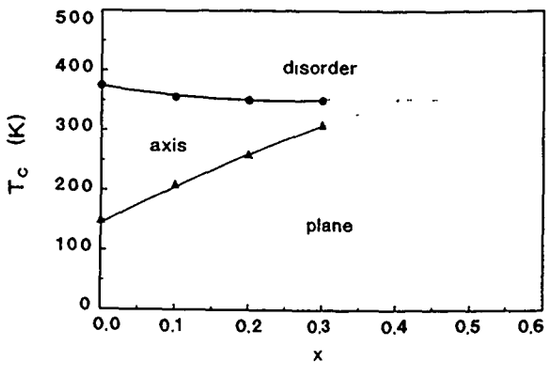

FIG. 2. Magnetic phase diagram of $Y_{1-x}Nd_xCo_4B$ compounds.

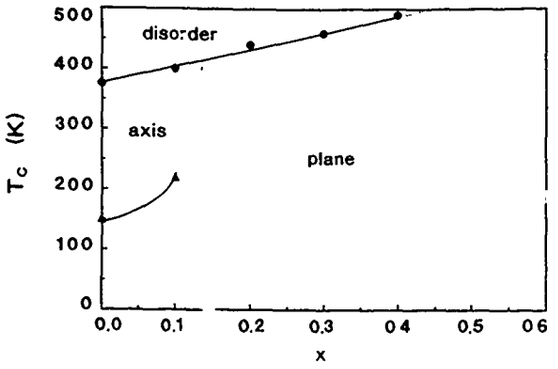

FIG. 4. Magnetic phase diagram of $YCo_{4-x}Fe_xB$ compounds

III. EXPERIMENTAL RESULTS AND DISCUSSION

A. $Y_{1-x}Nd_xCo_4B$

Substitution of Nd for Y markedly affects the anisotropy of YCo_4B. Figure 1 shows the temperature dependence of the a.c. susceptibility of the $Y_{1-x}Nd_xCo_4B$ compounds. The spin reorientation at 150 K in YCo_4B and the anomaly around 60 K are both strongly influenced by the introduction of Nd. The spin-reorientation temperature is found to increase with increasing Nd content. In the sample with $x=0.3$, the transition even occurs above room temperature, at 310 K. The anomaly at 60 K shifts to lower temperatures in a rather random way. The high-temperature parts of the a.c. susceptibility show that the Curie temperature of YCo_4B slightly decreases from 375 K for YCo_4B to 350 K for $Nd_{0.3}Y_{0.7}Co_4B$.[5] Since $NdCo_4B$ has easy-plane magnetization at room temperature,[6] the magnetization in the Nd-containing compounds can also be expected to change from easy axis at high temperature to easy plane at low temperature. Therefore we tentatively conclude from the composition dependence of the spin-reorientation temperature in the $Y_{1-x}Nd_xCo_4B$ system that the transition at 150 K in YCo_4B is also an axis-to-plane transition. The magnetic phase diagram of the (Y,Nd)Co_4B system constructed on the basis of these experimental results is shown in Fig. 2. The easy-axis region is only found in the Y-rich part and its width decreases strongly with increasing Nd content.

B. $YCo_{4-x}Fe_xB$

Substitution of Fe for Co in YCo_4B strongly influences the magnetic anisotropy of the 3d sublattice. Figure 3 shows the temperature dependence of the a.c. susceptibility of $YCo_{4-x}Fe_xB$ compounds between 4.2 and 300 K. The spin-reorientation temperature increases with increasing Fe content and for $x=0.2$, no spin reorientation is observed up to the Curie temperature. As YFe_4B also has easy-plane magnetization at room temperature,[7] this composition dependence of the transition temperature can be taken as evidence that the transition is from easy axis at high temperature to easy plane at low temperature. Substitution of Fe for Co strongly enhances the easy-plane anisotropy. With increasing Fe content, the Curie temperature increases strongly from 375 K for YCo_4B to 490 K for $YCo_{3.6}Fe_{0.4}B$.[7] This means that the $3d$–$3d$ exchange interaction is strongly increased

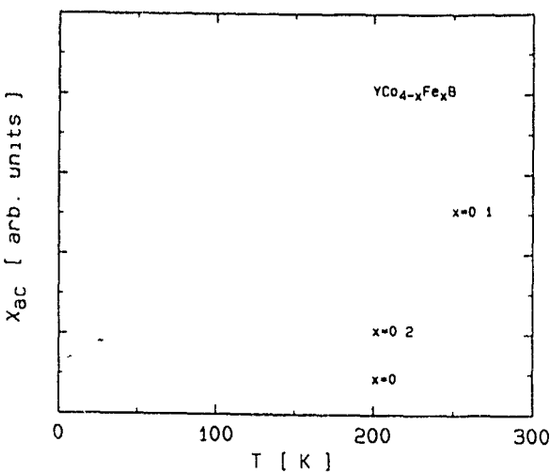

FIG. 3. Temperature dependence of ac susceptibility of $YCo_{4-x}Fe_xB$ compounds between 4.2 and 300 K.

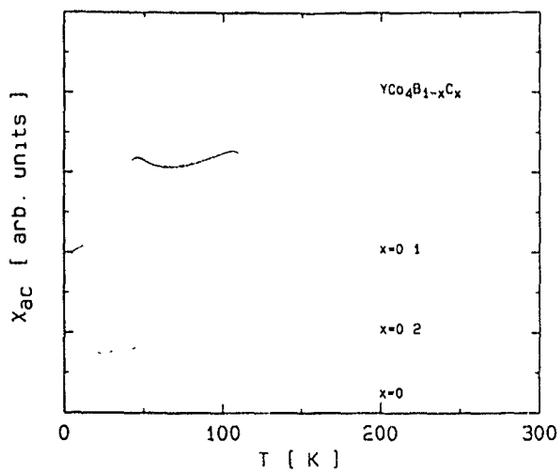

FIG. 5 Temperature dependence of the a c. susceptibility of $YCo_4B_{1-x}C_x$ compounds between 4.2 and 300 K.

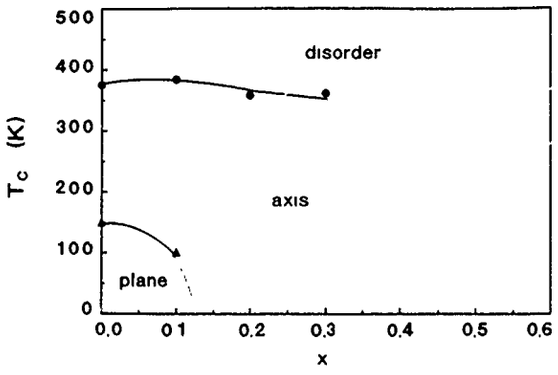

FIG. 6. Magnetic phase diagram of $YCo_4B_{1-x}C_x$ compounds.

upon the introduction of Fe. The magnetic phase diagram in Fig. 4 shows that the easy-axis region is small and restricted to the Co-rich part.

C. $YCo_4B_{1-x}C_x$

The magnetic properties of the Co sublattice for YCo_4B are also affected by substitution of C for B. Figure 5 shows the temperature dependence of the a.c. susceptibility of $YCo_4B_{1-x}C_x$ compounds with $x=0.0$, 0.1, and 0.2. Both transitions in the compound with $x=0.0$ at 60 and 150 K move to lower temperatures for $x=0.1$ and then disappear for $x=0.2$. In contrast to the types of substitution discussed before, substitution of C and B enlarges the temperature range of easy-axis magnetization, which is favorable for applications. Substitution of C for B in YCo_4B causes the Curie temperature to first slightly increase for $x=0.1$ and then to decrease for $x>0.1$. The phase diagram of the $YCo_4(B,C)$ system is shown in Fig. 6.

The magnetization curves are shown in Fig. 7. From the planar diagram shown in Fig. 6 one would have expected that the magnetic moment of the compound with $x=0.1$ when measured in low fields applied parallel to the alignment direction would have been lower than the moment measured perpendicular to the alignment field (as for $x=0$). It is possible that this latter situation is realized in applied fields lower than those considered here with an intersection point between the isotherm below 1.3 T. It can be seen from Fig. 7 that the saturation magnetization of the compound changes only slightly with x. This is similar to what has been observed in the $Nd_2Co_{14}(B,C)$ system.

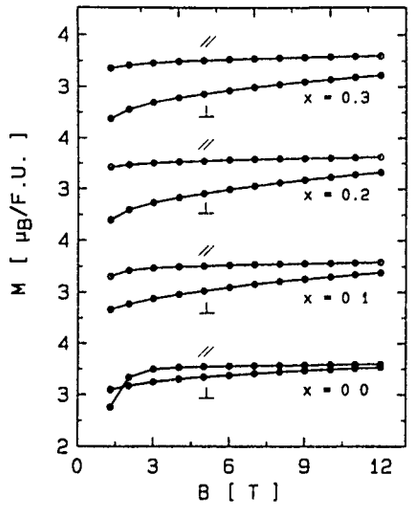

FIG. 7. Magnetization of $YCo_4B_{1-x}C_x$ compounds at 4.2 K for the field parallel (○) and perpendicular (●) to the alignment direction.

A systematic study on stability of flux in Nd-Fe-B magnets consolidated by direct joule heating

H. Fukunaga and H. Tomita

Magnetic aftereffect and irreversible flux loss at elevated temperatures were studied for fully dense isotropic and anisotropic Nd-Fe-Co−B magnets consolidated from rapidly quenched powder by direct joule heating. The consolidation process and the subsequent alignment of c axis do not affect the aftereffect constant S_v and the prepared magnets have roughly the same S_v as a bonded magnet, independent of coercivity at room temperature (650–1200 kA/m), exposure temperature (60–120 °C), and anisotropy of the magnets. Thus the magnitude of the aftereffect is determined mainly by the magnitude of the irreversible susceptibility χ_{irr}. It was also clarified empirically that the irreversible flux loss FL is proportional in magnitude to χ_{irr}. However, the slopes of the FL vs χ_{irr} line for isotropic magnets are much larger than those for the anisotropic ones. Thus FL can be reduced by decreasing χ_{irr} and/or making magnets anisotropic.

I. INTRODUCTION

Although Nd-Fe-B based magnets have superior hard magnetic properties, the thermal stability of their magnetic properties is poor compared with that of Sm-Co magnets because of their low Curie temperature.[1] Improvements in the thermal stability have been studied by many authors,[2] and it has been clarified that rapidly quenched powder has smaller temperature dependences of coercivity and remanence.[3] Therefore utilization of rapidly quenched powder would be one of the methods of improving their stability. Recently, two of the authors have developed a new method of preparing fully dense Nd-Fe-B magnets from rapidly quenched powder by direct joule heating.[4] The developed magnets, which consist of fine grains, exhibit smaller temperature variation of coercivity than conventional sintered magnets.[4,5]

Thus, in this study, the magnetic aftereffect and the flux loss due to exposure at elevated temperatures were investigated for Nd-Fe-Co-B magnets (H_c=650–1200 kA/m) prepared by the above-mentioned method.

II. EXPERIMENT

Fully dense anisotropic and isotropic magnets with a variety of coercivities were consolidated from $Nd_{14}Fe_{73}Co_7B_6$ rapidly quenched powder. Details of the preparation method have been reported in the previous papers.[4,6] Cylindrical specimens, 5 mm diam×6.6 mm long and 5 mm diam×4.1 mm long, were cut out of them. In this paper, anisotropic and isotropic specimens are designated as "ANISO" and "ISO," respectively, and long and short specimens as "L" and "S," respectively. Thus "ANISO-L" means a long anisotropic specimen.

The specimens were first premagnetized in a pulse magnetic field of 4 MA/m and were exposed at an elevated temperature T_a (60–120 °C). Then the decrease in magnetization ΔI due to magnetic aftereffect was measured with a flux meter as a function of the exposure time t_a [Fig. 1(a)]. The irreversible flux loss FL due to the exposure was determined by

$$FL=(\Phi_0-\Phi_1)/\Phi_0, \tag{1}$$

where Φ_0 and Φ_1 are the flux values measured at room temperature before and after the exposure, respectively [Fig. 1(b)]. Hysteresis loops were traced with a computer-aided hysteresis tracer and the demagnetizing effect was corrected by using a Ni cylinder. The coercivity H_c(RT) and the remanence M_r(RT) at room temperature are listed for the obtained magnets in Table I. The irreversible susceptibility χ_{irr} at a working point was calculated by subtracting the reversible susceptibility from the total susceptibility χ_{total}.

III. RESULTS AND DISCUSSION

Typical ΔI observed in our specimens is shown in Fig. 2 for an anisotropic magnet with H_c(RT)=990 kA/m. The magnetization decreases nearly linearly with the logarithm of t_a between 0.2 and 10 h and a unique slope $d(\Delta I)/d(\ln t_a)$ can be defined for each T_a. Figure 3 shows typical variation of $d(\Delta I)/d(\ln t_a)$ as a function of H_c(RT) for ISO-S and ANISO-S specimens. The slope of the anisotropic specimens at each T_a is smaller at H_c(RT)=1200 kA/m than that of the

TABLE I. Remanence and coercivity at room temperature of investigated magnets.

Specimens	Remanence (T)	Coercivity (kA/m)
ISO No. 1	0.76	680
ISO No. 2	0.82	950
ISO No. 3	0.84	1200
ANISO No. 1	1.24	650
ANISO No. 2	1.22	990
ANISO No. 3	1.20	1200

isotropic ones. However, it increases markedly with a decrease in H_c(RT) and then becomes larger at H_c(RT)=1000 kA/m than that of isotropic ones when T_a=100 and 120 °C. This behavior can be attributed to the fact that the working point of the anisotropic specimen with low H_c(RT) moves abruptly to a steep part of demagnetization curve from its flat part with increasing T_a.

It has been proposed that ΔI can be expressed[7,8] for specimens with a demagnetizing factor N as

$$\Delta I = S_v \chi_{irr} (\ln t_a - A)/(1+\chi_{total} N/\mu_0), \quad (2)$$

where S_v and A are the aftereffect constant and the constant related to the initial value of the magnetization, respectively. In general, S_v and χ_{irr} depend on material, T_a, and the magnetization state of a specimen. In order to clarify which of S_v and χ_{irr} is the dominant factor in affecting the magnitude of ΔI, $(1+\chi_{total}N/\mu_0)d(\Delta I)/d(\ln t_a)$ is plotted in Fig. 4 as a function of χ_{irr}. Figure 4 includes results obtained for isotropic as well as anisotropic specimens with various H_c(RT) (650–1200 kA/m), T_a (60–120 °C), and lengths (4.1 and 6.6 mm). As clearly seen in the figure, $(1+\chi_{total}N/\mu_0)d(\Delta I)/d(\ln t_a)$ has strong correlation with χ_{irr} and all the plotted points are near the one straight line indicated by the solid line. Since the slope of the line corresponds to the value of S_v as indicated in Eq. (2), this result suggests that S_v of our specimens is nearly constant, independent of H_c, T_a, the alignment of c axis, and the length of the specimens. Thus the magnitude of magnetic aftereffect is determined mainly by χ_{irr}.

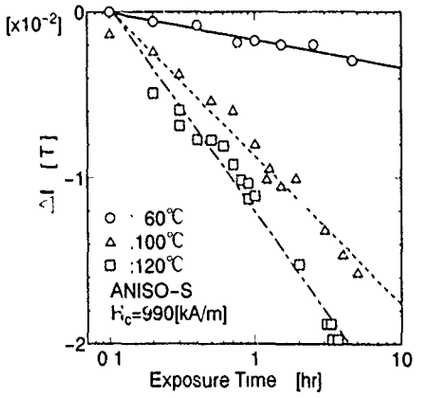

FIG. 2. Typical variation of magnetization ΔI due to magnetic aftereffect as a function of exposure t_a

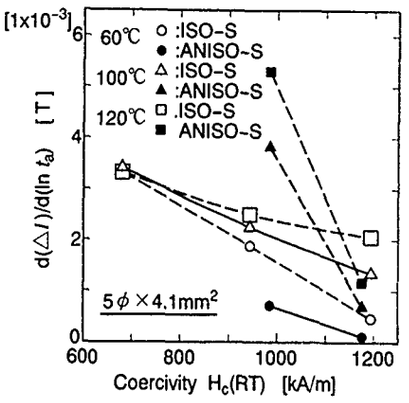

FIG. 3. Typical variation of $d(\Delta I)/d(\ln t_a)$ as a function of coercivity at room temperature H_c(RT).

Previously Nishio and Yamamoto[9] have reported that S_v of a $Nd_{12.2}Fe_{77}Co_{5.4}B_{5.4}$ compression bonded magnet, which has nearly the same composition as ours, is between 2.6 and 3.1 kA/m in the temperature range of 20–125 °C. The lines corresponding to these values of S_v are also shown in the figure by broken lines. Our measured data roughly agree with the broken lines, which suggests that the consolidation of rapidly quenched powder and the subsequent alignment of c axis do not affect S_v remarkably and that the prepared fully dense magnets preserve the value of S_v of rapidly quenched powder.

The irreversible flux loss FL due to 1 h exposure at T_a is shown in Fig. 5 as a function of χ_{irr}. From an empirical point of view, FL is proportional in magnitude to χ_{irr} at each T_a. Thus a decrease in χ_{irr} reduces FL. Irreversible flux loss can be attributed to magnetization reversals based on magnetic aftereffect and a reduction in H_c at an elevated temperature. As the magnetization reversal due to magnetic aftereffect has strong correlation with χ_{irr}, the reversal due to a reduction in H_c is also expected to correlate with χ_{irr}.

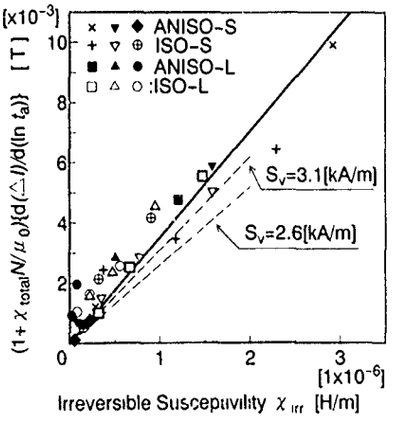

FIG 4. $(1+\chi_{total}N/\mu_0)d(\Delta I)/d(\ln t_a)$ for isotropic as well as anisotropic specimens with various H_c(RT), T_a, and lengths, as a function of χ_{irr}. Solid line. best-fit line for measured data, broken lines. lines corresponding to S_v=2.6 and 3.1 kA/m. The slopes of lines correspond to the values of S_v

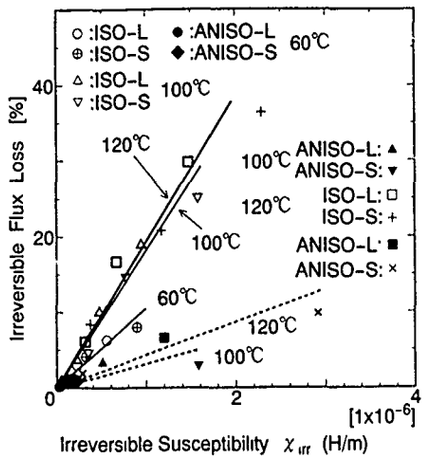

FIG. 5. Irreversible flux loss FL due to exposure for 1 h at elevated temperatures as a function of χ_{irr}. Solid lines: isotropic specimens, broken lines: anisotropic specimens.

It is also seen that FL can be reduced by making the magnets anisotropic. Large M_r(RT) of the anisotropic magnets is partly responsible for this improvement because FL is expressed after the zation by the initial value of flux as indicated by Eq.

IV. CONCLUSIONS

Stability of flux at elevated temperatures was studied for fully dense isotropic and anisotropic Nd-Fe-Co-B magnets consolidated from rapidly quenched powder by direct joule heating. Although the magnitude of aftereffect varied with coercivity, exposure temperature, anisotropy, and the shape of specimens, the unique aftereffect constant S_v was observed independently of these parameters. In addition, the observed S_v agreed roughly with that reported previously for a bonded magnet. These results suggest that the consolidation process and the subsequent alignment of c axis do not affect S_v and that the magnitude of the aftereffect is determined mainly by the irreversible susceptibility χ_{irr}.

The irreversible flux loss FL due to exposure at an elevated temperature was also proportional in magnitude to χ_{irr} which depends on the coercivity and the shape of specimens. However, FL of the anisotropic specimens was much smaller than that of isotropic ones. Therefore FL is expected to be reduced by decreasing χ_{irr} and/or making magnets anisotropic.

X-ray-diffraction patterns and Mössbauer spectra of $Sm_2(Fe,Ga)_{17}C_{1.5}$ alloys have been studied. The results of x-ray-diffraction patterns and Mössbauer spectra indicate that little α-Fe and carbonides appear in $Sm_2(Fe,Ga)_{17}C_{1.5}$ alloys. The addition of a few Ga atoms show that the thermal stability in $Sm_2(Fe,Ga)_{17}C_{1.5}$ alloys is getting better. Structural analyses indicate C atoms as interstitial atoms occupying the $9d$ site. Ga atoms seem to substitute partially for Fe atoms and occupy preferentially the $18h$ site.

I. INTRODUCTION

The binary R_2Fe_{17} compounds are not suitable for permanent magnetic materials because of their low Curie temperature and plane-preferred magnetocrystalline anisotropy. It has been recently shown that the presence of the interstitial C atoms in R_2Fe_{17} compounds gives rise to an increase of the Curie temperature by more than 100 K compared with their counterparts without carbon.[1,2] In particular, in the case of $Sm_2Fe_{17}C_x$, a relatively high uniaxial crystal anisotropy and an anisotropy field of about 6 T were found at room temperature for $x=1$.[3] But the carbon concentration was well below $x=2$ in $R_2Fe_{17}C_x$ compounds achieved by arc melting.[4,5] Liao *et al.*[6] reported that high carbon-containing $R_2Fe_{17}C_x$ ($x=2.5$) compounds were obtained by solid–gas phase reaction. Unfortunately, these carbides will decompose into the equilibrium phases RC and α-Fe on heating to 700 °C.[7] Recently, Shen and co-workers[8] have obtained $R_2Fe_{17}C_x$ ($x=0$–3.0) compounds by means of the melt-spinning method. These carbides are highly stable at least at high temperature up to 1100 °C. Shen's results shows that a few Ga, Si, and Al atoms substitutions for Fe can enhance the thermal stability in $Sm_2Fe_{17}C_x$ alloys. In order to better understand the influence of carbon and substitution atoms on the structure in $Sm_2Fe_{17}C_x$ alloys, we performed Mössbauer spectra study of melt-spun $Sm_2(Fe,Ga)_2C_{1.5}$ alloys.

II. EXPERIMENTAL DETAILS

The alloy $Sm_2Fe_{17-x}Ga_xC_{1.5}$ ($x=1$–6) was prepared by melting of 99.9%-pure primary elements in argon atmosphere. The buttons were melted at least three times to achieve homogeneity. Then the alloy buttons were annealed at 1000–1200 °C in vacuum for 50 h. $Sm_2(FeGa)_{17}C_{1.5}$ alloy buttons were melted and then made into ribbons by the melt-spinning technique. The obtained ribbons were about 1 mm wide and 20–30 μm thick. X-ray-diffraction experiments with Cu K_α radiation were made to determine the crystallographic structure. The ^{57}Fe Mössbauer spectra for $Sm_2Fe_{15}Ga_2C_{1.5}$ compounds (a natural abundance Fe used) at room temperature were collected using a constant acceleration spectrometer with a source of ^{57}Co (in Pd). The velocity scale was calibrated using an α-Fe absorber at room temperature.

III. RESULTS AND DISCUSSIONS

X-ray-diffraction patterns indicated that the main phases of all the samples is the 2:17 structure. $Sm_2(FeGa)_{17}C_{1.5}$ compounds crystallize in the rhombohedral Th_2Zh_{17}-type structure ($R3m$). The substitution of Fe with Ga results in a increase in the lattice constants. The results of x-ray diffraction show the unit-cell volume of $Sm_2(FeGa)_{17}C_{1.5}$ linearly increases with increasing Ga concentration.

For some samples in $Sm_2Fe_{17}C_x$ compounds with high carbon concentration, the α-Fe also has to be taken into account. But here, the x-ray pattern (Fig. 1) shows a slight trace of α-Fe in the $Sm_2(FeGa)_{17}C_{1.5}$ compound. That is to say, the addition of the few Ga atoms in $Sm_2(FeGa)_{17}C_{1.5}$ compounds will help to enhance a single phase in the carbides of $Sm_2(FeGa)_{17}C_{1.5}$.

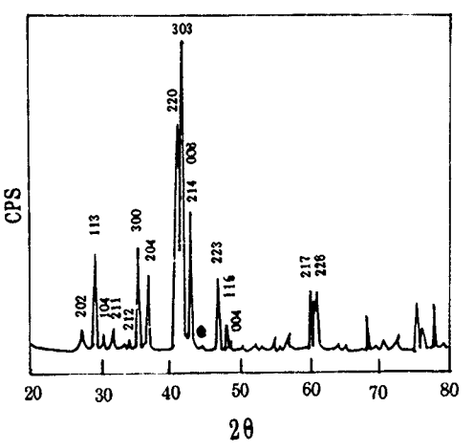

FIG. 1. X-ray-diffraction pattern of $Sm_2Fe_{15}Ga_2C_{1.5}$ compound (● α-Fe)

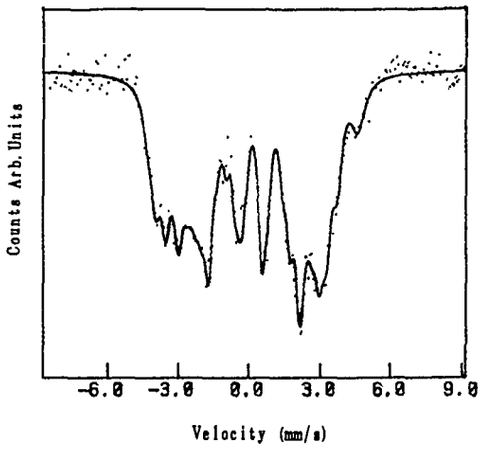

FIG. 2. Mossbauer spectrum of $Sm_2Fe_{15}Ga_2C_{1.5}$ compound.

The addition of the Ga atoms leads to an increase of axis anisotropies. At the optimal quenching rate, the intrinsic coercivity obtained is iH_c=14 kOe.

There are four nonequivalent types of Fe sites in the Th_2Zn_{17} unit cell ($6c$, $9d$, $18h$, and $18f$), and the C atoms could be statistically distributed over the $9d$ site in this structure.[9,10]

For the C-containing compounds, because of their uniaxial anisotropy, the Mössbauer subspectra for $18h$ and $18f$ sites have to be split into two subspectra with the intensity ratio of 1:2,[11] so that six subspectra were used in order to fit the Mössbauer spectrum of the $Sm_2Fe_{15}Ga_2C_{1.5}$ compound (Fig. 2).

During the fitting of the Mössbauer spectrum, six Ga atoms are regarded as entering into $18h$ and $18f$ sites with equivalent ratio, so an overall intensity constant of 6:9:(10:5):(10:5) for $6c$:$9d$:$18f$:$18h$ was imposed. We used the fitting procedure written by one author (Zu-xiong Xu) of this paper, which can impose the restricted condition of the above-mentioned intensity ratios to the fitting. The hyperfine fields for each crystallographic site of the $Sm_2Fe_{15}Ga_2C_{1.5}$ compound are listed in Table I.

TABLE I. Hyperfine fields for each crystallographic site of the $Sm_2Fe_{15}Ga_2C_{1.5}$ compound

$6c$ (T)	$9d$ (T)	$18f_1$ (T)	$18f_2$ (T)	$18h_1$ (T)	$18h_2$ (T)
27.6	23.5	20.9	16.8	18.8	14.0

There is no doubt that the $6c$ dumbell site should have the largest hyperfine field since it has the most Fe atoms, and the fewest rare-earth neighbors. Similarly, the $18f$ site has a larger hyperfine field than the $18h$ site. The $9d$ site can be distinguished by its intensity from the $18f$ and $18h$ sites. Hence we find hyperfine fields for the different Fe sites that decrease in the order $6c>9d>18f>18h$.

Low-temperature behavior of thermopower in rare-earth iron borides $R_2Fe_{14}B$ (R=Nd, Sm, Gd, Tb, Dy, Ho, Er)

Recently it was shown that the electrical resistivity behaves anomalously both at low temperatures and near the Curie point in rare-earth iron borides due to the subtle interplay between $4f$ and $3d$ transition elements. Here a systematic experimental study on the behavior of the thermoelectric power (S) of $R_2Fe_{14}B$ compounds with heavy (R=Gd, Tb, Dy, Ho, Er) and light (Nd, Sm) rare-earth elements is presented. Data for $La_2Fe_{14}B$, in the temperature range 10 K$<T<$350 K, is also included for comparison. The results are consistent with the spin-mixing model for electron scattering, with an intrinsic thermopower contribution related to Fe and a spin dependent impurity scattering term related to the rare-earth magnetic ions. From the interplay of both terms we can get maxima in S (for R=Td, Dy, Ho, Er samples) or minima (Gd, Nd, Sm) at low temperatures. The data indicates the ultimate dominance of impurity scattering at low temperatures, producing a linear variation in the magnetic thermopower (S). In $La_2Fe_{14}B$, only the intrinsic effect is observed, and $S(T)$ does not follow a linear temperature dependence.

I. INTRODUCTION

Studies on R-Fe-B compounds generally deal with their magnetic properties for applications at room temperature and above. These compounds, however, exhibit interesting effects in other physical properties, namely in transport phenomena, due to the subtle interplay between $4f$ and $3d$ transition elements. Recently, we have shown that the electrical resistivity behaves anomalously both at low temperatures and near the Curie point.[1,2] The results on the behavior of the thermoelectric power of $R_2Fe_{14}B$ compounds is here reported, for the case of heavy (R=Gd, Tb, Dy, Ho, Er) and light (Nd, Sm) rare earths, over the temperature range 10 K$<T<$350 K. For comparison we also include the data for $La_2Fe_{14}B$.

II. RESULTS AND DISCUSSION

As shown in Figs. 1 and 2, the thermoelectric power (S) is negative at high temperatures, exhibiting a flat curve from about 250 up to 350 K, with relatively large values, e.g., $S\cong -15\ \mu V\,K^{-1}$ for R=Gd and $S\cong -17\ \mu V\,K^{-1}$ for R=Sm.

Below ~200 K the thermopower rises rapidly with the decrease of temperature, exhibiting characteristic maxima at intermediate temperatures. For example, in $Er_2Fe_{14}B$ we observe $S_{max}=10.5\ \mu V\,K^{-1}$ at $T=37.5$ K.

In the heavy rare-earth samples with R=Tb, Dy, Ho, Er (Fig. 2), and also in $LaFe_{14}B$, the thermoelectric power decreases monotonically from such maxima, towards vanishing values at the lowest temperatures. In contrast, in the samples with R=Gd, Sm, Nd, a more complex behavior occurs, leading to the appearance of a negative minimum at lower temperatures. For example, in $Gd_2Er_{14}B$ we have $S_{min}=-2\ \mu V\,K^{-1}$ at $T=27$ K.

We have also measured the electric resistivity in the same samples, which enabled us to obtain the normalized quantity $S(T)/\rho(T)$ for each sample. As can be seen from the phenomenological transport equations, such quantity depends only on the cross-transport coefficient L_{10}, which is responsible for the appearance of any finite thermoelectric power:[3]

$$\frac{S(T)}{\rho(T)} \simeq \frac{L_{10}(T)}{T}.$$

As shown in Fig. 3, all the S/ρ high-temperature data closely approaches a common curve, indicating a similar behavior for all the samples in this temperature range. This quantity affords a more direct comparison with simpler theoretical expressions, obtained after the discarding of several scattering mechanisms which do not contribute to L_{10} although they give important effects in ρ.

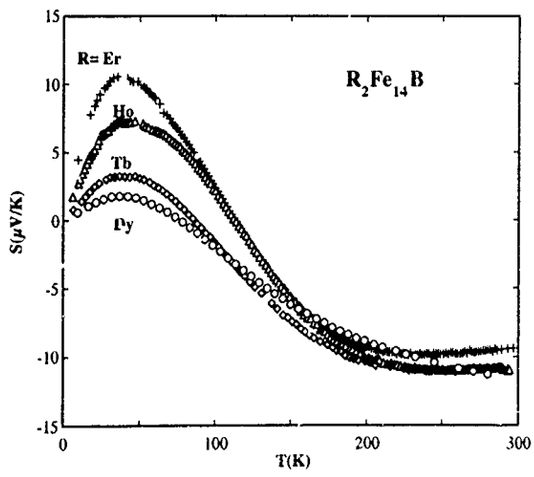

FIG. 1. Temperature dependence of the thermoelectric power for $R_2Fe_{14}B$ (R=Tb, Dy, Ho, Er) and $La_2Fe_{14}B$.

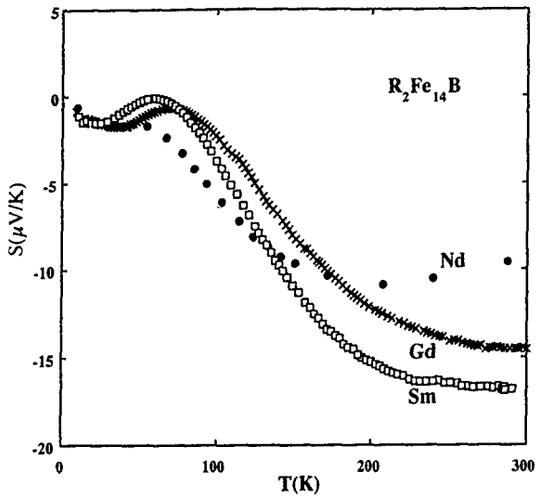

FIG. 2. Temperature dependence of the thermoelectric power for $R_2Fe_{14}B$ (R=Nd, Sm, Gd).

The low-temperature data shows a rapid rise of S with the increase of temperature, quickly reaching a maximum with relatively high values; for example, we have $S \cong 11$ $\mu V\,K^{-1}$ in $Er_2Fe_{14}B$ when $T \sim 35$ K. These effects are not due to the normal scattering mechanisms which invariably lead to small values, $S \sim (k/e)\,(kT/E_F)$ or $S \sim (k/e)\,(\Delta/E_F)$, since both the thermal (kT) and exchange (Δ) energies are much smaller than the Fermi energy.

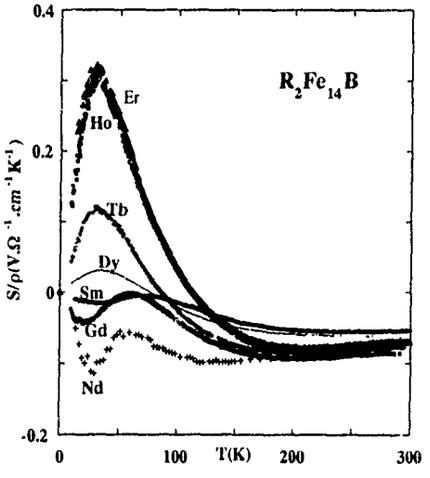

FIG. 3. Temperature dependence of S/ρ for $R_2Fe_{14}B$ (R=Nd, Sm, Gd, Tb, Dy, Ho, Er).

Large values of S at low temperatures, with sizable maxima or minima before fading away at high temperatures, occur frequently in ordered magnets caused by magnon scattering (spin-flip relaxation time $\tau_{\uparrow\downarrow}$) in the particular cases where impurity scattering leads to *different* electron collision times for spin-up or -down directions ($\tau_\uparrow \neq \tau_\downarrow$).[4–6]

If the concentration of impurities is sufficiently large so that relaxation of the electrons with respect to momentum (causing electrical resistivity) occurs on the impurities, while only energy relaxation occurs on the magnons, it can be shown that:[5,6]

$$S \propto (\tau_\uparrow - \tau_\downarrow) T,$$

$$S \propto (\tau_\uparrow - \tau_\downarrow) \frac{1}{T},$$

where the first regime ($S \propto T$) holds at low temperatures where $\tau_\uparrow$, $\tau_\downarrow \ll \tau_{\uparrow\downarrow}$ (when a cutoff exists for electron-magnon scattering, an exponential decrease of S takes over at still lower temperatures). The second regime ($S \propto T^{-1}$) occurs when the magnon scattering dominates over impurity scattering, $\tau_{\uparrow\downarrow} \ll \tau_\uparrow$, $\tau_\downarrow$. The absolute value of S should then go through a maximum at intermediate temperatures, when $\tau_{\uparrow\downarrow} \sim \sqrt{\tau_\uparrow \tau_\downarrow}$.

The $\tau_\uparrow \neq \tau_\downarrow$ asymmetry, which is absolutely necessary to produce large effects in S,[5–9] usually arises from the presence of impurities causing *spin-dependent s-s* electron scattering, such as magnetic impurities or transition-metal impurities.[10–12] In addition, the intrinsically spin transitions at temperatures below the Curie point, caused by magnons as well as by phonons, can play a role similar to the magnetic impurities.[6]

Effects of field orientation on field uniformity in permanent magnet structures

J. H. Jensen and M. G. Abele
Department of Radiology, New York University School of Medicine, New York, New York 10016

The effects of magnetic-field orientation are investigated for permanent magnet structures designed for the generation of highly uniform fields. The structures considered are based on closed cavities that produce exactly uniform internal fields. An open structure with an approximately uniform field is obtained by removing part of the wall from such a cavity. This paper explores how the magnetic-field uniformity depends on the field orientation relative to the opening. A yokeless, cylindrical cavity that is opened at both ends is considered in detail with the field oriented both perpendicular to and parallel to the cylinder's axis. The field uniformity is shown to be substantially better for the perpendicular orientation. The leakage field outside the magnet is also contrasted for the two cases.

I. INTRODUCTION

A general approach for designing open permanent magnet structures that generate highly uniform magnetic fields is to begin with a closed structure that generates an exactly uniform field in an internal cavity.[1] From the infinite variety of such closed structures, one may be selected to meet particular design criteria. To open the structure, which is necessary to allow access to the field, magnetic material is removed from the cavity wall. This paper examines how the character of the resulting approximately uniform field depends on the orientation of the field relative to the opening.

A yokeless, cylindrical structure (Fig. 1) is used as a prototype. If the cylinder is closed at both ends, the magnetization can be chosen, without changing the structure's geometry, to produce a perfectly uniform magnetic field inside the cavity oriented either perpendicular or parallel to the axis of the cylinder and with no magnetic field outside the cylinder. If the cylinder is then opened at both ends, the field will be approximately uniform in the center of the structure, but highly perturbed near the ends. There will also be a leakage field outside.

The degree of uniformity in the center, the nature of the perturbation at the end of the cylinder, and the amount of leakage field is shown to be substantially different for the two orientations. In particular, the perpendicular orientation gives a more uniform central field, better end behavior, and less leakage field. These advantages of the perpendicular orientation follow from general considerations and apply also to structures of direct practical interest.

II. DESCRIPTION OF MODEL

Consider first an infinitely long cylinder of inner radius r_1 and outer radius r_2. Assume magnetic material filling the region between r_1 and r_2 and having a magnetic polarization density $\mathbf{J}(r,\psi,z)$, where (r,ψ,z) are conventional cylindrical coordinates taken relative to the cylinder's symmetry axis. There is a unique choice of $\mathbf{J}$ that produces a uniform magnetic field $\mathbf{H}$ of specified magnitude and orientation in the region $r<r_1$ and zero magnetic field for $r>r_2$, and that obeys the constraints $\nabla\cdot\mathbf{J}=0$, $\nabla\times\mathbf{J}=0$, and $\int\mathbf{J}\cdot d\mathbf{a}=0$, where the integral is taken over the inner surface of the cylinder. The three constraints on $\mathbf{J}$ select, from the distributions producing the specified field, the one with the greatest possible figure of merit.

A perpendicular orientation, corresponding to the choice $\mathbf{H}=H_0(\sin\psi\hat{\mathbf{r}}+\cos\psi\hat{\boldsymbol{\psi}})$ for $r<r_1$, yields the distribution

$$\mathbf{J}=\mu_0 H_0\frac{2r_1^2r_2^2}{r^2(r_2^2-r_1^2)}(\sin\psi\hat{\mathbf{r}}-\cos\psi\hat{\boldsymbol{\psi}}), \tag{1}$$

while the parallel orientation $\mathbf{H}=H_0\hat{\mathbf{z}}$ produces

$$\mathbf{J}=\mu_0 H_0\left\{\frac{z}{r\ln(r_2/r_1)}\hat{\mathbf{r}}-\left[\frac{1}{(r_2/r_1)^2-1}+\frac{\ln(r_2/r)}{\ln(r_2/r_1)}\right]\hat{\mathbf{z}}\right\}. \tag{2}$$

By truncating the cylinder at $z=\pm z_0$, an open structure, shown in Fig. 1, is obtained, having an approximately uniform internal field.[2] This structure can also be properly considered the result of opening a finite closed cylinder, since end caps for the truncated cylinder can be designed that restore the perfect uniformity of the field.

III. RESULTS

Since $\nabla\cdot\mathbf{J}=0$, the magnetic charge density σ for the structure is nonzero only on it's surface and is readily found, for the two orientations, from Eqs. (1) and (2) using the expression $\sigma=\mathbf{J}\cdot\mathbf{n}$, where $\mathbf{n}$ is an outward pointing unit vec-

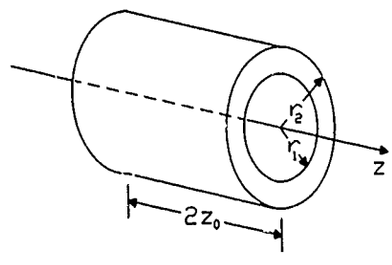

FIG. 1. Yokeless, cylindrical magnetic structure of length $2z_0$. Magnetic material fills the region between $r=r_1$ and $r=r_2$

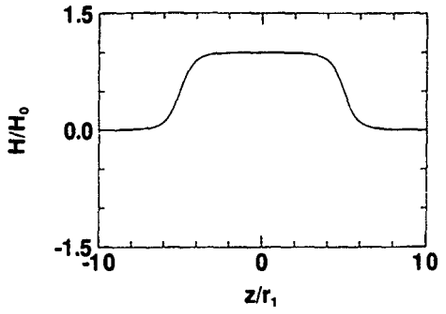

FIG. 2. H/H_0 on the z axis vs z/r_1 for $r_2/r_1=2.0$ and $z_0/r_1=5.0$. The uniformity of the central field is better for the perpendicular orientation (solid line) than for the parallel orientation (dotted line).

tor perpendicular to the surface.[1] The magnetostatic scalar potential Φ at a point $\mathbf{x}$ is computed from the integral

$$\Phi(\mathbf{x})=\frac{1}{4\pi\mu_0}\int_S \frac{\sigma(\mathbf{x}')}{|\mathbf{x}-\mathbf{x}'|}\,da', \tag{3}$$

taken over the surface of the structure, and the magnetic field is calculated from $\mathbf{H}=-\nabla\Phi$.

Figure 2 shows the magnetic field on the z axis, for the two orientations, with $r_2/r_1=2.0$ and $z_0/r_1=5.0$. For the perpendicular case, the perpendicular component is plotted, and for the parallel case the parallel component is plotted. The central field for the perpendicular orientation is significantly stronger and more uniform than for the parallel orientation. Moreover, the field for the parallel case varies rapidly near the end of the structure, acquiring large negative values, while the field for the perpendicular case falls monotonically to zero.

In Fig. 3, the magnitude of the field at the center of the structure is given as a function of z_0/r_1 for $r_2/r_1=2.0$, showing that the field approaches its asymptotic value of H_0 much more slowly for the parallel orientation. In Fig. 4, equipotential lines near the structure's end, in the two-dimensional cross section corresponding to $\psi=\pi/2$, are illustrated for the two orientations. For the parallel orientation a saddle point occurs near $(r/r_1=0.0,\ z/r_1=4.0)$.

Both inside and outside the cylinder, the potential can be expanded in spherical harmonics. Introducing spherical coordinates (ρ,θ,ψ), where ρ is the radial coordinate and θ is the angle to the z axis, the potential has the expansion, for $\rho<r_1$,

$$\Phi=\sum_{l=0}^{\infty}\rho^{l}\left\{a_{l0}P_l(\cos\theta)+\sum_{m=1}^{\infty}[a_{lm}\cos(m\psi)+b_{lm}\sin(m\psi)]P_l^m(\cos\theta)\right\}, \tag{4}$$

and for $\rho>(z_0^2+r_2^2)^{1/2}$,

$$\Phi=\sum_{l=0}^{\infty}\rho^{-(l+1)}\left\{c_{l0}P_l(\cos\theta)+\sum_{m=1}^{\infty}[c_{lm}\cos(m\psi)+d_{lm}\sin(m\psi)]P_l^m(\cos\theta)\right\}, \tag{5}$$

where P_l and P_l^m are Legendre functions. Using symmetry arguments, all the coefficients for the parallel case can be shown to vanish except the a_{l0} and c_{l0} with odd l. In Ref. 1, it is demonstrated for the perpendicular case that the only nonzero coefficients are the b_{l1} with odd l and the d_{l1} with odd l and $l\neq 1$.

Tables I and II show expansion coefficients for $l=1$, 3, and 5 with $r_2/r_1=2.0$ and $z_0/r_1=5.0$. For an exactly uniform field, the only nonzero coefficients would be $b_{11}=H_0$, for the perpendicular case, and $a_{10}=-H_0$, for the parallel case. Deviations from these values represent perturbations caused by the opening.

Aside from the b_{11} and a_{10}, the magnitudes of corresponding coefficients having the same l value are much

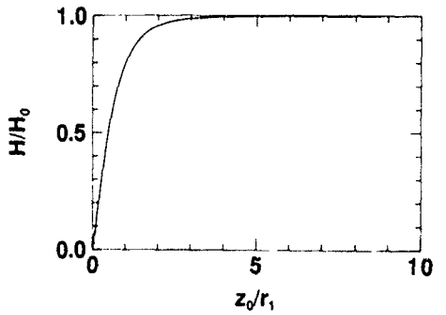

FIG. 3 H/H_0 at the center of the magnet vs z_0/r_1 for $r_2/r_1=2.0$. H/H_0 approaches its asymptotic value of 1.0 more rapidly for the perpendicular orientation (solid line) than for the parallel orientation (dotted line).

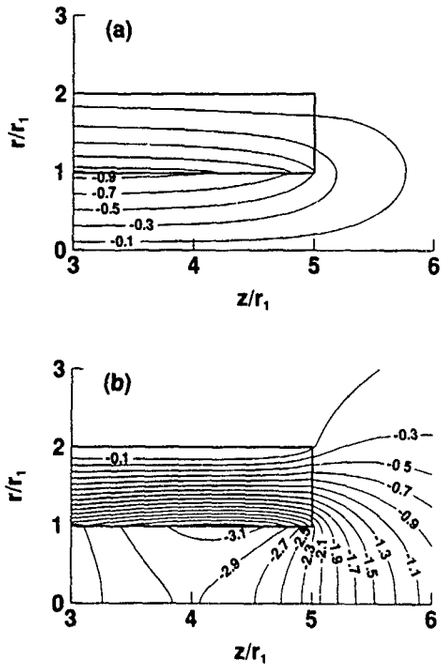

FIG. 4. Equipotential lines for (a) the perpendicular orientation and (b) the parallel orientation near the end of the magnet ($\psi=\pi/2$). The lines are labeled with the value of Φ/H_0r_1.

TABLE I. Expansion coefficients for perpendicular orientation ($r_2/r_1=2.0$, $z_0/r_1=5.0$).

l	m	$b_{lm}r_1^{(l-1)}/H_0$	$d_{lm}/[H_0r_1^{(l+2)}]$
1	1	0.998	0
3	1	-1.2×10^{-4}	5.0
5	1	-5.2×10^{-6}	2.4×10^{2}

greater for the parallel orientation than for the perpendicular orientation. In particular, the coefficients show that the uniformity in the central region is about 40× better for the perpendicular case. In addition, since the d_{11} coefficient vanishes for the perpendicular orientation, the leakage field has an octupole character and decays as ρ^{-5}, while the field for the parallel case is of dipole character and decays as ρ^{-3}.

IV. DISCUSSION

The magnetic fields for the the parallel and perpendicular orientations are different in three basic ways. First, the field for parallel orientation changes sign near the opening and becomes larger in magnitude than the field at the center of the structure. In contrast, the field for the perpendicular orientation decreases monotonically at the opening. Second, the distortion of the central field is much greater for the parallel case, as indicated by the spherical harmonic expansion coefficients. Third, the leakage field decays as an octupole for the perpendicular case, but only as a dipole for the parallel case.

The change in sign of the field for the parallel orientation is due to the fact that well inside the cylinder the magnitude of the potential on the z axis increases with z, as required by a parallel field, while outside the cylinder, the potential must decrease in magnitude. Thus, somewhere in between, the potential has an extremum where its derivative, the magnetic field, changes sign. Moreover, because the rate of change of the potential is most rapid, as is reasonable, near the opening, the magnitude of the field there exceeds the value at the center of the structure.

TABLE II Expansion coefficients for parallel orientation ($r_2/r_1=2.0$, $z_0/r_1=5.0$).

l	m	$a_{lm}r_1^{(l-1)}/H_0$	$c_{lm}/[H_0r_1^{(l+2)}]$
1	0	−0.923	−5.41
3	0	5.1×10^{-3}	-3.9×10^{2}
5	0	2.3×10^{-4}	-1.4×10^{4}

Since end caps designed to close the structure and restore the perfect field uniformity would have to generate a stronger near field for the parallel orientation than for the perpendicular orientation, it should be expected that the far field from such end caps also be stronger for the parallel case. Thus the greater distortion found in the central region for the parallel case may be regarded as a consequence of orienting the field in the parallel direction.

The vanishing of the dipole moment for the perpendicular orientation is not unique to the model considered here, but occurs generally for any cylindrical, yokeless structure where $\mathbf{J}$ is independent of z and perpendicular to $\hat{\mathbf{z}}$. Since these conditions can only be met for a perpendicularly oriented field, the zero dipole moment obtained for the perpendicular case can, in a sense, be attributed to the field's orientation.

Field orientation effects similar to those demonstrated for the truncated cylinder of this paper should also apply to other yokeless structures of similar geometry. Examples of practical interest include cylindrical structures generating perpendicular[3] and parallel[4–6] fields and structures of polygonal cross section made from uniformly magnetized polyhedra.[1]

V. SUMMARY

The effects of magnetic-field orientation have been investigated for a cylindrical permanent magnet structure opened at both ends and designed to generate a uniform central field. Fields oriented primarily perpendicular and parallel to the cylinder's axis have been compared. The distribution of magnetic polarization for both cases is chosen to maximize the figure of merit. It is found that: (1) The main component of the field decreases monotonically near the structure's end for the perpendicular orientation, but changes sign for the parallel orientation; (2) the field in the center of the structure is more uniform for the perpendicular orientation; 3) the leakage field for the perpendicular case is smaller due to a vanishing of the dipole moment.

A permanent magnet structure has been designed to provide field distortion-free access to large magnetic fields in cylindrical and spherical cavities without the unacceptably large mass increases usually incurred to provide it. For example, a spherical shell that produces a 1.2-T field in a spherical cavity of 2-cm radius has a mass of about 2.3 kg if material of 12.2-kOe coercivity and 12.2-kG remanence is used. If the sphere is compensated for distortion-free equatorial access, its mass must rise to 23 kg to maintain the same field in the cavity. If the geometry is altered by the new technique to maintain field integrity under access, the mass is only 1.7 kg. Some applications are discussed that afford, up to this time, unviable devices.

I. INTRODUCTION

The so-called "magic" rings and spheres[1,2] are capable of generating unusually high magnetic fields in their inner chambers and therefore afford a considerable expansion of the applicability of permanent magnets to technology. Since many of the new applications require access tunnels of diameter sufficient to significantly distort the internal working fields, the authors devised a method to greatly reduce such distortions[3] Figure 1 shows how this is done for a ring. In effect, each segment of the ring is given a magnetization which is the result of a uniform magnetization, which has no effect on the generated field, and the original ring magnetization which produces that field.

The uniform component of magnetization may be in any direction and of any magnitude so that it can be chosen to render the required magnetization zero in any desired segment, thereby making that segment dispensable and affording distortion-free access through it. Figure 1(a) shows a ring in which such access is provided at the poles and Fig. 1(b) where the access is at the equator. In the structure in Fig. 1(a), the magnetization is radial everywhere in direction while in Fig. 1(b) it is transverse in direction. The same procedure may be used in "magic spheres."

II. COMPACTION OF DISTORTION-FREE STRUCTURES

An often serious drawback of the described procedure is that it requires materials of double the remanence of those available if the maximum available remanence is used in the original unaltered sphere. If the original field is to be maintained in the distortionless configuration, its radius, and hence its mass must be increased considerably. For example, a "magic" sphere of 1.2-T remanence, B_r and 1.2-T cavity flux density, has an outer radius of 4.25 cm if its inner cavity is 2.0 cm in radius. An altered sphere would behave as a regular sphere with only 0.6-T remanence. For the altered sphere to produce the same internal field of 1.2 T, its outer radius r_o' must be increased according to the relation:[2]

$$\frac{\ln(r_o'/r_i)}{\ln(r_o/r_i)}=\frac{B_r}{B_r'}=\frac{1.2}{0.6}=2, \tag{1}$$

where r_o and r_i are the original outer and inner radii, respectively. This is a consequence of the expression for the flux density in the cavity of a "magic" sphere, viz: $B=(4/3)B_r \ln(r_o/r_i)$. Substituting $r_i=2.0$ and $r_o=4.25$, we obtain $r_o'=9$ cm and the resulting mass increase would be from 2.3 to 24 kg, a factor of more than ten.

The magnitude of remanence of an altered "magic" ring or sphere varies with the polar angle as

$$\begin{aligned} B_r&=2B_0 \sin\theta \quad \text{polar access} \\ B_r&=2B_0 \cos\theta \quad \text{equatorial access,} \end{aligned} \tag{2}$$

so that maximum remanence is required only at the poles in a spheroid designed for equatorial access or at the equator for those with polar access. This suggests that if the remanence was the maximum available everywhere, it might be possible to pare the local radius in compensation where maximum remanence is in excess of that specified and to augment the local radius only where the maximum remanence falls short of that required. In this way, the net addition of material to spheres to make them distortion-free would be minimized.

The field in the cavity of a "magic" ring or sphere arises from three sources: the poles σ on the inner and outer surfaces of the spheroidal or cylindrical shell and the volume polar distribution ρ. The surface pole contribution is zero for

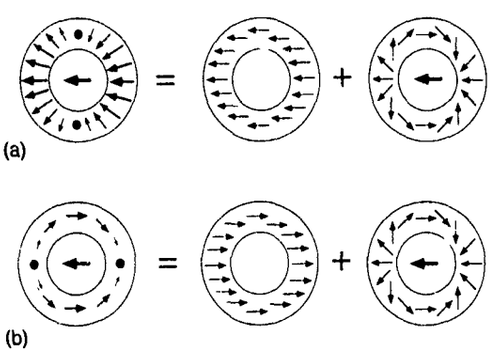

FIG. 1 Alteration of magnetization (small arrows) of "magic rings" and "spheres" to provide distortion-free access at the poles (a) and at the equator (b) The resultant magnetizations are transverse for polar access A and radial for equatorial access B The large central arrows represent the internal fields, the smaller arrows in the shel' the remanences and the dots the regions of zero remanence.

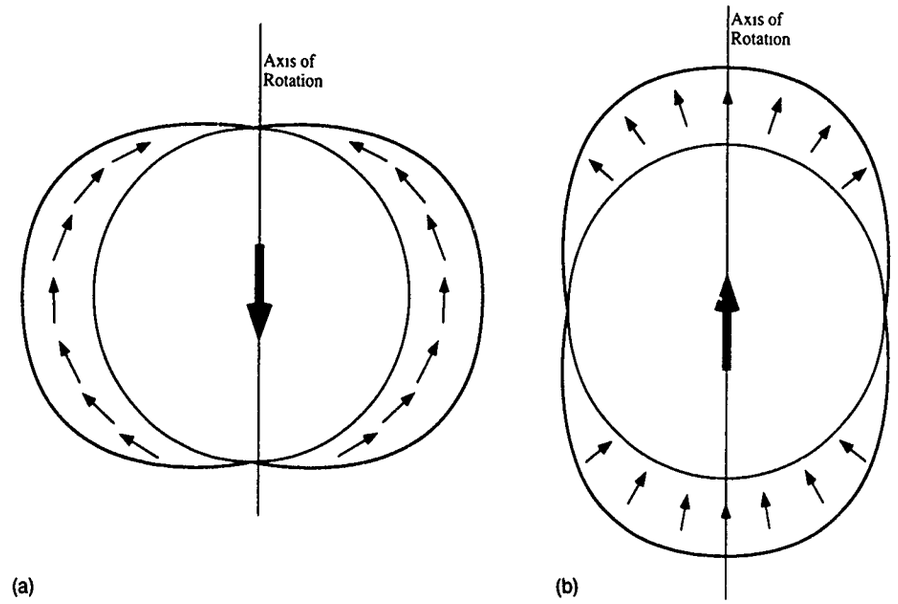

FIG 2. Cross sections and outer surfaces of (a) oblate and (b) prolate distortion-free structures.

structures of this type and the volumic distribution of poles is given by the divergence of the magnetization. For "magic" spheres and cylinders, ρ is equal to $4M\cos\theta/r$ and $2M\sin\theta/r$, respectively. This is true for both the conventional and distortion-free structures because the two differ only by a constant uniform magnetization which has no divergence and hence gives rise to no poles.

If in the cylinder the value of ρ is substituted into Coulomb's Law and the integration over r is performed, we have for the contribution of a segment at θ

$$dB = 4\int_0^{2\pi} M[\ln r_o/r_i]\sin^2\theta\, d\theta. \tag{3}$$

We note that if M is a function of θ as in the distortion-free cylinder (DFC) and if one wishes, as we do, to keep M constant at the maximum available value, we can do so by giving $r_o(\theta)$ the functional form that would leave the product $M(\theta)\ln[r_o(\theta)/r_i]$ the same as before. This is accomplished when

$$M_{\max}\ln r_o(\theta) = M_{\mathrm{DFC}}\ln(r_o)_{\mathrm{DFC}}. \tag{4}$$

Since for the polar access

$$\mu_0 M_{\mathrm{DFC}} = B_{\mathrm{DFC}} = 2B_0\sin\theta$$
$$\ln r_o = 2\sin\theta\ln(r_o)_{\mathrm{DFC}}. \tag{5}$$

If this procedure is applied to a sphere with polar access, the resulting spheroid of revolution is that in Fig. 2(a). For the same field and working space specifications as the spheres already discussed, the mass of the new structure is only 12.7 kg or about half that of the distortion-free sphere of varied remanence.

Even greater mass savings are obtainable for spheres compensated for equatorial access. In that case, our spheroid of uniform remanence construction yields the pinched-equator-prolate structure of Fig. 2(b) with a mass of 1.7 kg which is actually less than that of the unaltered parent sphere. This is because the paring of radius occurs where the azimuthal circles are large and the radius augmentation where they are small. The reverse is true for the "polar dimpled," apple-shaped oblate structure of Fig. 2(a).

III. APPLICATIONS

Many electron-beam microwave sources require strong, uniform magnetic fields parallel to the beam direction to focus the electrons. Often bulky, energy consuming solenoids are used. Recently, much more compact permanent magnet solenoids were developed for this purpose but they are limited to fields of about one-half the magnetic remanence or less.[4] For higher fields, the "magic spheres" are attractive alternatives. Often, electron beam tubes require access ports large enough to seriously distort the working fields in their vicinities. Also, electron beams are subject to abrupt field reversals upon transits through tunnels in the shells of standard "magic spheres." The new structures adequately solve both problems in many applications. Figure 3 compares the axial field profile of a standard with that of an oblate structure, both of which have large (25% of cavity diameter) axial access tunnels at the poles. The latter is seen to maintain its field to the tunnel entrance while that of the former drops to about one-half of the peak field. If desired, the "bumps" near the ends of the curve for the oblate spheroid can be smoothed out by a judicious tailoring of the local remanence[4] or by placement of axially magnetized toroidal correcting rings.[5]

For medical MRI devices, prolate structures would afford similarly improved transverse field profiles for equatorial access. Other potential applications are in Faraday rota-

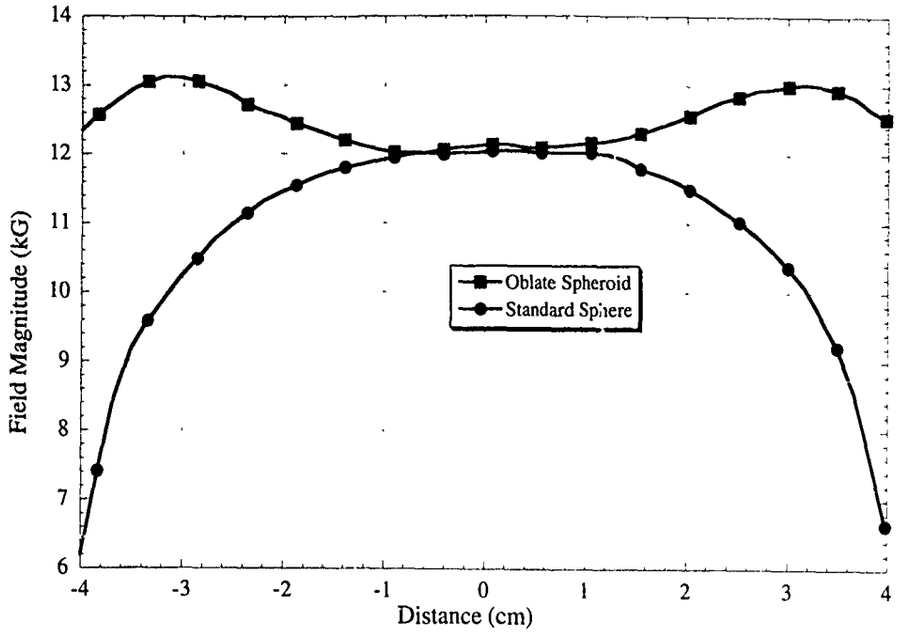

FIG. 3. Axial field profiles of (●) standard sphere and (■) oblate spheroid

tors, mass spectrometers, free-electron lasers, and wherever else access to large, uniform fields is needed.

IV. SUMMARY AND CONCLUSIONS

If a "magic sphere" with undistorting polar access is required, considerable mass savings are realized by uniform remanence, variable radius construction. Some configurations with equatorial access may actually have less mass than the unaltered spheres. It might seem that manufacture would be unduly complex and expensive, but both problems can be solved by a simple manufacturing procedure discussed in a companion article in this issue of the Journal of Applied Physics.

Laminar construction of spheroidal field sources with distortion-free access

H. A. Leupold, A. S. Tilak, and E. Potenziani, II
U.S. Army Research Laboratory, AMSRL-EP-EC-H, Fort Monmouth, New Jersey 07703-5601

Certain high-field permanent magnet structures in the forms of spheroidal and cylindrical shells can be altered so that access ports through specified areas of the shells have minimal detrimental effect on the field integrity in the internal working space. This can be effected either parametrically or geometrically. Both approaches result in an increase of fabricational complexity; the former because it entails components with a variety of magnetizations and the latter because it requires a variety of geometric dimensions. This article describes how simplifying approximations to either type of structure can be obtained by an assembly of laminar pieces cut from sheets or slabs of permanent magnet materials with their magnetization oriented parallel to their principal faces.

INTRODUCTION

Several variants of the high-field permanent magnet sources sometimes known as "magic" rings, spheres, or cylinders have been designed recently[1–3] to meet the demands of miscellaneous applications. Some of these are illustrated in Fig. 1 from which it can be seen that each has complexities of shape or distribution of magnetization that might make its fabrication seem unduly difficult and expensive. However, all such structures can be made from sheets or slabs of material that are uniformly magnetized parallel to their faces.

STANDARD RINGS, CYLINDERS, AND SPHERES

One can cut circular rings "cookie-cutter" style from a uniformly magnetized slab and then, as shown elsewhere,[4] divide the ring into the desired number of sectional segments. Each segment is then rotated about its local radius to form the "magic ring" as shown in Fig. 2(a). Such rings can be stacked congruently to form dipolar cylinders[5] or beveled to form melonlike components of a "magic sphere" and bounded together [Fig. 2(b)].

The discs cut from the centers of the ring shells can be used either to make smaller "magic" rings or spheres or to be formed into cylindrical or spherical dipoles for possible use for field defect compensation as in MRI systems.[5] The cylindrical versions could even be turned into adjustable-strength dipoles by a cutting of the center of the cylinder to form a smaller nested cylinder in a shell of equal dipole strength [Fig. 2(c)], then, by rotation of the two with respect to each other, any dipole strength from zero to plus/minus the maximum is obtainable.

SPHERES AND CYLINDERS WITH DISTORTION-FREE ACCESS

In these structures, the required magnetizations in the circular or spherical segments vary in magnitude and are always either radial or transverse in direction depending upon where zero magnetization is desired, so that distortion-free access holes can be drilled there.[6] If access is to be at the poles, magnetization is transverse or tangential, whereas if access and zero magnetization are to be at the equator, it is radial.

Such structures [Figs. 1(b) and 1(c)] also can be fabricated from uniformly magnetized sheets but then a variety of sheets with different magnitudes of magnetization are necessary. The closer the approximation to an ideal continuous

Arrow sizes are indicative of relative magnetizations.

structure, the more different magnetizations will be needed. Thus, the ideal structure can be approximated as closely as desired by substitution of the circular segments with trapezoids as in Figs. 3(a) and 3(b).

All of the segments of a given latitude have the same magnitude of magnetization and so can be fabricated entirely from a single uniformly magnetized slab. The pieces are cut from it in trapezoidal form with the ratio of lengths of the parallel sides equal to the ratio of the outer to inner radius of the finished structure. Figure 4 shows the cutting pattern for structures of Fig. 4(a) polar access and Fig. 4(b) equatorial access. Note that in the latter case, there are two kinds of segments: oriented inward and outward. Both are needed in equal numbers as produced by the cutting patterns of Fig. 4(b). In all cases, the final two-dimensional rings can be beveled to form segments of spheroids as already mentioned for the case of the standard "magic ring."

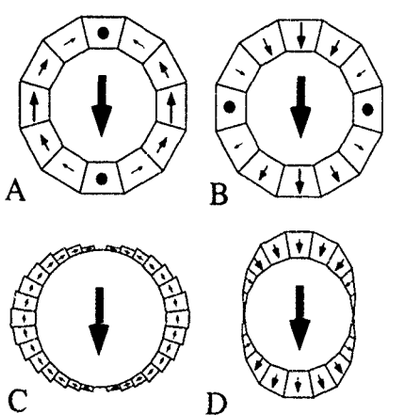

FIG. 3. Approximations to structures of Fig. 1 with trapezoidal segments. Arrow sizes indicate relative magnetizations

SPHEROIDS AND CYLINDERS WITH ONLY ONE MAGNITUDE OF MAGNETIZATION

The manufacture of structures of the previous section is complicated by the necessity of having a variety of magnetizations in the standardized sheets or slabs from which the segments are cut. Minimum-distortion access can also be effected by use of constant magnetization and segments whose radial dimension has the same angular dependence as does the magnetization in the circular cylindrical and spheroidal structures [Figs. 1(d) and 1(e)]. These are cut and assembled in the same way except that in the present case, the width of the cut zig–zag patterns varies instead of their magnetization [Figs. 4(c) and 4(d)].

SUMMARY AND CONCLUSIONS

"Magic" rings and spheres and all their uniform field variants can be manufactured by the proper cutting up of uniformly magnetized laminas and the subsequent reassembly of the resulting pieces.

The torque of magnetic coupling is sensitive to the number of magnetic poles, the magnetization profiles, the magnetic field strength of magnets, and the separation distance between the magnets of the coupling. For different multipole magnetic couplings with the same magnetic field strength, the torque of magnetic coupling is proportional to the number of magnetic poles at small separation distance, but it is inversely proportional to the number of magnetic poles as the separation distance becomes large. The theoretically calculated values of the torque of magnetic coupling are in excellent agreement with the experimentally measured values.

Magnetic coupling devices transmit torque between a primary driver and a secondary follower, without any mechanical contact. They can operate in gas or liquids, and can transmit torque through a separation wall. The magnetic coupling can also be used as an overload protection device or to transmit instrument readings from a vacuum or pressure enclosure.[1,2] From both fundamental and applied viewpoints, magnetic coupling devices are of considerable interest.[3–5]

The axial magnetic coupling device for this study was constructed by using a pair of hard ferrite ring magnets that were magnetized with a multipole configuration along the axial direction. For example, Fig. 1 shows a 10-pole magnetic coupling device. All ring magnets used in this study have an outer radius of 56 mm, an inner radius 40 mm, and a thickness of 9 mm. The magnetization profiles with 6, 8, and 10 poles were used to analyze the variation of magnetic coupling. The magnetic field distributions of the ring magnets were measured by placing a Hall probe over the surface of the magnets. The torque between the two magnets was measured by using a Kowa–Giken torque meter.

The torque and force between these two coaxial ferrite rings are functions of several variables including the number of pole pairs, dimensions, separation distance, material properties, the relative angular offset of the magnets, etc. Recently, a three-dimensional theoretical analysis has been developed by Furlani for computing the transmitted force and torque of an ideal magnetic coupling.[6,7] Therefore, the effect of magnetization profiles on the torque of magnetic coupling can be studied by both experimental measurement and theoretical calculation.

For the theoretical analysis, it is assumed that the magnetization profiles of the magnetic rings are uniform throughout the magnets, and it is characterized by a uniform polarization. The concept of this theoretical analysis is to represent one of the magnetic rings as a distribution of equivalent currents, and to consider the field due to the other

magnet as an external field. After mathematical derivation, the torque can be obtained by summing the contributions from all of the sectors and surfaces of the magnets. The final form of the formula for the torque $T_{z,\text{total}}(\theta)$ of a magnetic coupling is[7]

$$T_{z,\text{total}}(\theta) = \frac{\mu_0}{4\pi} M^2 N_{\text{pole}} \left[\frac{\pi(R_2^2 - R_1^2)}{N_{\text{pole}} N_r N_\theta} \right]^2 \sum_{i=1}^{N_r} \sum_{j=1}^{N_\theta} \sum_{i'=1}^{N_r} \sum_{j'=1}^{N_\theta} \sum_{n=1}^{N_{\text{pole}}} \sum_{m=0}^{2} \times \frac{(-1)^{(n+m)} \alpha_m r_i r_{i'} \sin(\theta_j - \theta_{j'})}{[r_i^2 + r_{i'}^2 - 2 r_i r_{i'} \cos(\theta_j - \theta_{j'}) + h^2]^{3/2}},$$

where N_{pole} is the number of poles, M is the uniform magnetization, R_1 is the inner radius of the magnet, R_2 is the outer radius of the magnet, and N_r and N_θ are the number of radial and angular mesh divisions, respectively, of the sectors used for calculation. The variables h_m and α_m are given by $h_m = h + m t_m$ and $\alpha_m = -m^2 + 2m + 1$, where t_m is the thickness of magnets, h is the separation distance, and $m = 1$ for this study. The theoretically predicted torque numerically evaluated using the above torque equation can easily be compared with the experimental torque measurements.

Figure 2 shows the torque of magnetic coupling as a function of the separation distance d of magnets that are magnetized with 6, 8, and 10 poles. The torque of magnetic coupling decreases quickly as d is increased at a small separation distance. This means that the rate of decrease of the torque at small d is a function of the number of poles. However, it becomes roughly the same value for large d. For different multipole magnetic couplings, under the same magnetic field strength of magnets, the magnitude of the torque is proportional to the number of poles at separation distances of magnets within a certain range, but it becomes inversely proportional to the number of poles as the separation increases outside of that range. For example, the torque of a 10-pole magnetic coupling is greater than that of a 6-pole magnetic coupling at d less than 8 mm, but the torque is inversely proportional to the number of poles at d over 8 mm. This

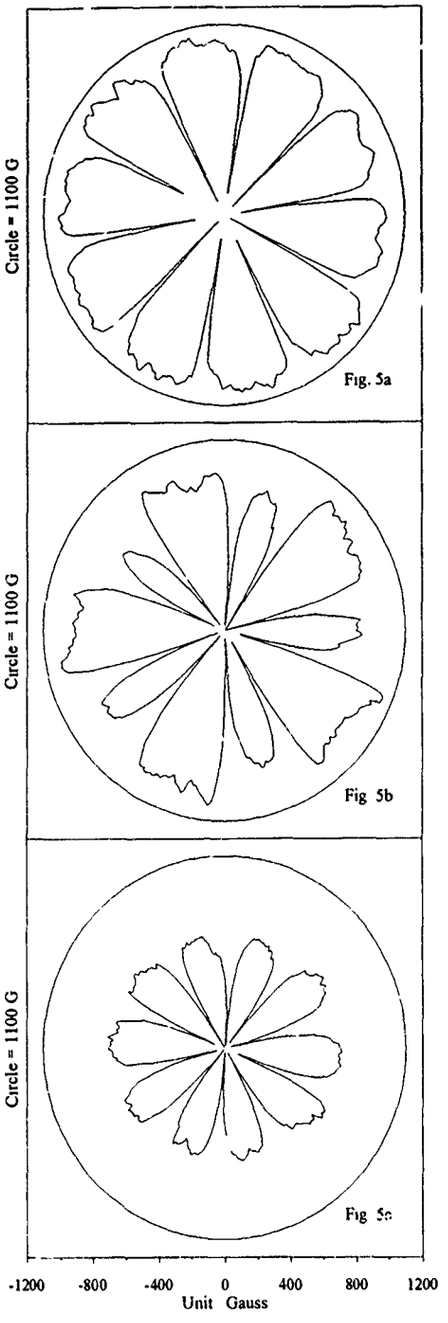

FIG. 5. The magnetic field distribution of the magnet measured at a distance of 0.3 mm above the magnet. (a) big square wave profile, (b) hybrid wave profile, (c) small wave profile.

phenomenon can be explained by analyzing the magnetic field distribution of the magnets used in the magnetic coupling. Figure 3 shows the magnetic field distribution of a 6-pole magnet and a 10-pole magnet at a distance 0.3 mm over the magnet. The average magnetic field strength is about 1 kG for both the 6-pole and 8-pole magnetic couplings. However, if we measure the magnetic field distribution of a 6-pole and a 10-pole magnet at a distance 10 mm over the magnet, the magnetic field strength is about 129 G

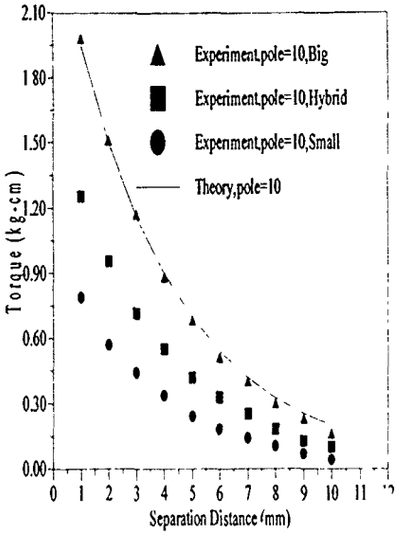

FIG. 6. The torque of magnetic couplings using different magnetization profiles

for the 6-pole magnet, but it is about 70 G for the 10-pole magnetic coupling, as shown in Fig. 4. This indicates that the magnetic field strength of the 10-pole magnet is less than that of the 6-pole magnet because the magnetic circuit loop of the 10-pole magnet is smaller than that of the 6-pole magnet at separation distance greater than 8 mm. Therefore, the torque of the 6-pole magnetic coupling is greater than that of the 10-pole magnetic coupling at separations greater than 8 mm. Considering the theoretical calculation, the torque of magnetic coupling at small separation distances matches well with the experimental data, as shown in Fig. 2.

The magnetization profiles of the multipole magnets can affect the torque of magnetic coupling markedly. Different magnetization profiles can be controlled by the design of the magnetizing fixtures. Figure 5 shows different magnetization profiles with a big square wave, hybrid wave, and small wave for a 10-pole magnet. The maximum magnetic field strength of the big square wave profile is about 1 kG as shown in Fig. 5(a), and the maximum magnetic field strength of the small wave profile is about 700 G as shown in Fig. 5(c). The magnetic field of the hybrid wave profile shown in Fig. 5(b) is a combination of the wave profiles from Figs. 5(a) and 5(c). The torque curves of the 10-pole magnetic coupling with different magnetization profiles are shown in Fig. 6. The torque of magnetic coupling with the big square wave profile is greater than that of the hybrid wave profile, and the torque of magnetic coupling with the hybrid wave profile is greater than that of the small wave profile.

A magnetic coupling without parasitic force for measuring devices

Jean-Paul Yonnet and Jérôme Delamare
Laboratoire d'Electrotechnique de Grenoble (URA 355 au CNRS), ENSIEG, B.P. 46, 38402 Saint Martin d'Heres Cedex, France

Original structures of permanent magnet couplings have been studied. They can transmit a torque without creating forces or stiffnesses between the driver and the driven part. Except for torque, the two parts are in indifferent equilibrium. These couplings have been designed for measuring devices in which they exert no force on the bearings but they can be used in other domains.

I. INTRODUCTION

Permanent magnet couplings (PMC) are synchronous devices which allow a torque to be transmitted through a partition wall. Two types of PMC are commonly used, the coaxial type operating with a cylindrical separation wall, and the face-type coupling which has a plane airgap.[1] Other types of PMC exist for specific applications. In this article, we shall present PMC configurations which are well-adapted to measuring devices. The main characteristic of these couplings is to transmit angular information without disturbing the measuring system.

In a PMC, magnet interaction allows torque transmission, but it also creates forces in the axial and radial direction. The stiffnesses, which are the force variations, are also very high. These forces have to be supported by the mechanical bearings, which produce frictional torque. Special configurations allow a torque to be transmitted without any force and stiffness,[2] but they are not well-adapted to large airgaps and only operate correctly with a high pole number.

The couplings presented in this article have been designed for measuring devices. They do not create any force between the two halves, even if the driver part is submitted to axial or radial displacement. Consequently, the friction on the mechanical bearings is reduced and does not disturb the accuracy and the sensitivity of the measurement. Moreover, these couplings operate with a large airgap, and have a reduced pole number, 2 or 4.

II. MAGIC CYLINDER COUPLING

A cylindrical magnet with rotating distribution of the magnetization direction creates a very homogeneous field in its central part.[3] This device is often called a "magic cylinder."[4] For a two-pole system, a constant dipole field is produced in the interior cylindrical cavity of magnitude

$$H_m = J_1 \ln(R_{ext}/R_{int}),$$

where J_1 is the magnet polarization in tesla, R_{ext} and R_{int} are the outer and the inner radii of the annular magnet.

This magic cylinder is the driver part of the coupling. The driven part is made of a small magnet in the middle of the hole (Fig. 1). Since the small magnet is situated inside an almost perfect homogeneous transversal field, it is not submitted to any force or stiffness, but it can transmit a torque whose maximum value is given by

$$\Gamma_{max} = J_2 v H_m,$$

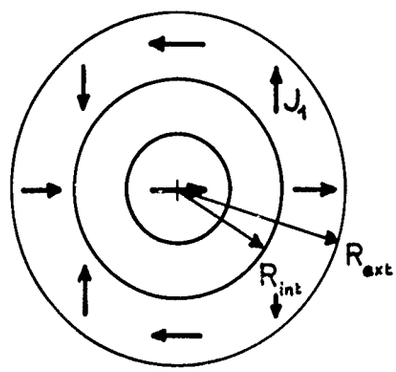
where v is the volume of the driven magnet and J_2 its polarization.

To obtain perfect insensitivity to the radial and axial displacement of one part from the other, a relatively long magic cylinder has to be used. The end effects produce a field distortion at a depth d which is about

$$d \approx 0,7(R_{ext}+R_{int});$$

consequently, the length of the cylinder L must be at least twice its diameter.

Figure 2 presents a four-pole version of the magic cylinder coupling. The end effects are reduced in this configu-



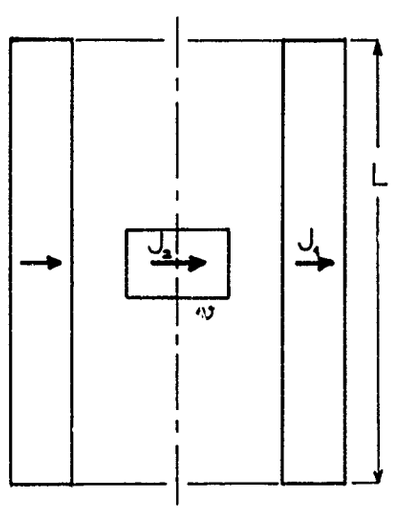


FIG. 1 A magic cylinder coupling.

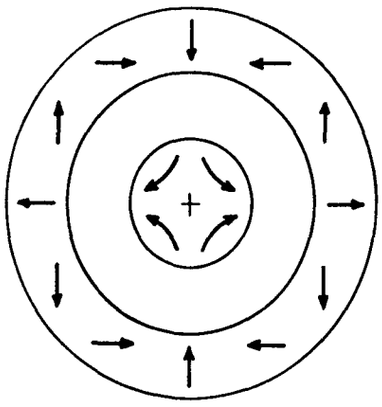

FIG. 2. A four-pole magic cylinder coupling.

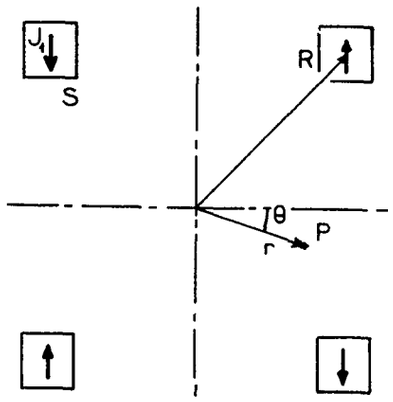

FIG. 4. Measurement of the field intensity in the four bar-shaped magnet coupling.

ration. A prototype has given very good results: the maximum torque transmitted was relatively high (2×10^{-2} Nm) and the absence of forces in a large domain of radial and axial displacements has been verified.

Several other configurations have been investigated. An interesting one uses a driver part made with four bar-shaped magnets.

III. BAR-SHAPED MAGNET COUPLING

The driven part is equipped with four bar-shaped magnets which are parallel to the rotation axis (Fig. 3). This system takes the place of the previous magic cylinder, and can be seen as an incomplete cylinder. The bar length is equivalent to the cylinder height L, and the end effects are identical.

In comparison with the magic cylinder system, the four bar-shaped magnet coupling has a lighter driver part which reduces the inertia of the measuring device. The volume of very good homogeneity of the magnetic field is smaller, especially in the radial direction. Consequently, the domain of null forces and stiffnesses is reduced, but it remains sufficient.

The maximum transmissible torque can be easily calculated by simplified expressions since the airgap is relatively large. By using the following notations:

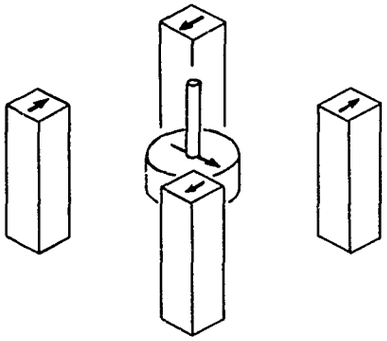

FIG. 3. The four bar-shaped magnet coupling.

(a) for the driver part;
S section of each bar,
L length of the bar,
J_1 magnet polarization,
R average distance between the center and each bar.
(b) for the driven part;
v magnet volume,
J_2 magnet polarization (in tesla).
The intensity of the magnetic field (H_{4b}) is given by

$$H_{4b}=\frac{2}{\pi\mu_0}J_1\frac{S}{R^2}$$

and the maximum torque is obtained by

$$C_{\max}=J_2 v H_{4b}=\frac{2}{\pi\mu_0}J_1 J_2\frac{Sv}{R^2}.$$

IV. EXPERIMENTAL STUDY

A prototype designed for a gas meter has been built. The following dimensions have been chosen
(a) for the driver part;
$S=9$ mm^2 (3 mm$\times$3 mm),
$L=20$ mm,
$R=10$ mm,
$J_1=0{,}4$ T (anisotropic ferrite magnets).
(b) for the driven part;
$r_2=5$ mm,
$h_2=4$ mm,
$v=314$ mm^3,
$J_2=1{,}20$ T (NdFeB magnet).

The domain of uniform field between the four bars has been investigated. In the center, we have measured a field H_{4b} of 18 kA/m.

We have studied variations of intensity of the field H_{4b} as a function of the distance from the center r and the direction θ (Fig. 4). The results are presented in Fig. 5. The homogeneity is very good for a radial distance lower than 2 mm. After, the field slowly increases when moving toward a bar magnet and decreases between two bars.

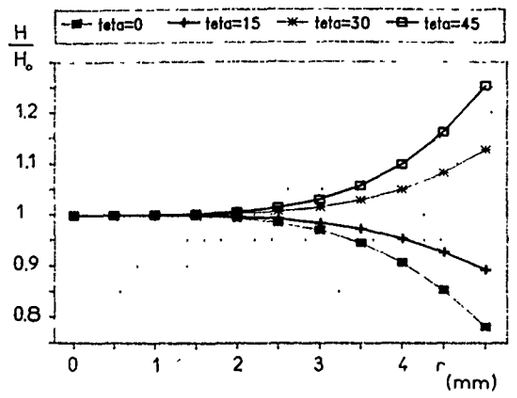

FIG. 5. Field variation around the centered position. In the center, $H_0=18$ kA/m.

The forces and stiffnesses have not been measured precisely because they are too small around the centered position. The magnetic interaction between the two parts creates very low parasitic forces.

The torque has a sinusoidal variation with the internal angle. Its maximum value is 6.3×10^{-3} Nm (63 g cm). It agrees correctly with the calculated value of 6.8×10^{-3} Nm.

V. CONCLUSION

Two unconventional types of permanent magnet couplings have been studied. They can transmit a torque without creating forces or stiffnesses between the two parts of the coupling. The first one uses the specific property of field homogeneity inside a magic cylinder. A magnet situated in this field can exert a torque, but it is not submitted to any force. The second one is built with four bar-shaped magnets. It is lighter and has lower inertia. For these two couplings, the measurements on prototypes are in good agreement with the calculated characteristics.

These couplings have been designed for measurement devices where they can be used to transmit a torque without creation of forces and friction on the mechanical bearings. They can have other applications, like for example vibration insulators.

Accurate determination of permanent magnet motor parameters by digital torque angle measurement

M. A. Rahman and Ping Zhou
Faculty of Engineering and Applied Science, Memorial University of Newfoundland, St. John's, Newfoundland A1B 3X5, Canada

This article presents a novel test method to determine the important load dependent reactance parameters X_d, X_q, and magnet-excited voltage E_0 of permanent magnet (PM) motors. The results bring forward a clear picture of the impact of the previous assumption of constant E_0 on the value of X_d. As improved accuracy and fast data sampling are required for online control, the traditional method for measuring torque angle is deficient. To this end, a new microprocessor-based digital torque angle measurement system was designed and built. At the same time, a scheme for accurately positioning the zero torque angle is proposed without referring to the interior structure of a motor. The proposed techniques have been successfully employed for a 1 hp laboratory permanent magnet motor.

INTRODUCTION

The effects of saturation for PM motor are profound. It was recognized that saturation would cause d-axis reactance X_d and q-axis reactance X_q to vary with load and supply voltage.[1,2] What is perhaps easily overlooked is the assumption that the E_0 is constant for all loads. In addition, the d-q axis quantities are no longer independent due to saturation. The significance of these effects has been clearly mentioned in the previous works from the simulation point of view.[3,4] The investigation from a testing point of view has been characterized by Miller's early work.[5] The load test method proposed by Miller is to determine X_d from the stator d-axis voltage component and X_q from the q-axis voltage component, respectively, under the assumption of constant E_0. The failure to consider the variation of E_0 with load is due to the fact that effects of the permanent magnet excitation voltage E_0 and the d-axis armature reaction are inherently linked together by the stator d-axis voltage component, and usually cannot be separated. In this article, a modified load test method is proposed to determine these load-dependent parameters, X_d, X_q, and E_0 more accurately for practical use.

It is necessary to properly measure the torque angle δ at any load condition for performance prediction. In addition, torque angle is also an important control parameter for variable frequency inverter driven PM motors. It is necessary that the measurement is conducted within an interval of time that should be very small compared to the mechanical time constant of the machine. With increasing emphasis on online digital control, it has also become necessary to obtain the quantities of torque angle in digital form, and the conventional stroboscopic method is no longer suitable for such applications. To this end, a fast-response microprocessor-based torque angle measurement system has been designed and built.

Due to the characteristics of PM motor, the precision of measured torque angle is highly related to the accuracy of the positioning of zero torque angle $\delta=0$. However, for a PM motor under normal voltage supply, the no-load operation is at $\delta=\delta_0$ and therefore cannot be used to position the zero torque angle. Usually, some approximate methods[5] are employed to determine the position of $\delta=0$. Therefore, it is desirable to find a way which can accurately locate the zero torque angle position for precision measurement and control purposes.

MODIFIED TORQUE TEST METHOD

Because the parameters X_d, X_q, and E_0 tend to vary widely with loads, their values must be quoted together with the load and voltage conditions under which they were determined. From the phasor diagram of a PM motor[4] one can get

$$E_t \sin \delta_i = I_1 \sin \beta X_q, \tag{1}$$

$$E_t \cos \delta_i = E_0 + I_1 \cos \beta X_d. \tag{2}$$

It is noted that once the data of applied voltage V, current I_1, input power P_1, and torque angle δ are known from the load test, other quantities in Eqs. (1) and (2) can be easily obtained as

$$\varphi = \arccos \frac{P_1}{3I_1 V}, \tag{3}$$

$$\beta = \frac{\pi}{2} + \delta - \varphi, \tag{4}$$

$$E_t = \sqrt{(V \sin \delta + I_1 r_1 \cos \beta)^2 + (V \cos \delta - I_1 r_1 \sin \beta)^2}, \tag{5}$$

and

$$\delta_i = \arctan \frac{V \sin \delta + I_1 r_1 \cos \beta}{V \cos \delta - r_1 I_1 \sin \beta}. \tag{6}$$

From Eq. (1), the X_q can be easily obtained. However, from Eq. (2), it is inadequate to evaluate the two unknown quantities E_0 and X_d. To this end, a small change of the load is exerted to obtain another set of test data and get the following equation as

$$E_t' \cos \delta_t' = E_0 + I_1' \cos \beta' X_d. \tag{7}$$

The solution of the simultaneous algebraic Eqs. (2) and (7) would give the saturated values E_0 and X_d for any operating point. In practice, the procedure is simply to produce three curves $E_t(\beta)$, $\delta_i(\beta)$, and $I_1(\beta)$ by curve fitting from re-

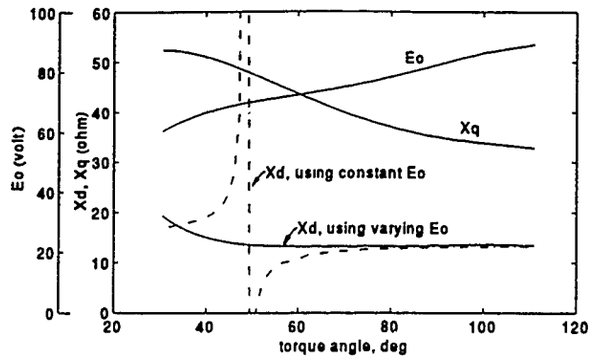

FIG. 1. Test results of X_d, X_q, and E_0 with torque angle δ.

corded data which cover the entire range of different loads. Then, the required information for both Eqs. (2) and (7) can be obtained from these curves.

Figure 1 shows the values of X_d, X_q, and E_0 for a 1 hp, 4-pole interior-type PM synchronous motor by using the above-proposed modified load test method. The effect of assuming constant E_0, as made in the original load test method,[1,5] on the value of X_d can be clearly seen from the dashed-line curve in Fig. 1. Over a load range around δ=47° where the armature reaction in d axis is changing from magnetizing to demagnetizing mode, the value of X_d becomes extremely irregular. This phenomenon was also observed in references.[5,6] This irregularity is mainly due to the assumption of constant E_0 which, in fact, is dependent on the saturation level, particularly in the region of ferromagnetic bridges. It is evident from Fig. 1 that E_0 is load dependent.

MICROPROCESSOR-BASED LOAD ANGLE MEASUREMENT

The torque angle of a synchronous machine is defined as the angular displacement between the excitation voltage E_0 and the terminal voltage V. For motoring operation, when the zero crossing of any one of the three phase terminal voltages as the reference to initiate a pulse and the zero crossing of the magnet excitation voltage in the same phase winding to terminate the pulse are used, the resulting pulse width will then represent the instantaneous torque angle. For generating mode, the reverse will happen.

The signal representing the excitation voltage is derived from a transducer consisting of a rotor shaft-mounted disc with an equispaced hole drilled on the circumference for each pole pair and a stator frame-fixed photocoupler. This photocoupler can produce a pulse whenever any one of the holes cuts across the photocoupler governed by the rotation of the shaft. This arrangement can always provide one pulse per cycle of the terminal voltage when the shaft rotates at synchronous speed. The produced chain of low voltage pulses are then amplified to TTL level using voltage comparator as shown in the block diagram of Fig. 2.

The reference phase voltage signal is derived through a step-down transformer. Before the reduced sinusoidal voltage is converted into a 5-V rectangular pulse by a zero-crossing detector, a phase-lag shifter with a range of 0°–180° is employed to provide an approximate means for positioning the zero torque angle. It is intended to ensure that the photopulse at point a in Fig. 2 will align with the terminal voltage pulse at point b at no-load operation by adjusting the variable resistor of the phase shifter. A compensator is then used to make the phase shifter work in both phase lead and phase lag.

It is noted that for the motoring mode, the pulses at point b in Fig. 2 have to be taken as reference; while for generating mode, the pulses at point a have to be taken as reference. Therefore, a multiplexer circuit is employed to enable this measurement device to be applicable to both the motoring and generating modes.

If the output gate pulse of the phase detector at d is combined with the 1-MHz clock pulses at f, a chain of the clock pulses at g are produced through an AND gate, and the number of these clock pulses is a measure of the torque angle. However, when these clock pulses are used to drive a 16-bit BCD counter, occasionally, false counting may occur. The reason is that in the case of high machine speed and heave load, the next output gate pulse at d may start before

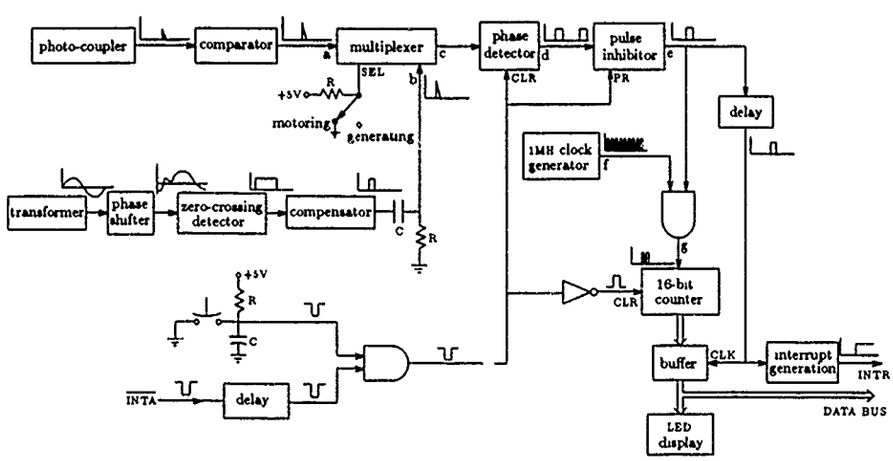

FIG 2. Block diagram for torque angle measurement.

the final settled number of the counting is latched to the buffer and counter is cleared. To avoid this undesirable operation, a pulse inhibitor is employed to ensure that no further gate pulses would pass to the AND gate until the reset signal is issued, which comes from the reset switch or interrupt acknowledgment signal ($\overline{INTA}$) from the microprocessor as indicated in Fig. 2.

Since 1-MHz clock frequency is employed, for a 60-Hz power supply system, there are 8333 pulses corresponding to 180° electrical, which is the maximum torque angle to be measured. Thus, a resolution of 0.02 electrical degree per pulse is obtained. To obtain a stable reading, the buffer is enabled after the counting is over and hold the information until the arrival of next count. The output of the buffer is further fed into a microprocessor using 8255 programmable parallel port as the interface. At the same time, the buffered data are also decoded by display driver into 7-segment LED display. The clock signal for latching the buffer and the interrupt signal can be derived from the output of the pulse inhibitor through a delay element to account for the propagation delay of the 16-bit cascade counter. The interrupt signal is produced using a JK flip–flop whose output goes high once the delay is over.

The above-mentioned torque angle measurement system was designed, built and tested on the 1 hp, 4-pole PM motor which is coupled to a conventional synchronous generator. The measurement system functioned properly as desired and was also found to be very stable over the entire range of operating conditions.

DETERMINATION OF ZERO TORQUE ANGLE POSITION

From the above discussion, it is noted that the signal representing the excitation voltage can be errorless only if the holes on the disc are aligned with the d axis of the rotor and the photocoupler is positioned at the axis of that stator phase winding whose applied voltage is taken as the reference signal. However, unless special marks were made on the rotor during assembly, there is no obvious reference to determine the position of the d axis. In order to overcome this difficulty, a scheme is introduced to find out the positions of the d axis of the rotor and the axis of the reference stator phase winding without the need to concern the interior structure of the motor. The procedure is described as follows:

(1) Mount the disc with an equispaced hole for each pole pair on the rotor shaft and fix the photocoupler to the stator frame, both at any position. Then, take any one of three phase voltages, e.g., phase A to provide the referenced phase voltage signal for the primary of the step-down transformer.

(2) Turn on the three-phase power supply and run the PM motor at no-load. By reversing the leads of the phase A power supply to the primary of the transformer and interchanging the three phase power supply leads A, B, and C to the three phase stator windings, find out the connection which would lead to a minimum torque angle reading. Under this connection, the stator winding connected to the phase A power supply is then the phase A stator winding.

(3) Run the motor first in one direction and get the torque angle reading, then do the same at the reverse direction by interchanging the phase B and phase C power supply. Assuming that the photocoupler was just positioned at the axis of phase A winding of the stator, then both the torque angle readings should be the same if the holes on the disc were aligned with the d axis of the rotor. This suggests that the disc has to be moved towards the rotating direction which has given the larger torque angle reading if both readings are not the same. This adjustment is repeated until the two readings corresponding to forward and backward rotating directions are reasonably close.

(4) In the step 3, it is assumed that the arbitrary positioning of the photocoupler was aligned with the axis of phase A winding. Generally speaking, it is not true. Hence, an adjustment is needed to relocate the position of the axis of phase A winding. It can be done by applying a low dc voltage between phase A and the shorted point of phases B and C of 3-phase Y-connected stator windings. What happens is that the disc will rotate in such a way that the holes on the disc, which represents the d axis of the rotor, should move to the axis of phase A winding. As a result, one can easily relocate the photocoupler to the position as indicated by the holes.

Due to the adjustment of photocoupler position in step 4, the holes on the disc have to be positioned again by repeating step 3. This iteration process is continued until no further adjustment is made in step 4. Practical application shows that only few iterations are required for both the holes on the disc and the photocoupler to converge to its desired position.

By using the proposed scheme, the initial torque angle for the 1 hp laboratory test PM motor was 29.6°; while using the approximate method, the initial torque angle was 22.2°. It can be seen that the error caused by the approximate method is quite significant.

CONCLUSION

In this article, a novel load test method is proposed to determine the saturated parameters X_d, X_q, and E_0. This method not only takes into account the variation of E_0 with load and the interaction between d-q axis quantities, but is also convenient to use for practical applications. The developed microprocessor-based torque angle measurement system can provide fast transient response with adequate resolution for measuring and control purposes. A prototype system was successfully built and tested in a 1 hp laboratory PM synchronous motor.

A three-material passive *dI/dt* limiter

S. J. Young, F. P. Dawson, and A. Konrad
Department of Electrical and Computer Engineering, University of Toronto, Toronto M5S-1A4, Canada

This article introduces and examines a composite magnetic device (called a *dI/dt* limiter) which functions as a bilevel inductor. For dc currents below a designed threshold level, the inductance and resistance of the device is quite low. However, the inductance of the device increases dramatically for all currents greater than the threshold level. In this article a set of performance equations are derived which describe the inductance of the *dI/dt* limiter as a function of current. The data obtained from these performance equations are compared to the results of a set of finite element simulations.

I. INTRODUCTION

In our earlier work,[1,2] we have examined a composite magnetic device which could function as a protective unit in voltage source fed circuits. This device, called a cylindrical *dI/dt* limiter, functions as a bilevel inductor. It has a low inductance value for all currents below a designed threshold level, and a dramatically increased inductance when the current in the device increases beyond the threshold level. This *dI/dt* limiter would limit the rate of current change in voltage source circuits during overcurrent fault conditions, while having only a modest effect on the circuits normal operation. During a fault it may also be possible to maintain the current in the *dI/dt* limiter, and hence in the series connected external circuit, at a nondestructive level long enough for the nature of the fault to be determined. Once determined, the appropriate actions would be taken to correct the source of the fault without the need for shutting down the circuit as a tripped fuse or breaker would.

This article examines a three-material square geometry *dI/dt* limiter which uses corner blocks of a high permeability material to bend the magnetic flux around the corners of the device. The result is that the flux density within the core and magnet materials is made more uniform, and the radial dependence of flux density is eliminated. Thus, not only is the transition region largely eliminated, but many of the other limitations associated with the cylindrical geometry are addressed as well.

II. THREE-MATERIAL *dI/dt* LIMITER

Stripped to its essential components, the three-material *dI/dt* limiter is shown in Fig. 1. This device consists of four coils with cores composed of alternating slices of a soft-core material, and a permanent magnet material. These solenoids are joined at the corners of the device by blocks of another type of soft-core material which has both a high permeability and a saturation flux density which is significantly higher than that of the sandwiched core material.

With zero coil current flowing, the permanent magnet slices cause a magnetic flux to flow through the permanent magnet and core materials with sufficient intensity to saturate the sandwiched core material. The corner pieces provide a low reluctance path for the magnetic flux, and so the flux exists in a closed path confined mainly to the device. Since the sandwiched core material is saturated, the incremental inductance (rate of change of flux linkage with respect to current) of the device is low. For all negative currents, and positive currents smaller than the designed threshold level, the core remains in saturation, and the incremental inductance of the *dI/dt* limiter is low. Still larger coil currents reduce the flux density in the core region below the saturation level and into the high permeability region. In this state the reluctance of the flux path is low, which causes the incremental inductance of the device to be greatly increased. It is this large device inductance which reduces the rate of current change in voltage-source-fed circuits.

III. DERIVATION

The flux density versus magnetic field intensity (B vs H) relationships of the core and permanent magnet materials are approximated by linear equations. The permanent magnet material is described by

$$B_{\text{mag}} = -B_m + \mu_0 \mu_m H_{\text{mag}}. \tag{1}$$

This may be either the natural recoil line of the magnetic material, or the result of stabilization. The linear approximation to the core's B versus H curve is given by

$$\text{In saturation } B_{\text{core}} = -B_c + \mu_0 \mu_{\text{sat}} H_{\text{core}}, \tag{2}$$

$$\text{Out of saturation } B_{\text{core}} = \mu_0 \mu_{\text{unsat}} H_{\text{core}}. \tag{3}$$

The analysis begins with Ampere's circuital law

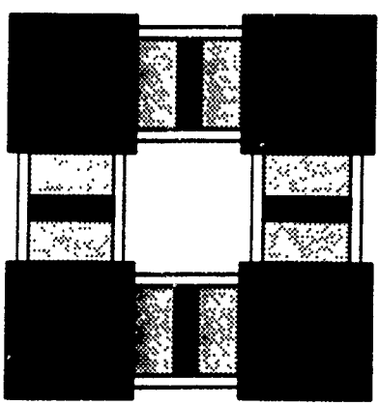

FIG 1 A three material *dI/dt* limiter: permanent magnet material (black); high permeability high saturation flux density material (dark gray); high permeability low saturation flux density material (light gray). The four coils (white) each surround a core.

 0021-8979/94/76(10)/6871/3/$6.00 © 1994 American Institute of Physics

$$\oint H \cdot dl = I_{\text{enclosed}}. \tag{4}$$

It will be assumed that the mmf drop within the corner pieces is negligible in comparison with the other mmf drops around the magnetic circuit. Thus, within the core and magnet materials

$$H_{\text{mag}} l_{\text{mag}} + H_{\text{core}} l_{\text{core}} = NI. \tag{5}$$

In Eq. (5), l_{mag} and l_{core} are the total magnetic path lengths through the magnet and core materials, respectively.

While the core material is saturated, the flux density within the core material is approximately described by

$$B_{\text{core}} = \frac{-B_m \mu_{\text{sat}} l_{\text{mag}} - \mu_m l_{\text{core}} B_c + \mu_0 \mu_m \mu_{\text{sat}} NI}{\mu_{\text{sat}} l_{\text{mag}} + \mu_m l_{\text{core}}}. \tag{6}$$

The flux linkage (Λ) within the dI/dt limiter is $\Lambda_{\text{sat}} = NB_{\text{core}} A_{\text{core}}$, and while the core is in saturation, the inductance of the dI/dt limiter is

$$L_{\text{sat}} = \frac{d\Lambda_{\text{sat}}}{dI} = \frac{N^2 A_{\text{core}} \mu_0 \mu_m \mu_{\text{sat}}}{\mu_{\text{sat}} l_{\text{mag}} + \mu_m l_{\text{core}}}. \tag{7}$$

When the core is operating in the high permeability region, the flux density within the core material is

$$B_{\text{core}} = \frac{-B_m l_{\text{mag}} \mu_{\text{unsat}} + \mu_0 \mu_m \mu_{\text{unsat}} NI}{l_{\text{mag}} \mu_{\text{unsat}} + \mu_m l_{\text{core}}}, \tag{8}$$

the flux linkage is given by $\Lambda_{\text{unsat}} = NB_{\text{core}} A_{\text{core}}$ and the inductance of the dI/dt limiter is

$$L_{\text{unsat}} = \frac{d\Lambda_{\text{unsat}}}{dI} = \frac{N^2 A_{\text{core}} \mu_0 \mu_m \mu_{\text{unsat}}}{l_{\text{mag}} \mu_{\text{unsat}} + \mu_m l_{\text{core}}}. \tag{9}$$

Let the intersection between Eqs. (2) and (3) be labeled B_x, then let the coil current required to achieve a flux density of B_x within the core material be called I_{knee}.

$$I_{\text{knee}} = \frac{-B_c (l_{\text{mag}} \mu_{\text{unsat}} + \mu_m l_{\text{core}}) + B_m l_{\text{mag}} (\mu_{\text{unsat}} - \mu_{\text{sat}})}{N \mu_0 \mu_m (\mu_{\text{unsat}} - \mu_{\text{sat}})}. \tag{10}$$

I_{knee} is the demarcation point between the low inductance region $I < I_{\text{knee}}$, and the high inductance region $I > I_{\text{knee}}$.

It can be shown that the volume of permanent magnet material required for a given I_{knee} and L_{unsat} is

$$\text{Magnet volume} = A_{\text{mag}} l_{\text{mag}} = \frac{\mu_0 \mu_m L_{\text{unsat}} I_{\text{knee}}^2}{\left(B_m - B_c \frac{A_{\text{core}}}{A_{\text{mag}}} \right)^2}. \tag{11}$$

IV. DESIGN OF A THREE-MATERIAL *dI/dt* LIMITER

The design process usually begins with a specification of the required fault inductance L_{unsat}, and the threshold current level I_{knee}. For the device pictured in Fig. 1, $A_{\text{core}} = A_{\text{mag}}$, and so the volume of permanent magnet material is determined by Eq. (11).

For most practical core and magnet materials $\mu_{\text{sat}} \approx \mu_m$, rearranging Eqs. (7) and (9) yields

$$\frac{L_{\text{unsat}}}{L_{\text{sat}}} = 1 + \frac{\text{core volume}}{\text{magnet volume}}. \tag{12}$$

TABLE I. Physical dimensions of six dI/dt limiters.

	$1+\frac{l_{\text{core}}}{l_{\text{mag}}}$	10	20
$N=100$	Square edge D_s (m)	0.1826	0.1826
	Solenoid length l_s (m)	0.0275	0.0550
	Resistance R_s (Ω)	0.057	0.053
$N=150$	Square edge D_s (m)	0.1491	0.1491
	Solenoid length l_s (m)	0.0412	0.0825
	Resistance R_s (Ω)	0.071	0.066
$N=250$	Square edge D_s (m)	0.1155	0.1155
	Solenoid length l_s (m)	0.0687	0.1374
	Resistance R_s (Ω)	0.095	0.087

Since the magnet volume is fixed by Eq. (11), for a given L_{unsat} and I_{knee}, the ratio $L_{\text{unsat}}/L_{\text{sat}}$ is increased at the expense of an increase in the volume and mass of the core material. Increasing A_{mag} reduces l_{mag}, for a given volume of magnet. This results in a decreased flux path reluctance; thus fewer winding turns are required in order to achieve the necessary L_{unsat}. With fewer turns, the resistance of the dI/dt limiter is reduced and the mass of the copper windings is lessened. However, increasing A_{mag} also increases the volume of the four corner blocks (which are proportional to $A_{\text{mag}}^{3/2}$); achieving the desired balance between device resistance and mass will determine the area A_{mag}.

Table I summarizes a set of dI/dt limiter designs in which $L_{\text{unsat}} = 40$ mH and $I_{\text{knee}} = 50$ A; Table II provides a breakdown of the mass of each of the Table I designs. It is assumed that the core and magnet cross sections are square, the length of each side being $D_s = (A_{\text{core}})^{1/2}$. The symbol l_s is simply the length of each core from one corner block to the next. The material constants for the core and magnet materials are $B_c = 0.4$ T, $\mu_{\text{sat}} = 1.0$, $\mu_{\text{unsat}} = 1000$, $B_m = 1.0$ T, and $\mu_m = 1.05$. The density of the permanent magnet material is 7.4×10^3 kg/m^3, and the density of both the sandwiched core material, and the corner block material is 4.9×10^3 kg/m^3.

TABLE II. Mass of various dI/dt limiter components.

	$1+\frac{l_{\text{core}}}{l_{\text{mag}}}$	10	20

	Total mass	104.8	120.6

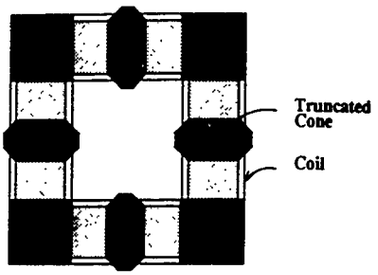

FIG. 2. A modified three-material dI/dt limiter in which $A_{mag}>A_{core}$. This device uses eight coils instead of four.

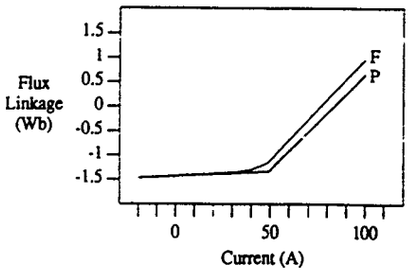

FIG. 3. Flux linkage (Λ) vs current (I) graph of the three material dI/dt limiter. Graph F was obtained from a finite element simulation, and curve P is from the performance equations of Sec. III.

As Table II shows, at low values of N, the mass of the corner pieces dominates the total device mass, and spoil what would otherwise be a promising design. A modification to the three-material dI/dt limiter which addresses this problem is shown in Fig. 2. In this modification, truncated cones of the high permeability, high saturation flux density material used for the corner pieces are employed to focus the flux from a large diameter magnet through a smaller diameter core material. Although a lack of space does not allow a complete analysis of this device, Table III shows that considerable savings in material mass and device dimensions can be achieved by using this modified design.

TABLE III. Three modified dI/dt limiter designs: $A_{mag}=4A_{core}$, $N=100$ $L_{unsat}=40$ mH, and $I_{knee}=50$ A.

$1+\frac{\mu_{mr}A_{mag}l_{core}}{\mu_{sat}A_{core}l_{mag}}$	10	20	100

Total mass	56.68	50.85	50.06

The flux linkage versus current graph for the $N=250$, l_{core}/l_{mag} device is shown in Fig. 3, along with the resulting curve from a finite element simulation. The slope of these curves is the incremental inductance of the dI/dt limiter.

V. CONCLUSIONS

This article examined a device which has the potential to function as a selective rate of current change (dI/dt) limiter. For currents below a designed threshold level, it was shown that the inductance of this device could be designed to be quite small; above this threshold level, the inductance of the device increases dramatically to another much larger designed value. A simple first-order analysis of the dI/dt limiter was favorably compared to a set of finite element simulations.

A modification to the basic dI/dt limiter was shown in which the flux from a large area permanent magnet was focused through a smaller diameter core material. The effect of this was to significantly reduce the total mass of the dI/dt limiting device.

An extended magnet in a passive *dI/dt* limiter

S. J. Young, F. P. Dawson, and A. Konrad
Department of Electrical and Computer Engineering, University of Toronto, Toronto M5S-1A4, Canada

This article examines a composite magnetic device which has the potential to function as a rate of current change (dI/dt) limiter. A possible application of such a device is to protect voltage-source-fed systems, either ac or dc, from overcurrents during fault situations. The operation of this dI/dt limiter is discussed, and performance equations are derived. Results obtained from this analysis are compared to a set of finite element simulations. An improvement to the basic design is suggested, in which the permanent magnet slices are extended in order to decrease the amount of leakage flux surrounding the dI/dt limiter.

I. INTRODUCTION

In all but the most trivial of electric circuits, some form of overcurrent protection must be provided. Although overcurrent protection has traditionally been provided by breakers and fuses, there are numerous applications where some additional method is needed in order to guarantee circuit and component security. This is especially true of certain semiconductor devices, which have a very low tolerance to overcurrents due to the very low thermal capacity of the thin semiconductor wafers from which these devices are made.

This article examines a device, called a cylindrical dI/dt limiter,[1,2] which could be placed in series with the fuse, and which for normal circuit operation would appear to the circuit as a low impedance conductor, but which would transform itself into a large inductance when the circuital currents exceeded some designed threshold level.

II. CYLINDRICAL *dI/dt* LIMITER

Stripped to its essential components, the cylindrical dI/dt limiter is shown in Fig. 1(a). In essence, it is a hollow cylinder made up of alternating slices of a soft saturable core material (dark gray) and a permanent magnet material (black). This cylinder is then surrounded by a coil having in general N turns.

The dI/dt limiter functions as follows: With zero coil current, the wedges of a permanent magnet cause a magnetic flux to flow in a near-circular path through the magnet and core materials with sufficient intensity to saturate the core. In this state, the incremental inductance (rate of change of flux linkage with respect to current) is low.

A positive coil current creates a magnetomotive force (mmf) which opposes the mmf of the permanent magnets. As long as the current does not exceed the designed threshold level, the mmf of the permanent magnets is sufficient to maintain the core material in saturation, and the incremental inductance of the device remains low. Larger positive coil currents reduce the flux density in the core region below the saturation level and into the high permeability region. In this state, the incremental inductance of the device is high. It is this increased device inductance which reduces the rate of current change in voltage-source-fed circuits.

The mmf due to negative currents supports the mmf of the magnets; the core is forced deeper into saturation, and the incremental inductance of the dI/dt limiter remains low.

III. MODEL OF THE CYLINDRICAL *dI/dt* LIMITER

A two-dimensional model of the dI/dt limiter is used as the basis for analysis. In essence, it neglects the end effects due to the finite length of the dI/dt limiter, and it assumes that the magnetic flux flows in circular paths through the device.

The flux density versus magnetic field intensity (B vs H) relationships of the core and permanent magnet materials are approximated by linear equations of the type shown below.

$$B_{\text{mag}} = -B_m + \mu_0 \mu_m H_{\text{mag}}. \tag{1}$$

This may be either the natural recoil line of the magnetic material or the result of stabilization. The linear approximation to the core's B vs H curve is shown in Fig. 2:

$$\text{In saturation} \quad B_{\text{core}} = -B_c + \mu_0 \mu_{\text{sat}} H_{\text{core}}, \tag{2}$$

$$\text{Out of saturation} \quad B_{\text{core}} = \mu_0 \mu_{\text{unsat}} H_{\text{core}}. \tag{3}$$

IV. DERIVATION OF FLUX LINKAGES AND INCREMENTAL INDUCTANCE

Applying Ampere's circuital law

$$\oint H \cdot dl = I_{\text{enclosed}} \tag{4}$$

to the two-dimensional dI/dt limiter model shown in Fig. 3 yields a set of equations which describe the static or low frequency flux linkages (Λ) within the dI/dt limiter. By low frequency, it is meant that the effects of eddy currents are not taken into account.

The operation of the dI/dt limiter is divided into three modes of operation determined by the state of the core. The state of the core is determined by the coil current. The total

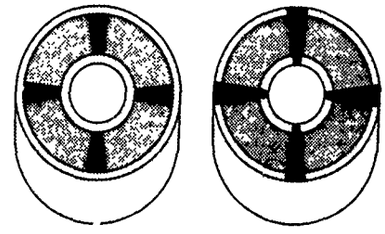

FIG. 1. The cylindrical dI/dt limiter (left-hand side) and the extended magnet version (right-hand side).

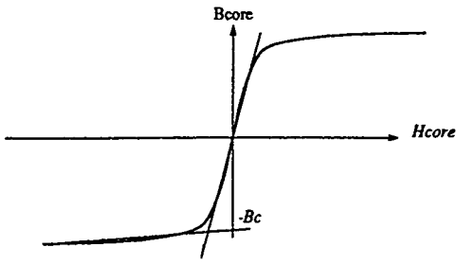

FIG. 2. The piecewise linear representation of the core material.

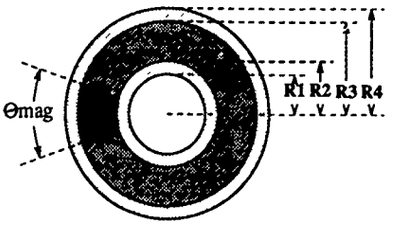

FIG. 3. The two-dimensional model of the dI/dt limiter.

flux linkage has three components: Λ_{in} is due to the inner conductor, Λ_{out} is due to the outer conductor, and the remaining component is due to the flux in the core.

Region 1: $NI<R_2\beta$; The core is completely saturated.

$$\Lambda_{SAT}=\Lambda_{in}+\Lambda_{sat}+\Lambda_{out}. \tag{5}$$

Region 2: $R_2\beta\leqslant NI\leqslant R_3\beta$; The core is partially saturated. This is a transition region.

$$\Lambda_{TRANS}=\Lambda_{in}+\Lambda_{trans}+\Lambda_{out}. \tag{6}$$

Region 3: $NI\geqslant R_3\beta$; The core is completely out of saturation.

$$\Lambda_{UNSAT}=\Lambda_{in}+\Lambda_{unsat}+\Lambda_{out} \tag{7}$$

$$\beta=\frac{B_m\theta_{mag}(\mu_{unsat}-\mu_{sat})-B_c((2\pi-\theta_{mag})\mu_m+\theta_{mag}\mu_{unsat})}{\mu_0\mu_m(\mu_{unsat}-\mu_{sat})}. \tag{8}$$

The incremental inductance ($L=d\Lambda/dI$) of the basic dI/dt limiter has a constant value L_{UNSAT} in the fault region, and a lower constant value L_{SAT} in the normal operating region. It is only in the transition region that the incremental inductance is a function of current. In the following equations, the symbol "Length" is the axial length of the three-dimensional device.

$$\Lambda_{in}=\frac{\mu_0N^2I\text{Length}}{2\pi}\left[\frac{R_2^2-3R_1^2}{4(R_2^2-R_1^2)}+\frac{R_1^4\ln(R_2/R_1)}{(R_2^2-R_1^2)^2}\right] \tag{9}$$

$$\Lambda_{out}=\frac{\mu_0N^2I\text{Length}}{2\pi}\left[\frac{R_3^2-3R_4^2}{4(R_4^2-R_3^2)}+\frac{R_4^4\ln(R_4/R_3)}{(R_4^2-R_3^2)^2}\right] \tag{10}$$

$$\Lambda_{sat}=N\text{Length}\times\left[\frac{-B_m\theta_{mag}\mu_{sat}-B_c(2\pi-\theta_{mag})\mu_m}{\theta_{mag}\mu_{sat}+(2\pi-\theta_{mag})\mu_m}(R_3-R_2)+\frac{\mu_0\mu_m\mu_{sat}NI}{\theta_{mag}\mu_{sat}+(2\pi-\theta_{mag})\mu_m}\ln\left(\frac{R_3}{R_2}\right)\right] \tag{11}$$

$$\Lambda_{trans}=N\text{Length}\left[\frac{-B_m\theta_{mag}\mu_{unsat}}{\theta_{mag}\mu_{unsat}+(2\pi-\theta_{mag})\mu_m}(R_x-R_2)+\frac{\mu_0\mu_m\mu_{unsat}NI}{\theta_{mag}\mu_{unsat}+(2\pi-\theta_{mag})\mu_m}\ln\left(\frac{R_x}{R_2}\right)\right]+N\text{Length}\left[\frac{-B_m\theta_{mag}\mu_{sat}-B_c(2\pi-\theta_{mag})\mu_m}{\theta_{mag}\mu_{sat}+(2\pi-\theta_{mag})\mu_m}(R_3-R_x)+\frac{\mu_0\mu_m\mu_{sat}NI}{\theta_{mag}\mu_{sat}+(2\pi-\theta_{mag})\mu_m}\ln\left(\frac{R_3}{R_x}\right)\right] \tag{12}$$

$$R_x=NI/\beta. \tag{13}$$

R_x is the dividing radius between the unsaturated core region (inside this radius) and the saturated core region (outside the radius).

$$\Lambda_{unsat}=N\text{Length}\times\left[\frac{-B_m\theta_{mag}\mu_{unsat}}{\theta_{mag}\mu_{unsat}+(2\pi-\theta_{mag})\mu_m}(R_3-R_2)+\frac{\mu_0\mu_m\mu_{unsat}NI}{\theta_{mag}\mu_{unsat}+(2\pi-\theta_{mag})\mu_m}\ln\left(\frac{R_3}{R_2}\right)\right]. \tag{14}$$

Table I summarizes the physical dimensions of three example dI/dt limiters. Each device has a low inductance region extending up to $I_{knee}=50$ A, and each has a fault inductance $L_{UNSAT}\approx 45$ mH. In these examples, the material constants for the core and magnet material are: $\mu_{sat}=1.0$, $\mu_{unsat}=1000$, $B_c=0.4$ T, $\mu_m=1.05$, and $B_m=1.0$ T. The coil is made of square No. 4 wire ($A_{wire}=39\,842.5$ mil^2), which has a dc resistance of 0.686Ω/1000 mil at 25 °C and a mass of 0.2335 kg/m.

In Fig. 4, the flux linkage versus current graph for the $\theta_{mag}=2\pi/20$ device of Table I is shown along with the results from a set of finite element simulations. The only difference between the 16 and 64 segment devices is the number of permanent magnet wedges that the magnetic angle θ_{mag} is divided into. Many thin wedges tend to reduce the amount of leakage flux outside the device, i.e., more of the flux is confined to the core. Hence, the transition from the low to high inductance state is sharpened as the number of wedges increases. However, large numbers of core and magnet wedges may be undesirable from a cost and construction perspective.

In Fig. 1(b), a modified device is depicted in which the permanent magnet wedges are extended to the outer edge of

TABLE I. Physical characteristics of three dI/dt limiters.

θ_{mag}	$\frac{2\pi}{10}$	$\frac{2\pi}{20}$	$\frac{2\pi}{100}$
R_1	0.2998	0.3964	0.6960
R_2	0.3241	0.4083	0.6983
R_3	0.3565	0.4491	0.7681
R_4	0.3771	0.4596	0.7702
Length	0.06482	0.08166	0.1397
N	1852	1167	399
Magnet mass (kg)	3.33	3.33	3.33
Core mass	19.8	41.8	217.9
Coil mass	122.9	78.95	39.86
Total mass	146.0	124.1	261.1
Resistance (Ω)	0.36	0.23	0.12
L_{SAT} (mH)	6.22	2.51	0.43
L_{UNSAT} (mH)	46.0	44.0	40.3
$\frac{L_{UNSAT}}{L_{SAT}}$	7.4	17.5	93.1

the conductors. Extending the magnets helps to maintain a more uniform flux density in the core material. Thus, fewer magnetic wedges are required to achieve a sharp transition from the low to high inductance state of the device.

It can be shown, that for the cylindrical dI/dt limiter, the combined volume of the core and permanent magnets is

$$\text{Volume} > \frac{2\pi\mu_0\mu_m I_{knee}^2 L_{UNSAT}}{\theta_{mag}(B_m - B_c)^2}. \tag{15}$$

This is an unavoidable characteristic of the cylindrical dI/dt limiter which tends to result in a fairly heavy device for large values of I_{knee} and L_{UNSAT}, or small values of θ_{mag}. For instance, the mass of the $2\pi/20$ device is 124.1 kg, of which 3.33 kg is due to the permanent magnets, 41.8 kg is due to the ferrite core, and 78.95 kg is due to the copper conductors. For smaller values of L_{UNSAT} and I_{knee}, the weight of the device is more reasonable, and the simplicity of the cylindrical device makes it attractive.

V. CONCLUSIONS

This article examined a device which has the potential to function as a selective rate of current change (dI/dt) limiter.

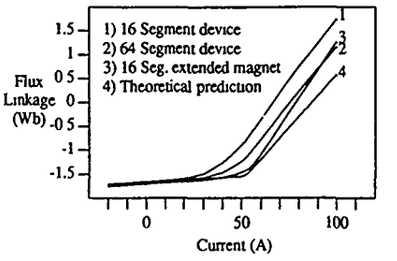

FIG. 4. Flux linkage vs current graphs for the $\theta_{mag}=2\pi/20$ device of Table I. The "theoretical prediction" line was obtained from the performance equations. The remaining curves are from a set of finite element simulations.

For currents below a designed threshold level, it was shown that the inductance of this device could be designed to be quite small; above this threshold level, the inductance of the device increases dramatically to another much larger designed value.

A modification to the basic dI/dt limiter was shown in which the permanent magnet wedges were extended to the outer edge of the current conductors. The effect of this was to reduce the number of wedges required to achieve acceptable device performance.

It was also seen that at larger values of threshold current and device inductance that the volume and mass of the device could be considerable, thus the cylindrical dI/dt limiter would likely only be practical for applications in which $I_{knee}^2 L_{UNSAT}$ is small.

$Sr_{0.75}Ba_{0.25}Fe_{12}O_{19}$ hexagonal ferrite has attracted much attention due to its large $(BH)_{MAX}$ values and workability. We have prepared sheet magnets by the Dr. Blade method. To examine the effects of additives, such as SiO_2, TiO_2, Al_2O_3, and Cr_2O_3, on magnetic properties of sheet magnets, we used VSM magnetometer, x-ray diffraction, and Mössbauer spectrometer. The crystal structure is found to be a magnetoplumbite of typical M-type hexagonal ferrite, but the α-Fe_2O_3 phase develops with increasing additives concentration. Using our refined computer program, we have analyzed the Mössbauer spectra in the temperature range from 13 to 800 K. The Mössbauer spectra indicate that the line intensity for the 12k site is reduced with increasing SiO_2 concentration, which is different from the reports of Fe-substituted Ba ferrite. This suggests that the developing α-Fe_2O_3 phase is related to 12k sites. The isomer shifts show the charge states of Fe ions is ferric. When the additives concentrations increase, the Curie temperatures, T_c go down. One sextet for α-Fe_2O_3 phase still persists above T_c, so it suggests that the high-T_c values do not result from α-Fe_2O_3. While Al_2O_3 and Cr_2O_3 additives increase coercive force H_c, the other additives reduce it.

I. INTRODUCTION

The hexagonal ferrite of the M-type $(Ba,Sr)Fe_{12}O_{19}$, have attracted much attention as permanent magnets, perpendicular magnetic recording media, and microwave device materials.[1-3] They are widely used because of their high coercivity and low cost. Besides, they are very stable and have electrical resistivity.[4] In optimizing hard ferrites for permanent magnet applications, a compromise is usually struck between obtaining a high remanence value or a high coercivity, which is dependent on microstructural features.

The remanence Br is a strong function of density, chemistry, and orientation, while the coercive force, H_c is related to grain size. The problem is to achieve fine grain size and high density simultaneously. It has been reported that some additives such as SiO_2,TiO_2, Ba_2O_3, Cr_2O_3, and Ga_2O_3 are active ingredients that definitely influence the microstructure.[5-7]

Additives play a role as an activator and inhibitor. The method of addition and amounts are also very important techniques. Kools[5] has found that SiO_2 in the correct proportion inhibited grain growth by forming a second phase at the grain boundaries. Okumura[8] has found Bi_2O_3 improves the reaction rate and increases the density of barium, strontium, and lead ferrites. Seok[9] noticed that Al_2O_3 reduces the size of unit cell of barium ferrite, raises the coercive force, lowers the saturation magnetization, remanence, Curie temperature, and rate of growth of the crystallites. On the other hand, Wolski[7] has investigated the influence of the admixtures (Al_2O_3, Ga_2O_3, B_2O_3) upon the magnetic properties of the strontium-barium ferrite $Sr_{0.75}Ba_{0.25}Fe_{12}O_{19}$.

In this work, the effects of trivalent base oxides (Al_2O_3, Cr_2O_3) and tetravalent base oxides (TiO_2, SiO_2) on magnetic properties of the Sr-Ba ferrite are discussed. There has not

been an exploration of the effects of substituting part of Fe^{3+} with the cations of additives by Mössbauer spectroscopy.

II. EXPERIMENT

Strontium-barium ferrite $Sr_{0.75}Ba_{0.25}Fe_{12}O_{19}$ was prepared by the citric sol–gel method. The starting materials were $Sr(NO_2)_2$, $Ba(NO)_2$, $Fe(NO_3)\cdot 9H_2O$ of 99% purity. After grinding and drying citrate gel, the ferrite powder was reacted by calcining it at 850 °C for 2 h. The green sheets of $Sr_{0.75}Ba_{0.25}Fe_{12}O_{19}$ to which additives oxides were introduced were made by Dr. Blade. Sintering was done at 500 °C for 1 h and for the second time at 1200 °C for 2 h.

Mössbauer spectra were recorded using a conventional Mössbauer spectrometer of the electromechanical-type[10] with a ^{57}Co source in a rhodium matrix.

III. RESULTS AND DISCUSSION

The x-ray diffraction patterns of the samples showed that the crystal structure was a typical magnetoplumbite of the *M*-type hexagonal. The lattice constants of $Sr_{0.75}Ba_{0.25}Fe_{12}O_{19}$ were found to be $a=5.875$ Å, $c=23.03$ Å. Adding oxides has no appreciable effect on the dimensions of unit cell. In the case of SiO_2, the a axis of the hexagonal cell is almost unchanged, while the c axis seems to decrease slightly. α-Fe_2O_3 phase appear above 2.0 wt % of SiO_2 additives. The effect of substituting part of the Fe^{3+} with oxides was not noticed in powder diffraction patterns.

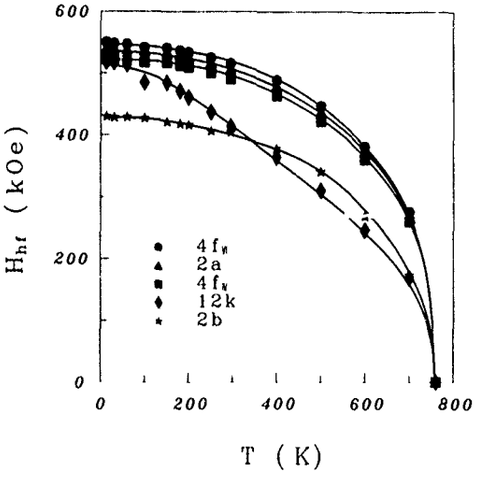

FIG. 4. Temperature dependence of magnetic hyperfine fields of Sr-Ba ferrite with 1.0-wt % TiO_2 additives.

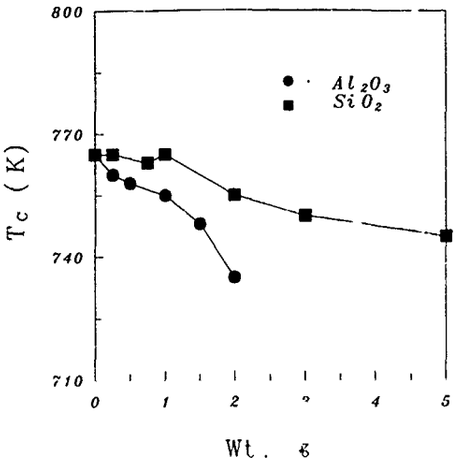

FIG. 5. Dependence of Curie temperature, T_c upon the concentration of additives Al_2O_3 and SiO_2.

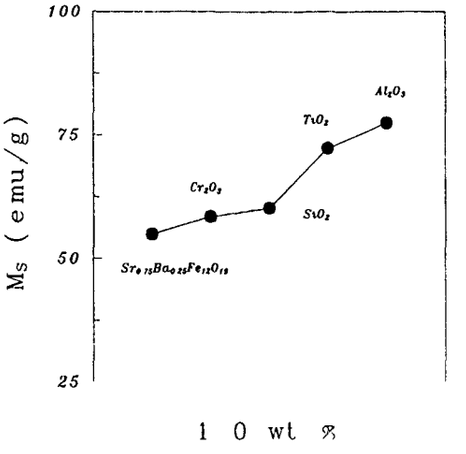

FIG. 6 Saturation magnetization M_w of Sr-Ba ferrites with and without admixtures.

Mössbauer spectra of Sr-Ba ferrite with 1.0-wt % SiO_2, TiO_2, Al_2O_3, and Cr_2O_3 are shown in Figs. 1 and 2. Each sites contributes a magnetic hyperfine sextet, in proportion to site population times the recoil-free fraction, to the total Mössbauer spectrum. With the assignments shown in Figs. 1 and 2, peaks of five sites may be identified visually. They are a typical Mössbauer spectra of the Sr-Ba ferrite.[11] The isomer shifts at room temperature are in the range of 0.18–0.27 mm/s relative to Fe metal,[12] which means that the ionic state of iron ions with respect to five sites is ferric. The effects of Fe^{3+} substitution with trivalent and tetravalent cation of additive is not found in the Mössbauer spectra.

The quadrupole splittings of sublattice as a function of temperature show no abrupt change near 80 K. Kreber[13] had proposed a model in which Fe^{3+} occupies randomly one of the two equivalent sites of 4*e* instead of 2*b* at low temperature. Figure 3 show Mössbauer spectra of Sr-Ba ferrites with changing weight percent of the additives Al_2O_3 and SiO_2.

When the portion of additives is increased, the Mössbauer spectra of the Sr-Ba ferrite with Al_2O_3 admixture is almost unchanged, while that of SiO_2 is obviously changed. The line intensity of the 12*k* site is reduced with the addition of SiO_2, which indicates that Fe^{3+} substitutes for Si^{4+}. As shown in Fig. 4, the variation of magnetic hyperfine fields of Sr-Ba ferrite with the use of 1.0-wt % TiO_2 additives is similar to that of the typical Sr ferrite.

The variation of Curie temperatures with the weight percent of additives are shown in Fig. 5. When the weight percent of additives of samples increase, the Curie temperatures T_c decreases, but remain high, and one sextet for α-Fe_2O_3 still persists about T_c. It suggests that this high value of the Curie temperature T_c due to additive oxides may be explained as the small substitution of Fe^{3+} on 2*b* or 12*k* sites by the trivalent or tetravalent cation, which effects changes in the distance or the angle between Fe-O-Fe involved in superexchange interaction, however changes of Mössbauer spectra due to these ions are not detectable below the Curie temperature.

It is noted in Fig. 6 that additives increase the saturation magnetization. Of all the additives Al_2O_3 has the greatest effect on M_s in the range of 1.0 wt %. However, an increase in additives reduces the saturation magnetization. The coercive force, H_c is increased with the addition of the admixture Al_2O_3 and Cr_2O_3, but is decreased with the other additives.

In general, H_c and M_s partly depend upon density and grain size, and it has been shown that the coercive force, H_c depends on the anisotropy field which is related to five Fe^{3+} sites, but any effects due to the replacement of trivalent by tetravalent cations in Mössbauer spectra was not observed.

In conclusion, it may be said that when the concentration of additives is less than 5 wt % the magnetic properties such as H_c, M_s, and M_r depend more on microstructure characteristics than on the additives. Additives can also play a role as inhibitor or activator when the cation concentration is less than 5 wt %.

Critical scattering of electromagnetic waves on spin fluctuations in nonsaturated magnetic films under acoustic pump

I. E. Dikshtein, R. G. Kryshtal, and A. V. Medved
Institute of Radioengineering & Electronics of Russian Academy of Sciences, Mokhovaya, Moscow GSP-3, Russia 103907

The theoretical and experimental investigation of the microwave (MW) combination scattering on spin fluctuations (SF) in the yttrium iron garnet film under acoustic pump were pursued. MW frequency $f \cong 3.5-4.1$ GHz was well above spin wave spectrum at a preassigned magnetic field. At the external magnetic field range $H_0 \cong 5-40$ Oe one (or more) intensity peaks of MW scattering were observed. The positions of these peaks do not depend on MW and surface acoustic wave (SAW) amplitudes and frequencies and depend heavily on the magnetic field directions in a film plane. Because these phenomena were closely associated with the domain walls (DW) reorientation or at the domain structure transformations, e.g., at the flexural instability of DW, one may speculate that critical scattering of MW on SAW and SF was observed. Cross section for such scattering was calculated. In nonsaturated magnetic films the phenomena of MW scattering on SAW and spin fluctuations at high amplitudes of the MW and SAW were investigated as well. In the area of external magnetic fields $H_0 \geqslant 250$ Oe a stepped dependence of intensity of scattering MW was observed. There is no appropriate explanation of this effect now.

Experimental investigations of nonelastic scattering of magnetostatic waves (MSW) by a surface acoustic wave (SAW) in yttrium iron garnet (YIG) films were shown to be rather useful methods for measuring MSW propagation parameters,[1-3] as well as for studying MSW nonlinear peculiarity.[4] The experimental procedure in this case consists mainly of measuring the output microwave (MW) signal level of frequency $f+F$ (or $f-F$) as a function of the input microwave signal frequency f at fixed SAW frequency F and external magnetic field H_0. Usually under nonelastic scattering of MSW by a SAW the maximum level of the output signal takes place at a certain input MW signal frequency f_0, when the phase synchronism conditions of nonelastic scattering are satisfied.

Recently, when investigating nonlinear MSW scattering by a SAW in YIG films we observed that the output signal of the $f \pm F$ frequency may have, under a certain condition, rather essential level in relatively wide input signal frequency range which is far away from the phase synchronism frequency f_0 and even outside the MSW frequency spectrum. Furthermore, such a signal appears also in nonsaturated YIG films at low external magnetic fields and its behavior as a function of input microwave signal power shows a steplike dependence.

We have no reliable explanation of these experimental results now, and we would like to present here some of these results and discuss one of the possible hypotheses which may probably serve as an approach for explaining these results.

The experimental setup is similar to that used by us for surface MSW (SMSW) nonelastic scattering by SAW investigations.

Figure 1 shows the experimental setup and the configuration of a gadolinium gallium garnet (GGG)–YIG film samples used for studying of the SMSW scattering by SAW phenomenon as well in our latest experiments. For excitation and reception of SMSW use was made of ordinary transducers, i.e., planar conductor antennas deposited on the surface of Y-Z $LiNbO_3$ plates and YIG film was placed on the top of these antennas, a very thin layer of vacuum oil being between the surface of $LiNbO_3$ plates and that of YIG film, providing rather good acoustic contact. SAW was excited by interdigital transducers (IDT). The insertion loss of such a SAW device was no higher than 20 dB at 15–40 MHz SAW frequencies in 50-Ω-measurement circuit. The dimensions of the antennas were $5 \times 0.025 \times 0.002$ mm^3.

We used 3–30 μ thick YIG films fabricated on ⟨111⟩ GGG substrates by the liquid phase epitaxy method. The structures under investigation were installed between the poles of an electromagnet as shown in Fig. 1.

At a certain input MW signal frequency f_0 at which the

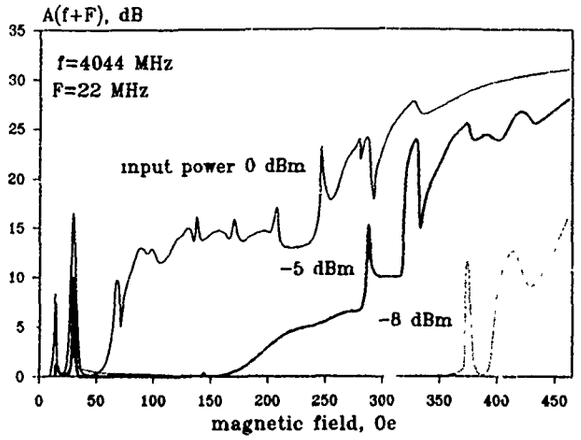

FIG. 2. The output signal level A of frequency $(f+F)$ as a function of the external magnetic field at three values of he input cw microwave powers. SAW—in pulse regime, pulse duration 10 μs, repetition rate 200 kHz. YIG film thickness 5 μ, planar dimensions of the samples 4×10 mm^2.

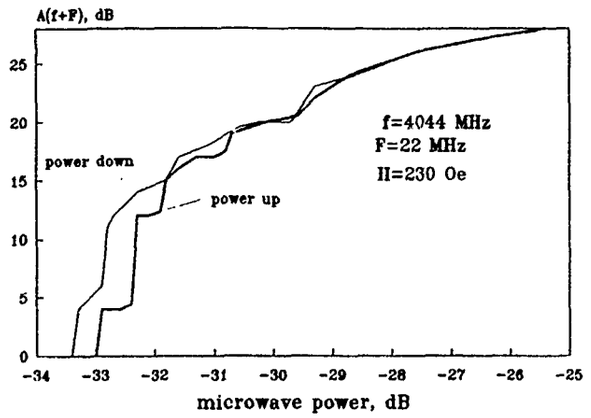

FIG. 4. Output signal level as a function of the input signal level for a 5-μ YIG film sample. $H=230$ Oe, SAW pulse power 50 mW. -30 dB in horizontal axis corresponds to 0 dBm.

phase synchronism conditions for the scattering are satisfied and at sufficient SAW power a substantial decreasing in the output MW signal level (transmitting SMSW level) is observed in the sample. This decreasing is proportional to the SAW power in a relatively wide range of SAW power variation. In this case a reflected (scattered) SMSW also can be observed. The reflected SMSW frequency in the case of the SMSW and SAW propagating in the same direction is less and in the counter-propagation case is higher than the frequency of the incident SMSW by the SAW frequency, F. The signal corresponding to the reflected SMSW may be taken from the input antenna with the help of a circulator as is shown in Fig. 1 and measured by a selective receiver tuned to $(f_0\pm F)$ frequency. It should be noted that such a technique is rather sensitive, because no problems connected with interference between the output signal of frequency $(f\pm F)$ and the input MW signal of frequency f arise.

When investigating SMSW scattering by SAW the input MW power usually did not exceed -20 dBm and experimental results were in good agreement with the theory.[1,3,5] At higher MW powers we observed the output signal of $(f\pm F)$ frequency at low external magnetic fields when the input signal frequencies f did not correspond to the scattering phase synchronism conditions and even were outside the MSW spectra for a given value of the external magnetic field. The measured output signal level of $(f+F)$ frequency as a function of external magnetic field H at three different values of the input signal powers is presented in Fig. 2 for 5-μ-thick YIG film (magnetic field was parallel to the antennas). One can see two relatively narrow peaks at low magnetic fields (one at 5–15 Oe and the second at 25–40 Oe). It should be noted that the power level of these peaks is directly proportional to the input MW signal power, though the output signal level at higher magnetic fields is essentially nonlinear function of the input power. The experimental results presented in Fig. 2 were obtained at 4044 MHz. Our investigations have shown that qualitatively similar dependences, including these two peaks, take place also at other frequencies in the range from 3500 MHz up to 4100 MHz.

In relatively thick YIG films (thicker than 20 μ) a series of two or more peaks at the 5–15 Oe position was observed, while only one peak was at 25–40 Oe as in the thin film case.

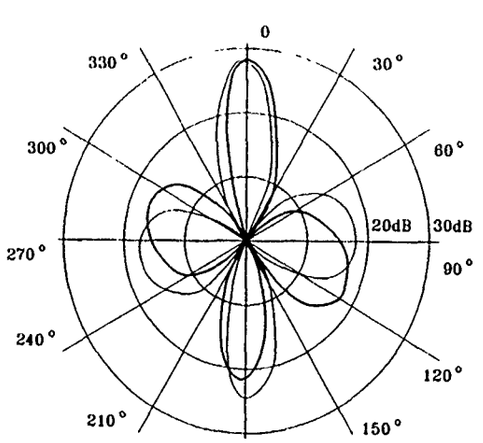

FIG. 3. The output signal level of $(f+F)$ frequency as a function of the angle between the external magnetic field vector and the direction of SAW propagation. $f=4044$ MHz, $F=22$ MHz, input microwave power 5 dBm, SAW power 20 dBm (pulse regime, 10-μs pulse duration), $H=37$ Oe.

Figure 3 represents the angular dependence of the output signal level measured for 5-μ YIG sample at 37-Oe magnetic field (the second peak in Fig. 2) at 0-dBm input power when the sample was turned around its vertical axes between the magnet poles. Zero degrees corresponds to a sample position when the direction of magnetic field is parallel to the antennas (see Fig. 1). The thick line in Fig. 3 represents the measurement result when a sample was rotated clockwise from 0° to 360°; the thin line represents the result when the sample was rotated in the opposite direction from 360° to 0°. Curves of the angular dependences of the output signal level measured at higher magnetic fields differed from these in Fig. 3 and were stretched along the 90° and 180° directions, when antennas were perpendicular to the magnetic field vector.

Measured output signal level as a function of the input microwave power for a 5-μ YIG film sample at 230-Oe magnetic field value is presented in Fig. 4. This measurement

was produced at magnetic field directed parallel to the antennas. SAW power was 50 mW. A steplike dependence and a hysteresis are clear seen in this picture.

It should be noted that a stripe domain structure (DS) with 120° blocks was observed in all our YIG film samples under investigation without external magnetic field. This DS was reconstructing under the action of external magnetic field.

We are coming now to the theoretical investigation of the MW combination scattering by spin fluctuations (SF) under acoustic pump in nonsaturated magnetic films at the first- and second-order phase transitions (PT) accompanied by the stripe DS transformations. The equilibrium orientation of domain walls (DW) depends on a DW type, the magnetic anisotropy and a direction of a magnetization field H_0 in a film plane. At the specific values H_0 the first- and second-order PT of DW reorientation type takes place in a film. On the other hand, as a magnetization field changes a DS with fixed period d can become unstable with respect to a sinusoidal (or zigzag) disturbance of a DW profile.[6] A long-order parameter of such PT is a displacement field amplitude $u(\mathbf{r},t)$ of DW points about their positions in a regular DS. Soft modes corresponding to the order parameter are DW flexural vibrations.

The intensity of the MW scattering U can be represented in the following form

$$U=(\omega^4/32\pi^4c^2)(e_\beta)^2V\ \mathrm{Re}\ i\int d\mathbf{k}'\langle\langle\Delta\epsilon_{\alpha\beta}(\mathbf{k}'-\mathbf{k},\omega-\omega')\Delta\epsilon_{\alpha\beta}(\mathbf{k}'-\mathbf{k},\omega-\omega')\rangle\rangle, \quad (1)$$

where V is a scattering volume, ω (ω') and $\mathbf{k}$ ($\mathbf{k}'$) are a frequency and a wave vector of falling (scattering) MW, respectively; wave vector $\mathbf{k}$ ($\mathbf{k}'$) is determined in a film plane (x,y); e is an intensity of the electric field of falling MW; $\Delta\epsilon_{\alpha\beta}(\mathbf{r},t)$ is a difference between the local and equilibrium value of dielectric permeability of ferromagnet; c is a MW speed; $\langle\langle...\rangle\rangle$ denotes the average over the statistical ensemble and over film thickness.

We will be further interested in the microwave scattering on the order parameter fluctuations. Therefore, it will be considered the corrections to the tensor of the dielectric permeability in the form

$$\Delta\epsilon_{\alpha\beta}=\Gamma_{\alpha\beta\gamma\delta\nu\sigma ik}U_{\gamma\delta}M_\nu\partial^2M_\sigma/\partial x_i\partial x_k, \quad (2)$$

where $\hat{\Gamma}$ is a magneto-optoelastic tensor, $U_{\gamma\delta}$ is the elastic deformation tensor induced by SAW; $U_{\alpha\beta}=U^0_{\alpha\beta}\times\exp i(\mathbf{k}_A\mathbf{r}_\perp-\omega_At)$; $\mathbf{k}_A$ and ω_A are a frequency and a wave vector of SAW, respectively; a tensor $\hat{U}$ corresponds to the Love waves.

Substituting Eq. (2) into Eq. (1) we find the intensity of the scattering microwave on the frequency interval $d\omega'$ and on the solid angle interval $d0$ in the form

$$dU=(V/16\pi)\times(\epsilon_0^{1/2}/c^2d^2)\omega^4(\Gamma_{\alpha\beta\gamma\delta\nu\sigma ik}Q_iQ_kU_{\gamma\delta}M_\nu M_\sigma e_\beta)^{2*}\times\langle\langle|u(\mathbf{Q},\omega)|^2\rangle\rangle d\omega'\ d0, \quad (3)$$

where a correlator of order parameter fluctuations is

$$\langle\langle|u(\mathbf{Q},\omega)|^2\rangle\rangle\propto 2\gamma T\Omega[(\Omega^2-\omega_s^2)^2+4\gamma^2\Omega^2]^{-1}, \quad (4)$$

a frequency of the DW flexural vibrations is $\omega_s(\mathbf{Q})=(S_x^2Q_x^2+S_y^2Q_y^2)^{1/2}$, S is a velocity of the DW flexural vibrations, γ is the DW flexural vibrations damping, $\Omega=\omega'-\omega-\omega_A$, $\mathbf{Q}=\mathbf{k}-\mathbf{k}'-\mathbf{k}_A$. The following relations for frequencies and wave vectors: $\omega\approx\omega'\gg\omega_A\gg\Omega$, $k\approx k'\ll k_A\approx Q$ take place.

Generally, the magnitude of dU is negligibly small. Situation reverses in the vicinity of the second-order PT point H_c when DS loses stability with respect to the DW reorientation or with respect to the sinusoidal disturbance of a DW profile. Then the projection of the velocity of the DW flexural vibrations on the DW direction (for definiteness sake we denote this projection S_x) tends to zero ($S_x\propto|H_0-H_c|^{1/2}$). In that case, when the conditions $\Omega=\omega_s(\mathbf{Q})$, $\mathbf{Q}=\mathbf{k}'-\mathbf{k}-\mathbf{k}_A$ are fulfilled, the MW scattering intensity increases abruptly and the scattering effect can be accessible to observation. MW scattering intensity depends heavily on the direction of MW and SAW propagation in a film plane. It has a maximum $dU\propto(\gamma\omega_s)^{-1}\propto|H_0-H_c|^{-1/2}$ for $\mathbf{k}\parallel\mathbf{k}_A\parallel\mathbf{x}$.

At the first-order PT point a discontinuous jump of the DW direction or DW profile disturbance of finite amplitude takes place. In that case a correlator $\langle\langle|u(\mathbf{Q},\omega)|^2\rangle\rangle$ has δ-shaped peculiarity. In real crystals even a weak dispersion of magnetic parameters of a film leads to blurring of such a peculiarity and decreasing of MW scattering intensity peak. So the intensity peak has a finite width and can be accessible to observation.

Thus we suppose a hypothesis for explaining the formation of intensity peaks of the MW scattering in the weak magnetic fields. In line with it we observed the MW combination scattering by SF under acoustic pump in nonsaturated magnetic films at the first- and second-order PT accompanied by DS transformations. This hypothesis gives the reasonable qualitative explanation of the following experimental results: (1) the linear dependence of the MW scattering intensity on MW and SAW power; (2) a weak dependence of the positions of peaks of the MW scattering intensity on MW and SAW frequencies; (3) abrupt increase of the MW scattering power $dU\propto|H_0-H_c|^{-1/2}$ in the vicinity the PT field $H_0=H_c$; (4) the strong dependence of the MW scattering power on the direction of a magnetization field in a film plane.

There is no appropriate explanation of effects of high MW scattering far away from the phase synchronism fre quency range. For the calculation of these effects it is necessary to take into account the high order processes involving MW, SAW, and SF. Jumps of MW scattering intensity can be associated with the DS transformation in the high MW fields.

Measurements of the weak one-magnon light scattering in the antiferromagnet MnF_2, including Stokes and anti-Stokes scattering, as a function of temperature are reported. From the theoretical analysis of the temperature and polarization dependences of the integrated Raman intensities, values are deduced for the ratio of quadratic and linear magneto-optical coupling coefficients.

The observation of one-magnon light scattering in the tetragonal, insulating antiferromagnet MnF_2(T_N=68 K, S=5/2) was reported earlier.[1] However, experimental difficulties due to the low frequency of the spin waves and their weak light scattering intensity precluded an accurate study of their temperature dependence. The advent of a high-resolution spectrometer with high stray-light rejection has now enabled a detailed study of the Stokes and, for the first time, the anti-Stokes scattering as a function of temperature. The magnon frequency in zero-applied magnetic field renormalized from 8.7 cm^{-1} at low temperature [consistent with antiferromagnetic resonance results (Ref. 2)] to 4.8 cm^{-1} at 57 K, while the linewidth increased slightly from about 0.6 to 0.8 cm^{-1} over the same temperature range. The magnon Raman integrated intensity exhibited a pronounced polarization dependence in both Stokes and anti-Stokes scattering. The measured temperature and polarization dependences of the Stokes and anti-Stokes intensities has enabled a theoretical study to be carried out for the magneto-optical coupling in MnF_2.

The MnF_2 crystal used in this study has been described elsewhere.[1] The sample was mounted in a Janis DT cryostat for the low-temperature measurements and the sample temperature was controlled and measured to within ±0.1 K. The magnon Raman spectrum was excited with 800 mW of argon laser light at 476.5 nm, which resulted in little laser heating of the sample[1] (the temperatures quoted have been corrected for a 1.0-K laser heating). The light scattered at 90° was analyzed with a SOPRA DMDP2000 double monochromator, which has the high-resolution capability (better than 0.03 cm^{-1}) and high stray-light rejection needed for this experiment,[3] and detected with a cooled Hammamatsu R928P photomultiplier. In the analysis of the scattered light polarization, the X,Y,Z labels refer to the a,b,c crystallographic axes, respectively. A typical anti-Stokes–Stokes Raman spectrum is shown in Fig. 1.

The relevant theories for the temperature dependence of the magnon frequencies and the one-magnon Raman intensities are already well established for antiferromagnets with the rutile crystal structure of MnF_2 (see, e.g., Refs. 1, 4, and 5). Here, we test the theories by comparing with the experimental data and, from the analysis, we deduce results for the nature of the magneto-optical coupling in MnF_2.

The Raman peak positions for the temperature dependence of the magnon frequency are shown in Fig. 2, combining results from Stokes and anti-Stokes scattering in several polarizations. The peak frequencies were measured to within ±0.05 cm^{-1} for the stronger lines. Comparisons are made with two types of theory, as described before.[1] The broken and solid lines refer, respectively, to predictions of a linear spin-wave theory and a perturbation theory. The latter includes effects of magnon–magnon interactions and is valid over a limited range of temperature (up to $\sim 0.6T_N$ in this case). We assumed J=2.49 cm^{-1} for the dominant exchange interaction (neglecting the small effect of the other exchange interactions for the zone-center magnons excited by Raman scattering) and $g\mu_B H_A$=0.75 cm^{-1} for the uniaxial anisotropy at low temperatures, consistent with neutron scattering data.[6] The temperature dependence of the anisotropy is conventionally introduced by writing $H_A \propto \langle S^z \rangle^n$, where $\langle S^z \rangle$ is the sublattice spin average and n is a positive index[1] with a value depending on the physical origin of the anisotropy. If the neighboring spins are considered as being either completely uncorrelated (implying $\langle S_i S_j \rangle = \langle S_i \rangle \langle S_j \rangle$ for sites $i \neq j$ as in mean-field theory) or strongly correlated, then this would lead to n=1 and n=2, respectively, as limiting values. In Figure 2 we show the theory curves for n=1 and n=2. On

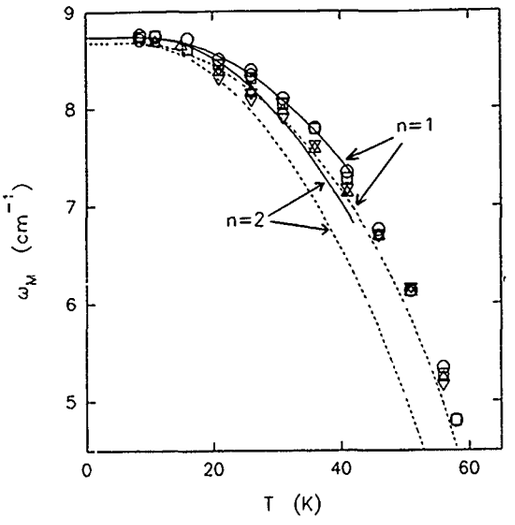

FIG. 2. Comparison of experiment and theory for the temperature dependence of the magnon frequency. The data points refer to ○, Stokes scattering in (XZ) polarization; □, Stokes scattering in (YZ) polarization; △, anti-Stokes scattering in (ZX) polarization; ▽, anti-Stokes scattering in (ZY) polarization. The broken and solid lines refer to linear and interacting spin-wave theories, respectively (see text).

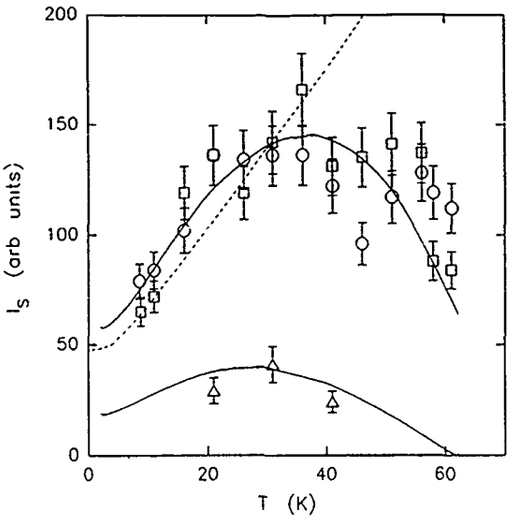

FIG. 3. Experiment and theory for the temperature dependence of the integrated intensity for Stokes scattering in several polarizations. The experimental points refer to ○, (XZ) polarization; □, (YZ) polarization; △, (ZX) polarization. The theory curves are for $G_+/K_+=0$ (broken line) and $G_+/K_+=0.08$ (solid lines).

comparing with the experimental data, which are more detailed and extend to higher temperatures than in Ref. 1, we see that taking $n=1$ provides a clearly better fit in the case of the linear theory and a marginally better fit also in the case where spin-wave interactions are included.

We next discuss the results for the light-scattering intensities. Data have been obtained for both Stokes and anti-Stokes scattering in $X(ZX)Y$ and $Z(YZ)Y$ polarizations, for Stokes scattering in $Z(XZ)Y$ polarization, and for anti-Stokes scattering in $Y(ZY)Z$ polarization. Some results for the temperature dependences of the Stokes and anti-Stokes integrated intensities, I_S and I_{AS}, are shown in Figs. 3 and 4, respectively, and will be discussed later. The units are arbitrary, but are consistent between the two figures. According to theory, I_S for Stokes scattering takes the general form[1,4]

$$I_S=A\langle S^z\rangle(n_M+1)(F_{in}+F_{out})/\omega_M, \quad (1)$$
